Second, the relatively short stretch of DNA containing a microsatellite allows it to be readily assayed using the polymerase chain reaction (PCR). PCR is a chemical reaction that can exponentially amplify DNA fragments [11]. In the case of SSLP assays, short oligonucleotide primers (~18–25 nucleotides in length) are generated that are complimentary to sequences flanking either side of the tandem repeat. The double-stranded genomic DNA is denatured (unraveled) by heating to 94°C, after which the reaction is cooled to approximately 55°C to 60°C. This temperature allows the oligonucleotide primers to anneal to the denatured genomic DNA. Finally the reaction is heated to 72°C, which allows a temperature stable polymerase, generally *Taq* polymerase isolated from a thermostable bacterium (*Thermus aquaticus*), to extend the oligonucleotide chain, using the complimentary genomic DNA strand as its template and the four dNTPs (dATP, dTTP, dCTP, and dGTP) as building blocks to extend the DNA fragment. This procedure is repeated multiple times, doubling the copy of the sequence contained between the primers with each cycle. Therefore, at the end of 30 cycles of consecutive denaturing, annealing, and extension, there are 2^{30} copies of the desired fragment, which is a sufficient amount of product for detection using radioactive isotopes or fluorescent dyes, as described below. Because PCR can be carried out in high-density microtiter plates (up to 1536 wells/plate) on commercial thermocyclers (machines that heat and cool the reaction samples required for PCR), genotyping of thousands of individuals can be performed in a single day.

Radioactive Detection. Initially, PCR amplified product (amplicon) containing an SSLP, was most commonly detected using gel electrophoresis and a radioactively labeled nucleotide. This was done by either directly incorporating a radioactive tag in the PCR amplicon or by labeling the oligonucleotide primer. For direct incorporation, a radioactively tagged nucleotide, either ^{32}P or ^{35}S attached to the α position of one of the dNTPs (i.e., $\alpha^{32}P$-dCTP or $\alpha^{35}S$-dATP), is added to the PCR reaction (for detailed protocol, see Ref. 12). During each extension step of the reaction, labeled nucleotides are directly incorporated into the amplicon. An alternative approach used to detect the PCR amplicon is to label one primer used

in PCR. In this approach, ^{32}P attached to the γ position of a dNTP (generally $\gamma^{32}P$-dATP or $\gamma^{32}P$-dCTP) is added to the 3′ end of one PCR primer, using T4 DNA kinase (for detailed protocol, see Ref. 12) before the PCR reaction. During PCR, this labeled primer is annealed to the target sequence and extended, thereby labeling the PCR amplicon. The advantage of direct incorporation is that only a single step amplifies and labels the desired PCR fragment; however, this method can also lead to labeling of nonspecific PCR product, making results more difficult to interpret. End-labeling of the PCR primer can eliminate the detection of nonspecific product, but also it requires high levels of radioactivity and an extra experimental step. However, both approaches have been used extensively and successfully, and which approach is used depends on individual preference.

To detect the radio-labeled SSLP amplicon, one must be able to separate the labeled fragments, based on their length. With radioactively labeled amplicons, this is done using denaturing gel electrophoresis. Reaction samples are mixed with a loading buffer containing blue tracking dye and formamide, and then heated to 94°C to denature the product. The formamide keeps the product denatured. Samples are then loaded onto a standard denaturing polyacrylamide sequencing gel. As the fragments migrate through the gel, the smaller sized fragments (containing fewer tandem repeats) migrate more quickly, whereas the larger fragments move more slowly, separating the two alleles. The blue dye allows tracking of the migration so that the product does not travel off the end of the gel. The polyacrylamide gel is then transferred to a piece of paper, dried, and exposed to autoradiographic film for detection and genotype determination. Figure 5.7-2 shows an example of an autoradiograph result of the radioactive genotyping method.

Fluorescence Detection. The use of radioactivity has been largely supplanted by fluorescent dyes for genotyping, due to the obvious reduction of health hazards and a greater flexibility (as discussed later). As with radioactive labeling, the PCR amplification of the specific SSLP is largely the same, except that one dNTP is labeled with a fluorescent dye (fluorophore). Also, rather than detecting the electrophoresed product by autoradiography, the fluorescently labeled amplicon is

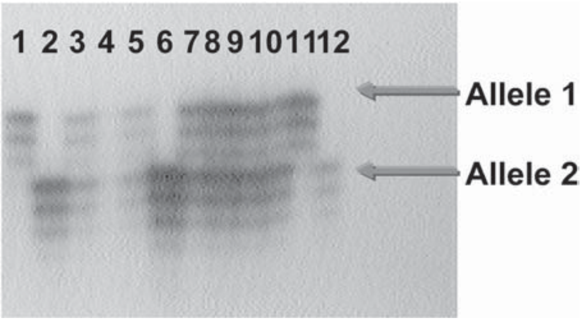

Figure 5.7-2. X-ray autoradiographic film from radioactive genotyping. As in Figure 5.7-1 each column (labeled lanes 1–12) is the genotype of a single SSLP marker in 12 individuals. The two possible alleles are indicated by the red arrows. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_med/pharmaceutical_biotech/.)

detected as it passes a laser detector, either on a gel-based (e.g., an ABI 377 automated slab gel sequencer) or capillary-based DNA sequencer (e.g., an ABI 3700 or 3730 capillary sequencer). A major advantage of using fluorescent detection lies in the automation of genotype determination. As the labeled product passes by the laser detector, the signal is transferred to a computer algorithm that automatically converts the signal detection to a genotype. This greatly reduces manual genotype interpretation, reducing technical time and error as well as increasing overall genotyping throughput. Another important advantage of fluorescent geno-typing lies in the ability to label different SSLP amplicons with different fluorophores. Up to three different fluorophores are commonly used, 6-FAM, HEX, and NED, each of which has a distinct excitation and emission profile. A fourth dye, ROX, is used to label a common internal size standard, allowing accurate determination of product size [13]. The ability to distinguish multiple SSLP amplicons, each labeled with a different fluorophore, allows for simultaneous detection of multiple SSLPs in a single assay, increasing genotyping throughput. This approach is also amenable to high-throughput robotic sample preparation, as it eliminates the precautions necessary for handling radioactivity.

Again, as with radioactive detection, the fluorescent tags can either be directly incorporated into the amplicon or added to the PCR primer. A disadvantage of the labeled primer is that each SSLP must be synthesized with the fluorescent tag attached, which greatly increases the cost of the primer. Oetting et al. [14] devised a method to overcome this cost issue by combining unlabeled template-specific primers and a labeled, common M13 primer. By this method, one template-specific primer for each SSLP is synthesized with an 18-bp tail specific to the M13 phage on its 5′ end. This primer is combined with its template-specific mate, as well as a common M13 primer labeled with a particular fluorophore, and subject to PCR amplification. Figure 5.7-3 shows the general strategy for this method. The amplification begins with the tailed primer incorporating into the template sequence in the initial cycles. In subsequent reactions, the incorporated sequence becomes the docking site for the M13 primer-dye conjugate. The single M13 tailed primer-dye conjugate is common for all SSLPs, greatly reducing the cost of genotyping.

Multiplex Analysis. As discussed, using fluorescent detection of SSLPs greatly improves genotyping throughput because of the availability of multiple fluorophores and the ability to multiplex (determine genotypes of multiple SSLPs simultaneously). The amplicon size of SSLPs varies not only within a single SSLP but also from one SSLP to another, depending on the distance from the repeat the flanking primers are chosen. This allows for the ability to detect multiple SSLPs within a single sample on a gel or capillary, as again each SSLP migrates according to size. For example, the allele size range for one SSLP amplicon may be 120–140 bp, whereas another may range from 200 to 250 bp, and a third may range from 325 to 341 bp. Therefore, all three amplicons could be combined in a single reaction, as the laser can detect the size differences and their ranges are sufficiently different to differentiate the genotypes of the three SSLPs. Furthermore, because the fluorophores have distinct excitation/emission profiles, multiple fluorophores can also be combined in a single sample. Therefore, by combining amplicons of distinct sizes labeled with one fluorophore with those labeled with other fluorophores, one

Figure 5.7-3. Schematic of fluorescent genotyping using an M13-tailed unique PCR primer (green with pink 5′ tail), an untagged unique PCR primer (green), and a common M13-dye conjugated primer (yellow). In the first PCR cycles (top), the unique primers hybridize to the DNA flanking either side of the $(CA)_n$ repeat. The M13 tag is incorporated into the PCR product (middle), creating a site for the fluorescently tagged complementary M13 primer to anneal to and label the PCR product with a particular fluorescent tag (FAM; dark blue star). This product is then detected by either a gel-based or capillary-based DNA sequencer. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

can genotype up to nine SSLPs in a single sample. Figure 5.7-4 displays the results of multiplexing six SSLPs of different sizes and colors (indicating different fluorophores) on a single electrophoretic gel.

Two means of multiplexing are possible, either at the PCR or the electrophoresis steps. It is possible to combine PCR primers specific for multiple SSLPs in a single PCR reaction, whereby each SSLP is amplified simultaneously. The advantage of this approach is the reduction in PCR costs, as the overall reaction size is not modified. However, this approach requires up-front knowledge of the allele-size range of each SSLP in the samples being genotyped. Furthermore, some level of up-front optimization of the PCR reaction may be required so that each SSLP amplicon is generated with the same efficiency within the reaction. Once a set of two or three SSLPs are optimized for PCR multiplexing, these combinations are generally not modified. This approach is most efficient when the same set of SSLPs is used time and time again with varying DNA samples. The other multiplexing approach involves independent PCR amplification of each SSLP, followed by pooling of the amplicons before electrophoresis (gel or capillary). The advantage of this approach lies in the freedom to mix and match different marker sets. Marker sets may be slightly different depending on the population being genotyped. In some cases, the entire genome may be screened for initial linkage results. In other cases, an

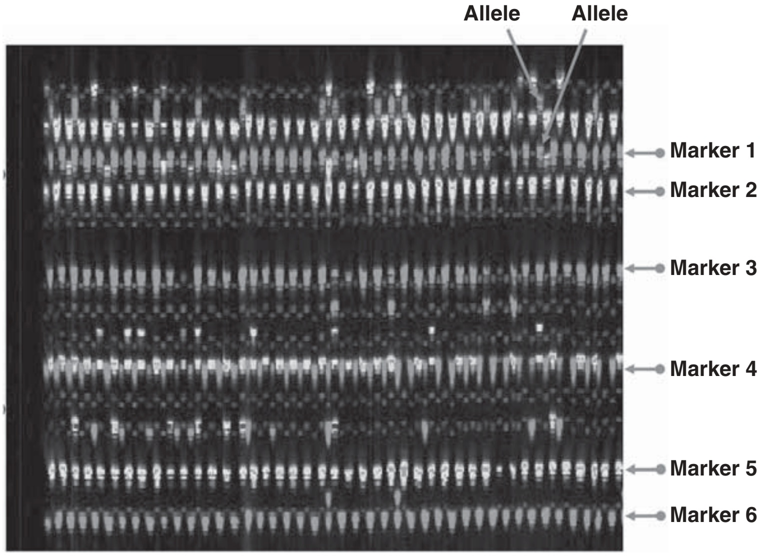

Figure 5.7-4. Multiplex genotyping results from an ABI 377 DNA sequencer. PCR product from six different SSLPs in the same DNA sample were pooled and electrophoresed on the ABI 377 slab gel sequencer. Three SSLPs of independent size ranges were labeled with FAM (blue), and three SSLPs of independent size ranges were labeled with NED (yellow) according to the method outlined in Figure 5.7-3. The red product is a ROX-labeled internal size standard that allows automated determination of allele sizes and conversion to individual genotypes. The laser detection can distinguish between the overlapping FAM-labeled and the NED-labeled SSLP products. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_med/pharmaceutical_biotech/.)

individual locus may be the focus of higher density mapping, for instance, to narrow a disease gene interval by identifying critical recombinant individuals. This assay allows the individual to mix and match markers from a characterized set to do these specific scans. By this approach, multiple pooled amplicons, regardless of primer sequence, have a high success rate.

The use of fluorescent detection, combined with robotics and automated data analysis pipelines, facilitate highly automated, high-throughput genotyping platforms, resulting in thousands of genotypes per day at a relatively low cost.

5.7.2.4 Tools and Resources

To increase the efficiency of genotyping, major efforts have been made to generate a well-characterized and highly efficient marker set for genetic linkage analysis. One such effort was the Cooperative Human Linkage Center (CHLC). This National Institutes of Health (NIH)-funded project characterized thousands of di-, tri-, and tetranucleotide repeat polymorphisms to determine their informativeness (i.e., the number and frequency of SSLP alleles) [6, 10] and to array them according to their genetic position in the human genome (i.e., to develop high-quality genetic maps) [15]. Dr James Weber, a member of this Center, and his colleagues developed several genome-wide marker sets (http://research.marshfieldclinic.org/genetics/

Genotyping_Service/mgsver2.htm). Furthermore, the NIH went on to fund a centralized genotyping center, allowing investigators to submit research proposals for genome-wide linkage scans of their study populations (http://www.nhlbi.nih.gov/resources/medres/genotype.htm). A European group, Genethon, also led a major effort to develop human SSLPs and generate high-density genetic maps for use in genetic linkage studies [16]. These efforts have also reached the commercial arena, where companies such as DeCode will generate genotypes on a genome-wide or region-specific basis on a fee-for-service basis (http://www.decode.com/).

The discovery and use of microsatellites have revolutionized the ability to perform genome-wide genetic linkage studies, resulting in the positional cloning of many important genetic diseases ranging from mental retardation, glaucoma, heart defects, to neurological disease. They are particularly powerful for the localization and identification of single-gene disorders. Furthermore, the high-density genetic maps generated using microsatellite markers were instrumental to laying the groundwork for the eventual sequencing of not only the human genome, but also several other model organisms.

5.7.3 SINGLE NUCLEOTIDE POLYMORPHISMS (SNPs)

5.7.3.1 General Description

DNA is constantly modifying and mutating. During DNA replication, the duplication of the genetic material during cell divisions and inaccurate copying of the existing DNA leads to minor sequence changes in the copied version of the genome. Likewise, environmental influences such as mutagenic chemicals, ultraviolet (UV), or other radiation can also alter the DNA. On the basis of these constantly occurring changes in the DNA sequence of any organism, it becomes obvious that all individuals of a species are slightly different based on their DNA sequence. Most of these differences are single base changes in the DNA. Essentially one nucleotide in the sequence of one individual is replaced by a different nucleotide in another individual. These differences, illustrated in Figure 5.7-5, are called *single nucleotide*

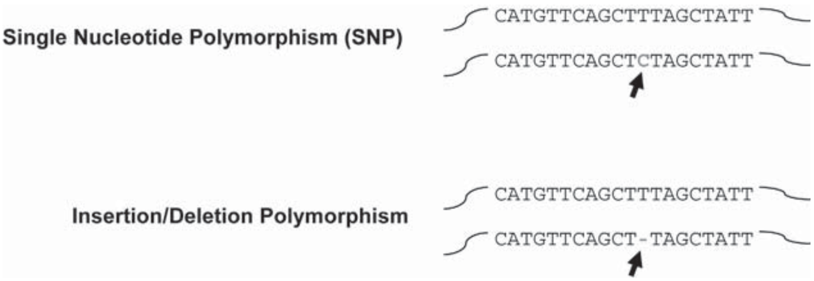

Figure 5.7-5. Single nucleotide polymorphisms and insertion/deletion polymorphisms. Two sections of a DNA strand are shown. The top of the figure shows a SNP, a single nucleotide difference between the two DNA strands (highlighted by a red nucleotide and the arrow). In the bottom diagram, one base is missing in the lower DNA strand (deletion polymorphism), leading to a frame shift in the DNA sequence. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_med/pharmaceutical_biotech/.)

polymorphisms (SNPs). SNPs are the most common genome sequence variation. For the human genome, a comparison of two individuals reveals on average one SNP every 800 bases [17]. As a consequence, two humans differ in their DNA sequence at over 3 million positions, or approximately 0.1%. Similarly, other mammalian species show significant sequence variation as well. In mice, one SNP can be found every 250 bases across the genome when 13 inbred (i.e., genetically identical) and two wild strains are compared [18]. Inbred rat strains show a similar rate of SNPs [19]. These sequence differences are responsible for all genetically caused differences between individuals, such as eye color, hair or coat color, or disease susceptibility. If we could unravel the DNA sequence of every human individual, we would be able to decipher all genetic mutations that cause the most common diseases such as diabetes, stroke, or Alzheimer's disease. Unfortunately, though, the cost of sequencing every patient far exceeds the available budgets for these studies. Therefore, scientists have focused on discovering the most important and most common SNPs in the human genome, and now use this subset of SNPs in the human genome to investigate the genetic causes of these disorders [20]. Similar efforts are under way in other mammalian (and nonmammalian) species that serve as model organisms for specific diseases or traits in humans. Below we will describe and discuss the methods commonly used to discover SNPs, and the methodologies used to interrogate these SNPs in large numbers of individuals simultaneously by genotyping.

5.7.3.2 Discovery

Often, SNPs are discovered by sequencing the same genomic sequence in a number of unrelated samples. For this approach, a region of genomic DNA is amplified by PCR from different DNA samples. The resulting amplicons are resequenced using common sequencing technology. Approaches using gel-based resequencing and hybridization-based oligonucleotide array sequencing have successfully been used for large-scale SNP discovery efforts in the human and mouse genome as well as in other species. Analysis of the resulting sequences reveals base pair differences, or SNPs. Software tools have been developed to automate the SNP discovery from sequencing data [21], and these tools are routinely used today in a variety of organisms for SNP discovery. An example of an SNP as it would appear in sequencing data is shown in Figure 5.7-6.

Although sequencing is commonly used for SNP discovery today, other indirect methods exist to uncover genomic sequences containing SNPs. Given the cost of sequencing, it may be desirable to preselect these DNA fragments for subsequent sequencing, and to eliminate DNA sequences that do not contain polymorphisms.

One of the first reported methodologies for SNP discovery was the PCR-based single-stranded conformational polymorphism method [22]. In this approach, a region of DNA is amplified using PCR. The resulting amplicons are denatured, and they are allowed to re-anneal under conditions that favor the formation of single-stranded secondary structures. As the formation of secondary structures is sequence-dependent, any difference in the sequence of the PCR amplicon would lead to different folding. These differently folded products can be separated through non-denaturing polyacrylamide gel electrophoresis. Samples with different

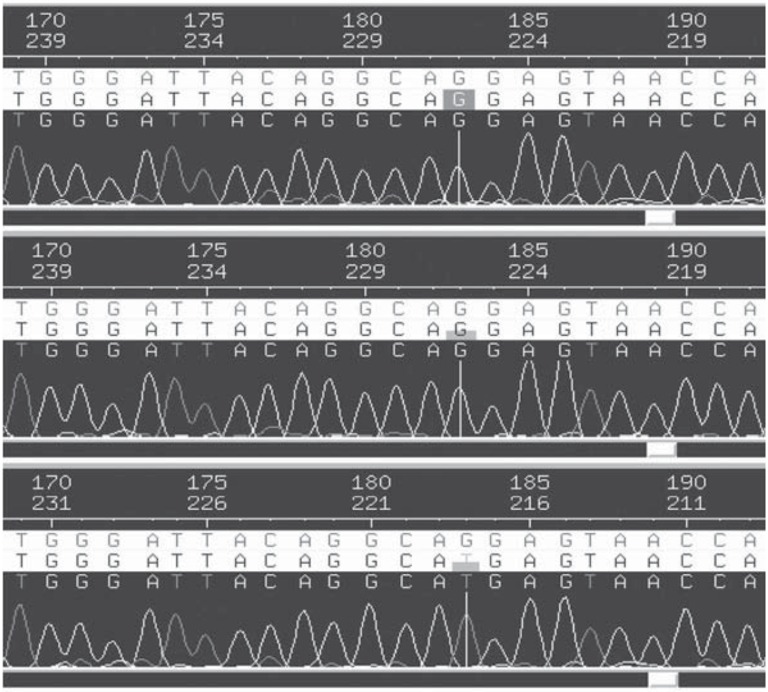

Figure 5.7-6. SNP discovery using the consed and polyphred software tools. The figure depicts three DNA traces from different individuals. Sequencing was performed using BigDye Terminator Chemistry. The white vertical bar highlights a variant nucleotide in the sequence. The top two traces have a "G" at this position, and the bottom trace shows a "T". (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

sequences will fold differently and, as a result, migrate differently in the gel, allowing for the detection of SNPs. This method has been used extensively for targeted screening of genes for potential disease-causing mutations in a variety of species. Recently, it has been adapted for capillary electrophoresis to facilitate large-scale screening (for a recent review, see Ref. 23).

Another approach to identify PCR amplicons that contain sequence variants uses denaturing high-performance liquid chromatography (DHPLC) [24]. In this approach, PCR amplicons are first denatured and then reannealed. In contrast to SSCP analysis, products are then allowed to form double-stranded duplexes. If the PCR product contains an SNP, this re-annealing process will generate homoduplexes (matching sequences reanneal) and heteroduplexes (strands containing the different two alleles of an SNP will anneal and form a single base pair mismatch). When these duplexes are separated on a liquid chromatography column under partially denaturing conditions (separation at temperatures close to the melting temperature of the duplex), the elution times of homo- and heteroduplexes will differ because the melting temperature of the heteroduplex will be slightly lower than the homoduplex due to the base pair mismatch in the sequence. The method and instrumentation has been automated, and it is commercially available. DHPLC has been used successfully for the identification of mutations in a large number of

disease genes, and it has been adapted for the analysis of cancer samples and chromosomal abnormalities [25–32]. Other modifications of the heteroduplex analysis exist, and they have been used by laboratories for a variety of studies. These include mobility analysis [33] or enzymatic cleavage of heteroduplexes [34].

One additional methodology for SNP discovery should be mentioned because it is based on an entirely different experimental approach. In 1995, Faham and Cox [35] described a method called mismatch repair detection (MRD) that used the bacterial mismatch repair system in *E. coli* to enrich for DNA fragments containing SNPs. The template for mismatch repair in *E. coli* is hemi-methylated double-stranded DNA (only one strand of the DNA is methylated), which is formed by mixing and annealing different single-stranded DNA samples grown in methylation-competent and -incompetent *E. coli* strains. The method has been developed into a high-throughput screening platform that can simultaneously analyze pooled PCR amplicons from large numbers of individuals [36, 37]. The method has been shown to enhance the discovery of rare SNPs that would be missed in pooled sequencing (or would require large numbers of individual samples to be sequenced).

In summary, several methods exist to identify SNPs in genomic DNA. Although some of them may be useful to enrich for SNP-containing PCR amplicons before traditional DNA sequencing, the commonly used approach of discovering SNPs from aligned sequence data from different individuals remains the "gold standard" and the basis of the majority of SNPs publicly available in databases.

5.7.3.3 Methods for Genotyping

Numerous methods have been developed and are being marketed for SNP genotyping, i.e., the specific determination of the nucleotide present at a polymorphic site in a genome. Theoretically, this information could be obtained by resequencing each and every sample using the same approach as for SNP discovery. However, this process is labor- and cost-intensive and provides significantly more information than is needed; i.e., it delineates the complete flanking sequence of the SNP, which, in most cases, will not differ between samples, and therefore is redundant. Instead, genotyping methods provide a cost-efficient alternative that can quickly generate genotype information on large numbers of samples. No attention is paid to the remainder of the genome sequence and its potential variation; the only information obtained is the nucleotide present in the sequence at the specific site of a known SNP. To develop methodologies for this genotyping procedure, the SNP in question, its possible nucleotides (alleles) that can be present at the site, and the sequence adjacent to the SNP need to be known. All methods discussed below use this information to obtain genotyping information for a large number of DNA samples. As outlined below, the different methods allow the analysis (genotyping) of individual SNPs in large numbers of samples, or varying numbers of SNPs for one sample at a time. All methods have been shown to result in reliable genotyping results with low error rates. The choice of the appropriate methodology primarily depends on the number of SNPs and the number of samples that need to be interrogated.

Essentially all genotyping approaches used to date fall into one of four categories: allele-specific hybridization, primer extension, oligonucleotide ligation, or invasive cleavage. Figure 5.7-7 illustrates these different approaches. We will first

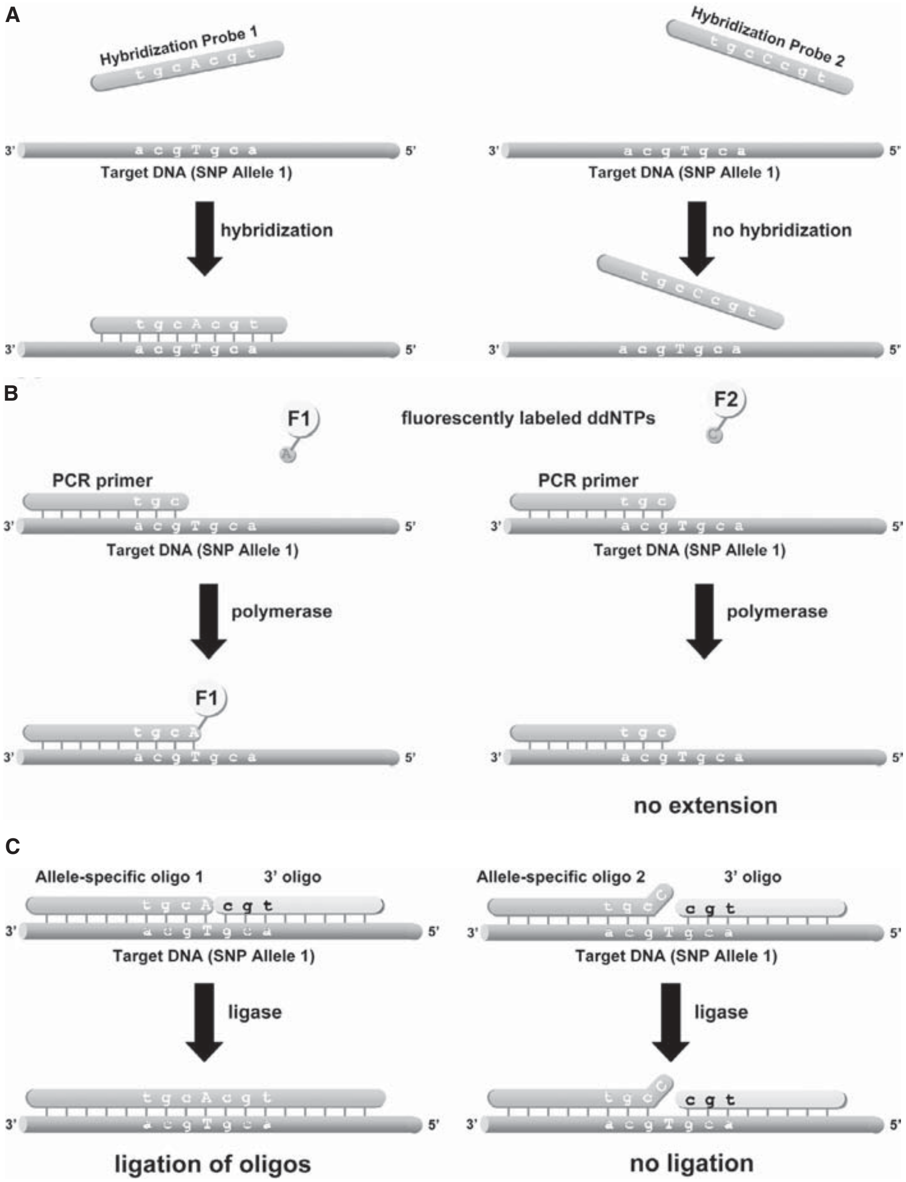

Figure 5.7-7. Schematic overview of different SNP genotyping approaches. (**A**) Allelic hybridization. (**B**) Primer extension. (**C**) Oligonucleotide ligation. (**D**) Invasive cleavage. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

briefly describe the principles of each approach and then outline commercially available genotyping platforms based on these approaches for different study applications.

Allele-specific Hybridization. Allele-specific hybridization distinguishes the allele present at an SNP using two different oligonucleotide probes. Each probe

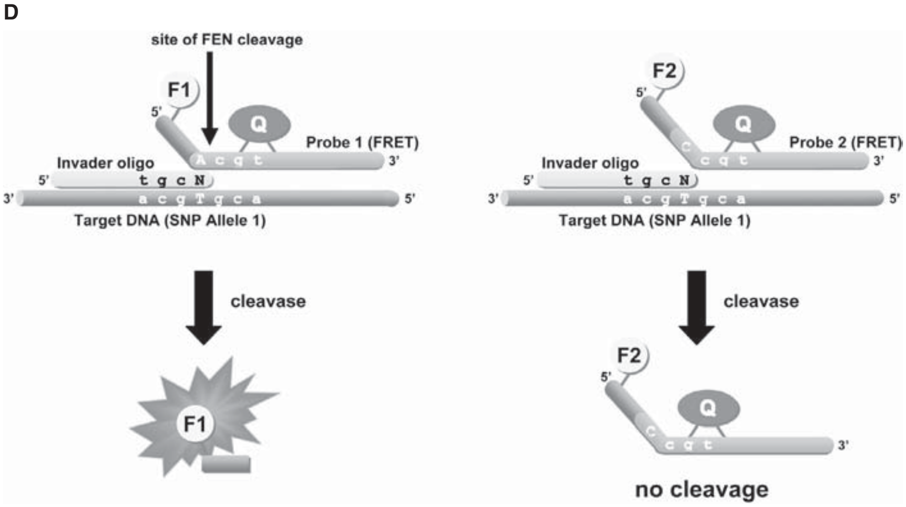

Figure 5.7-7. *Continued*

contains the SNP position in the middle and is complementary to one allele of the SNP. For hybridization to genomic DNA or PCR amplicons, conditions are chosen that allow the hybridization of the matching probe but not the mismatch probe. The successful hybrids between the target DNA and the oligonucleotide probes can be detected using a variety of approaches. Methods include the use of fluorescence resonance energy transfer (FRET) probes (e.g., in the 5′ exonuclease TaqMan assay, described below), molecular beacon probes, or oligonucleotide arrays (Affymetrix GeneChip system, see below).

Primer Extension. Primer extension uses the standard principle of PCR. Here, an oligonucleotide primer extends up to the SNP site. The assay then determines what nucleotide is incorporated into the extended PCR product by the polymerase. Often, the assay is performed in two steps. First, the genomic interval is amplified by PCR. The amplified product is subsequently mixed with another primer that anneals adjacent to the SNP site. Then individual dideoxynucleotides are added to the reaction. Upon incorporation of the matching nucleotide at the SNP site, the resulting extension product can no longer be extended further because it lacks a 3′–OH group required for nucleotide incorporation. Thus, the reaction essentially stops once the nucleotide has been incorporated.

Dideoxynucleotides are commercially available with different fluorescent tags; therefore, the resulting extension products can be examined using laser scanners to see which fluorophore has been incorporated. This method directly reveals the genotype of the template DNA. The method can be multiplexed and is commercially available (SNaPshot, see below). Alternatively to the use of dideoxynucleotides, regular deoxynucleotides can be used sequentially in the extension reaction. Here, the primer is essentially extended as in a regular PCR reaction. The only difference is the sequential addition of one nucleotide at a time. This method is commercially available (see pyrosequencing, described below).

Oligonucleotide Ligation. Similar to DNA polymerase, DNA ligase is a highly specific enzyme that repairs nicks in the DNA. Nicks are missing phosphodiester

bonds in one of the two strands of the DNA molecule. DNA ligase detects and repairs these nicks, provided the nucleotides on both sides of the missing bond are complementary to the nucleotides in the intact DNA strand. Landergren et al. [38] first described a novel approach for SNP genotyping that uses specific oligonucleotides that will hybridize to single-stranded DNA templates. One oligonucleotide will align with the sequence upstream of an SNP, including the actual nucleotide at the SNP site. A second oligonucleotide is complementary to the downstream template sequence, starting with the first nucleotide adjacent to the SNP. Although the latter oligonucleotide can be used to interrogate both alleles of the SNP, the first oligonucleotide is specific for one allele of the SNP, because it will end with the specific SNP nucleotide. Only the oligonucleotides perfectly matching the template sequence will be ligated by the ligase, whereas a mismatch will prevent the ligation of the alternate oligonucleotide. The method has been incorporated in a variety of commercial platforms such as the SNPlex platform or the Illumina GoldenGate technology, which is described below in more detail.

Invasive Cleavage. The last SNP genotyping method we describe is invasive cleavage, which is commercially available as the Invader assay. This method depends on the ability of flap endonucleases to recognize specific three-dimensional structures that are formed when two overlapping oligonucleotides hybridize perfectly to a target DNA molecule [39]. The overlap occurs at the SNP site, and only the oligonucleotide combination that is complementary to the SNP allele will be cleaved by the enzyme. The reaction is highly specific, and a mismatch to the target DNA will prohibit the enzymatic reaction. This methodology has been adapted for SNP genotyping assays, as described in more detail below.

Analysis of Individual SNPs. Historically, investigators have used a variety of PCR-based methods to genotype individual SNPs. For all of these methods, the genomic sequence around the SNP was known and amplified using specific PCR primers that selectively amplified the genomic interval, including the SNP. SNPs that alter a restriction enzyme recognition site could then be genotyped by performing a restriction digest of the PCR product and by separating the resulting DNA segments by agarose gel electrophoresis. PCR products that contain the restriction enzyme recognition site will be cleaved into two products and will result in two bands of different size on the agarose gel. In contrast, PCR products from samples that contain an SNP in the recognition site will no longer be cleaved by the enzyme, and will result in a single band of larger molecular weight upon gel electrophoresis. Finally, PCR products from samples heterozygous for the SNP would result in a total of three bands, one band for the uncleaved product and two additional bands from the portion of the PCR product that can be cleaved. A schematic of the procedure is shown in Figure 5.7-8. The method enjoys widespread use to this day because it is robust and uses basic molecular biology technology available to most laboratories. With the ever increasing number of commercially available restriction enzymes uncovered from various microbes, the repertoire of SNPs that can be genotyped by this approach has been steadily increasing.

Unfortunately, many SNPs do not lead to an alteration of a restriction enzyme recognition site in the genome sequence. For these SNPs, alternative approaches have been developed that use PCR and gel electrophoresis. In one approach, one

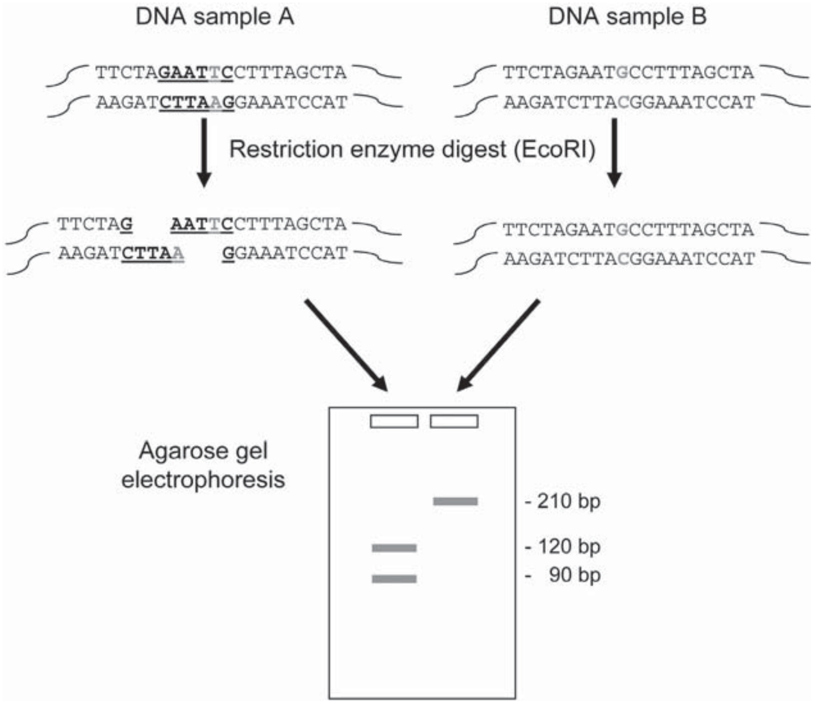

Figure 5.7-8. Schematic overview of PCR–RFLP. Double-stranded DNA molecules are shown for DNA sample A and B. These two samples are PCR amplicons from genomic DNA. The two sequences differ for the base pair highlighted in red. Sample A contains a restriction enzyme recognition site for *Eco*RI (underlined), and sample B does not. After restriction enzyme digestion, agarose gel electrophoresis results in different DNA fragments for the two samples. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_med/pharmaceutical_biotech/.)

initial PCR primer is designed so that it includes the polymorphic SNP site at its 3′ end. Two separate primers are used in two PCR reactions. One reaction includes the forward primer ending with one nucleotide present at the SNP, and the other reaction includes a primer ending with the alternative nucleotide. As the thermostable DNA polymerase used in PCR requires a perfect match of the primer at the 3′ end to attach additional nucleotides and amplify the DNA segment, the PCR reaction will only yield a PCR product when the forward primer perfectly matches the DNA template. Accordingly, the presence or absence of PCR product depending on the primer used indicates the genotype for the template DNA. Although this method works well for established assays, each assay needs to be optimized individually to ensure that both alleles of the SNP are successfully amplified when present. Furthermore, the design of the PCR primers may be difficult for some SNP sequences.

As an alternative to the allele-specific PCR and the restriction digest of PCR products (often called PCR–RFLP), several commercial platforms are available to genotype individual SNPs in large numbers of samples. In our discussion here, we will focus on three commonly used platforms: the 5′-exonuclease TaqMan assay,

based on allele-specific hybridization; pyrosequencing, based on the primer extension principle; and the Invader assay, based on the invasive cleavage reaction of a flap endonuclease.

TaqMan Assay. The TaqMan assay uses the 5′ exonuclease activity of Taq polymerase [40]. Two FRET oligonucleotide probes complementary to the sequence around an SNP are hybridized to the target DNA. Each contains a different fluorescent dye that is quenched in the FRET probe. Each probe is specific for one of the two SNP alleles; i.e., it contains the complementary base to the SNP allele in the middle of the probe. The hybridization temperature is chosen such that only the matching probe hybridizes efficiently. After hybridization, a normal PCR extension reaction begins starting from an oligonucleotide primer annealed upstream of the FRET probe. The Taq polymerase extends the primer and, upon reaching the hybridized FRET probe, begins to remove it from the template DNA by cleaving one nucleotide at a time. The reaction is mediated by the specific 5′ exonuclease activity of the *Taq* polymerase. Once the entire oligonucleotide FRET probe has been cleaved, the fluorophore and the quencher molecule have been separated, and the energy transfer can no longer take place because the two molecules are no longer in close physical proximity. As a consequence, the fluorophore will now emit light upon excitation. As the two FRET probes contain different fluorophores depending on the allele, the resulting fluorescent color unambiguously determines the allele of the SNP in the target DNA.

TaqMan assays are commercially available for many SNPs and can be designed on demand by Applied Biosystems. The method requires a real-time PCR instrument or a fluorescent plate reader to measure the fluorescence of the two dyes at the end of the PCR reaction.

Pyrosequencing. Pyrosequencing [41] has been described as a sequencing-by-synthesis method. In this approach, four different enzymes and specific substrates are used in a sequential reaction to produce light whenever a nucleotide complementary to the template DNA strand is incorporated. If the added nucleotide is not complementary to the base in the template DNA, no light is generated. The light-generating reaction is depended on the pyrophosphate that is released during the DNA polymerase reaction. If the added nucleotide forms a base pair, the DNA polymerase incorporates the nucleotide and pyrophosphate will be released. The released pyrophosphate will be converted to ATP by another enzyme (ATP sulfurylase). Luciferase then uses the ATP to generate a detectable light signal. The light intensity is proportional to the number of the ATP molecules, which in turn is proportional to the number of the incorporated nucleotides. After the completion of the reaction, the excess of each nucleotide is degraded by apyrase.

The reaction is repeated in the same order, with a different nucleotide added. If the added nucleotide does not form an incorporated base pair with DNA template, no light will be produced. The four nucleotides are added to the mixture in a defined order (e.g., ACGT), and thus, the sequence of the template DNA can be deduced by matching the nucleotide with the light signal generation.

Pyrosequencing provides rapid real-time determination of 20–30 nucleotides of target DNA sequence. With this technology, not only the SNP alleles but also the

adjacent nucleotides are determined, providing greater confidence in the correct SNP detection. The reaction is automated and requires a dedicated instrument.

Invader Assay. The Invader assay [39] uses two oligonucleotide probes that are hybridized to target DNA containing an SNP site. The two oligonucleotides hybridize to the single-stranded target and form an overlapping invader structure at the site of the SNP, as illustrated in Figure 5.7-7. One oligonucleo-tide, the Invader oligo, is complementary to the target sequence 3′ of the polymorphic site, and it ends with a nonmatching base overlapping the SNP nucleotide. The second oligonucleotide, the allele-specific probe, contains the complementary base of the SNP allele, and extends to the sequence 5′ of the polymorphic site. This probe can also extend on its 5′ site with additional noncomplementary nucleotides. Once the two oligonucleotides anneal to the target DNA, they form a three-dimensional invader structure over the SNP site that can be recognized by a specific enzyme, cleavase, or flap endonuclease. The enzyme cleaves the probe 3′ of the base complementary to the polymorphic site (i.e., 3′ of the overlapping invader structure). If the probe is designed as a fluorescence resonance energy transfer (FRET) molecule containing a fluorophore at the 5′ end and an internal quencher molecule, the cleavage reaction will separate the fluorophore from the quencher and generate a fluorescent signal. If, in contrast, the probe oligonucleotide does not match the SNP allele present in the target DNA (i.e., the probe is complementary to the alternate SNP allele), then no overlapping invader structure is formed, and the probe is not cleaved. This distinction is highly specific, with only minimal unspecific cleavage of the mismatch probe.

Often, the Invader oligonucleotide is designed to permanently anneal to the target DNA at the assay temperature. In contrast, the probe oligonucleotide is designed to have a melting temperature close to the assay temperature. As a consequence, the probe constantly anneals and detaches. During the annealing, cleavase can cleave the oligonucleotide, the remnant detaches, and a new uncleaved oligonucleotide probe can reanneal to the same site. This design ensures the cleavage of a large number of probes, resulting in a strong signal even from small amounts of template DNA. Therefore, SNPs can be genotyped directly from genomic DNA using Invader assays, eliminating the need for additional PCR amplification. In addition to the FRET probes, other methods of detection (polarized light, mass spectrometry) have been used [42–44]. However, the benefit of the fluorescence detection is the ability to read the assay after isothermic incubation in a standard fluorescence plate reader.

Multiplex Analysis. Although the methods described above work well and reliably, they are not suited for genotyping multiple SNPs in large sets of samples. As each SNP has to be assayed individually, all SNPs have to be interrogated sequentially rather than in parallel. However, numerous other platforms exist that allow the genotyping of several SNPs at the same time. Here, we will discuss methods that allow up to 10 SNPs to be genotyped in one reaction. In addition, we will discuss high-throughput approaches in the next section.

Both methods described here are based on the primer extension reaction. In both platforms, oligonucleotide primers are designed that extend up to the nucleotide adjacent to the SNP site. The following primer extension reaction will use ddNTPs

to incorporate the matching base for the SNP allele present in the target DNA. The resulting products are then separated and detected by different methods.

The first detection method, as implemented in the MassEXTEND platform from Sequenom, uses mass spectrometry to determine the accurate molecular weight of the resulting extension reaction product, using matrix-assisted laser desorption/ionization time-of-flight (MALDI–TOF) mass spectrometry. For this approach, the reaction products are mixed with a matrix and deposited on the surface of a metal plate. The matrix and the reaction products are hit with a pulse from a laser beam, resulting in the vaporization of a small number of DNA molecules from the reaction product. The vaporized molecules are transferred into a vacuum flight tube and charged with an electrical field pulse. This accelerates the resulting ions toward the detector at the end of the tube. The time between the application of the electrical field pulse and the collision of the ions with the detector is referred to as the time of flight. As the time it takes for the ion to pass through the flight tube to the detector is directly proportional to the mass of the ion (with larger molecules flying slower), this is a very precise measure of the molecular weight of the DNA products. The detectable mass differences are small, and the difference between an incorporated ddA and ddT of 9 mass units can be clearly distinguished. The assay allows further multiplexing even for reactions resulting in very similar mass for the products by adding noncomplementary tail sequences to the 5′ end of the primer, thus increasing the mass of the extension product. A 12-plex has been described by Ross et al. [45] and even a 20-plex by Kim et al. [46].

Alternatively, the single base extension products can be analyzed using the SNaPShot technology from Applied Biosystems. In this approach, fluorescently labeled ddNTPs are used in the primer extension reaction, and the resulting extension products are separated and detected using commercially available capillary sequencers. Each ddNTP is labeled with a different fluorescent dye; thus, the different alleles of a SNP can be distinguished by the different color. Similar to the MassEXTEND approach, multiplexing can be improved by adding noncomplementary tail sequences to the primer. According to the manufacturer, 10-plex reactions can be performed with high accuracy.

High-Throughput Approaches. Currently, three high-throughput platforms for SNP genotyping are commercially available. All platforms allow the genotyping of large numbers of SNPs (1000–500,000) in a single experiment for one DNA sample. Although this significantly reduces the genotyping cost per SNP, it results in a tremendous cost for a project when 1000–2000 DNA samples need to be genotyped for thousands of SNPs. In addition, all approaches require specialized equipment and therefore are only of interest to laboratories that intend to perform large numbers of genotyping projects.

The first assay platform, developed by Illumina, combines allele-specific ligation with an extension reaction. The method, called the GoldenGate assay, uses the BeadArray technology, a method using fiberoptic substrates with randomly assembled arrays of beads. Detailed information and flow charts of the methodology can be found at the Illumina website (http://www.illumina.com/products/prod_snp.ilmn).

In the assay, three oligonucleotides are designed for each SNP locus. Two oligos are specific to each allele of the SNP site, called the Allele-Specific Oligos (ASOs).

A third oligo that hybridizes downstream from the SNP site is the Locus-Specific Oligo (LSO). All three oligonucleotide sequences are complementary to the target sequence and contain universal PCR primer sites. During the primer hybridization process, the assay oligonucleotides hybridize to the genomic DNA sample bound to paramagnetic particles. Hybridization occurs before any PCR amplification step; therefore, no amplification bias is introduced into the assay. Extension of the appropriate ASO and ligation of the extended product to the LSO joins information about the genotype present at the SNP site to a unique address sequence on the LSO. These joined, full-length products provide a template for PCR using universal PCR primers, two of which are fluorescently labeled. As a last step, the single-stranded, dye-labeled amplification products are hybridized to the complement bead type through their unique address sequences, and the labeled beads can be analyzed using arrayed optical fibers. Up to 1536 SNPs may be interrogated simultaneously in this manner using this Golden-Gate technology.

Similar degrees of multiplexing can be achieved using oligonucleotide array technology from Affymetrix. These arrays contain 25-mers that are synthesized directly on chip surfaces. In recent iterations, Affymetrix has developed arrays that allow the interrogation of 10,000, 100,000, or even 500,000 SNPs per reaction. The 500K array methodology uses an approach called whole-genome sampling analysis to selectively amplify regions of the genome containing SNPs, and subsequently interrogate the alleles present in the amplification products by hybridization to allele-specific oligonucleotides.

In the first step of the analysis, a single genomic DNA sample is digested with a restriction enzyme. After complete digestion, adaptors are ligated to the digestion products that allow the amplification of a subset of the fragments using a universal primer pair complementary to the adaptor sequence. Any SNP located in close proximity to the restriction site will be amplified by PCR and can be interrogated on the chip. The resolution is primarily driven by the restriction enzyme used. The more it cuts the genomic DNA, the more small amplification products can be obtained and hybridized to the chip. Accordingly, the different chips, (10K, 100K, 500K) use different enzymes in the initial step of the reaction, but subsequent steps are identical.

Although the assay allows the interrogation of a large number of SNPs simultaneously, the user has no influence on the composition of the chip, i.e., the SNPs that will be interrogated. The complete panel of 500,000 SNPs has been preselected during the design of the chip, primarily driven by the technical requirements of the restriction digest and amplification described above. However, a novel methodology developed by Parallele Biosciences (now Affymetrix) uses the chip-based hybridization approach for the ultimate analysis, but it uses a different approach for the SNP interrogation. A more detailed description and illustrations of the method can be found at http://www.affymetrix.com/technology/mip_technology.affx. The approach, termed molecular inversion probe (MIP) technology, uses a long oligonucleotide that will hybridize with its end sequences in inverted fashion to the flanking sequences of an SNP [47, 48]. Using one dNTP in four different reactions, the SNP site can be filled in to form a circular padlock probe around the SNP site. The probe will only circularize when the dNTP added is complementary to the SNP allele present. The circular probe is resistant to DNAse digestion. Once the nonfilled probes have been digested using DNAse, the padlock probe is opened,

using a cleavage site within the MIP to form a linear template for a PCR reaction using universal primers. The amplification product contains a unique tag sequence for each MIP that can be detected by hybridization to an Affymetrix TrueTag array. Assays can be designed and genotyped in parallel for up to 10,000 SNPs. This platform offers a new tool to design custom panels of SNPs for a specific study, rather than depend on a preselected set of SNPs on other Affymetrix chips.

Overall, all three approaches allow the efficient genotyping of large numbers of SNPs. All require specialized equipment, and although the cost of genotyping per SNP is low, the total cost of any genotyping project is high due to the large number of SNPs. These technologies are only suitable for large-scale studies, and they are best performed in collaboration with or support from institutional core facilities.

5.7.3.4 Linkage Disequilibrium and Haplotypes

Most SNPs in a genome probably arose from individual single mutation events at an early time during the history of the species hundreds of generations ago. From the time of each mutation event, the new allele (i.e., the new "mutant" nucleotide) is located on an individual chromosome that has specific alleles of other SNPs that arose previously on the same chromosome. This physical arrangement of SNP alleles along a chromosome is called a *haplotype*. Over multiple successive generations, recombination and novel mutation events will lead to a rearrangement or modification of this ancestral haplotype around the new SNP allele. As a consequence, the new allele only remains on the same portion of the ancestral haplotype with other SNP alleles that are on a short distance away; i.e., recombination events are less likely to separate the two alleles. This nonrandom arrangement of SNPs along the chromosome, i.e., the maintenance of a small segment of the ancestral haplotype, is called *linkage disequilibrium* (LD) or *allelic association*. This arrangement is used in disease association analyses that are based on the idea that it should be possible to identify the effect of any common disease-causing SNP allele by determining the ancient haplotype segment on which it is located. By using a sufficient number of SNP markers in a genetic study, any common variant, even if it was not assayed directly, should display significant LD with a neighboring marker SNP. This approach has been used successfully in human genetic studies to identify genes responsible for Mendelian disorders such as Hirschprung's Disease or cystic fibrosis [49, 50].

The LD structure has been primarily studied in the human genome [51–53], although initial analyses have been performed for the mouse, rat, and dog genome as well. In the human genome, it has become clear over the past several years that the extent of LD and haplotypes in the human genome is not simply a function of distance between SNPs. Rather, the size of regions of significant LD is highly variable in different regions of the genome and reflects the complex history and interplay of recombination and mutation on different regions of the genome. If SNPs are not in LD, the alleles of the SNPs occur in seemingly random combination on individual chromosomes. As a consequence, the alleles of neighboring SNPs, in the absence of LD between them, can form a large number of different haplotypes (2^n for n SNPs). In contrast, regions where neighboring SNPs are in significant LD, only a small number of resulting haplotypes is observed. These haplotypes are representative of the ancient haplotypes that have not been broken up by

recombination. Therefore, an analysis of haplotype patterns would not only identify regions of significant LD between SNPs, but it would also identify those common (presumably ancient) haplotype patterns that represent the majority of chromosomes in that particular genomic interval. Knowledge of these common haplotypes would then permit the identification of "tag SNPs," individual representative nonredundant SNPs that would unambiguously differentiate all major haplotypes without analyzing all SNPs in that particular region.

To facilitate the selection of these tag SNPs, the International HapMap Consortium, a publicly funded effort by the National Institutes of Health, has analyzed the genome-wide LD structure comprehensively in four different human populations: A cohort of North Americans of Northern European descent, an African population, a cohort of Han Chinese, and Japanese individuals [20]. In total, over 5.8 million SNPs have been genotyped in each of these populations, and the data of this effort are publicly available. It is the hope that selecting an informative subset of SNPs based on LD information from this study will provide a genome-wide coverage in whole genome disease association studies [54–57]. Here, SNPs would be selected so that all other SNPs from the HapMap study not included in the representative set would be in LD with one or more of the selected SNPs. It has been estimated that this comprehensive coverage of the human genome will require around 500,000 SNPs across all chromosomes. Undoubtedly, commercial providers of genotyping platforms will offer high-throughput SNP panels based on the HapMap information in the near future.

5.7.4 APPLICATION FOR GENETIC ANALYSES

As mentioned in Section 5.7.1, genotyping of SSLPs and SNPs is essential for the analysis of the genetic basis of common disorders. In the following section, we will briefly discuss the use of these polymorphisms in linkage and association analysis.

5.7.4.1 Linkage Analysis

A powerful means of identifying the location of genes causing disease is by genetic linkage mapping. During meiosis, when germ cells are being generated, homologous chromosomes can recombine, or cross over. As a result, offspring will have different combinations of parental alleles. We can use the percentage of recombinant offspring as a measure of physical distance, making a genetic linkage map. Linkage maps are based on probability. For instance, if two genes or loci are on different chromosomes, the probability of cosegregation of these loci is 50%. However, the closer loci are on the genome, the lower the probability of recombination between them. The measure of genetic distance is approximately the recombination frequency between loci. Although linkage is defined as <50% recombination, 47% recombination, for example, is not a reassuring or reliable measure of distance. Therefore, a genetic map needs many genetic markers to be reliable. Because of their relatively high abundance, their high informativeness, and their representation across all eukaryotes, SSLPs are the backbone of nearly every eukaryotic genetic map. To generate a genetic linkage map, large families, such as the

three-generation families from The Foundation Jean Dausset-Centre d'Etude du Polymorphisme Humain (CEPH), are typically genotyped with hundreds or thousands of SSLPs. Analytical computer programs determine the frequency of recombination between parents and offspring, thus determining the distance between markers, and arrange the SSLPs according to their order and distance on each chromosome.

High-density genetic maps spanning the entire human genome have been generated by several groups and are commonly used for mapping disease genes and quantitative trait loci (QTL) [15, 16]. Just as recombination determines the genetic distance between SSLPs, it also determines the distance between a disease gene and an SSLP. If a particular gene determines a specific phenotype or disease, then one can genotype families with SSLPs spanning the genome and identify cosegregation of an SSLP allele and a clinical phenotype. If recombination is significantly lower than expected between an SSLP allele and a clinical outcome, e.g., hemophilia, then the gene causing the disease is *linked* to that marker. Because the genome location of that marker is known, the location of that disease gene is also known. The first disease linked by the use of microsatellite genotyping was facioscapulohumeral muscular dystrophy in 1990 [58]. Since that time, thousands of loci have been mapped using this approach. Genetic linkage studies are most powerful when studying large, multigenerational families affected by a single gene (Mendelian) disease. However, linkage has proven more of a challenge with common complex diseases. Because multiple genes with relatively small effects are thought to be involved in common diseases such as hypertension or diabetes, combined with the fact that these diseases often affect older patients, it is often impossible to find large families with multiple generations. To address these issues, association studies offer the advantages of being able to study cases and controls or small families, which are much more readily ascertained. Furthermore, the large number of SNPs and high-throughput SNP genotyping technologies now makes genome-wide association studies feasible, as discussed below.

5.7.4.2 Association Analysis

When it proves difficult to recruit a sufficient number of families for a genetic study, a popular alternative is an association study to elucidate the genetic basis of common diseases. In contrast to linkage studies where SSLP markers are used to identify a region of the genome that is inherited by affected offspring from affected parents, association studies aim to identify alleles that are found more often in individuals affected by a disease than in a control group. In the perfect association study, one would test the causal mutation for association with disease. However, in almost all cases, the causal mutation is unknown. As a consequence, association studies resort to indirect approaches relying on linkage disequilibrium (LD) between the causal mutation and another SNP that is being genotyped. If the SNP was associated with the disease, one would expect to find a higher frequency of the associated allele of the SNP in individuals affected by the disease (cases) when compared with a healthy control group.

Association studies can be performed in family-based cohorts. Numerous statistical approaches have been developed to test for association of SNP alleles with disease in small trios, nuclear, or even extended families. However, most

association studies use unrelated patients in their analysis. In these cohorts, it is assumed that individuals are affected because they share a similar genetic susceptibility. However, as it is possible that some individuals may be affected for reasons other than genetic susceptibility (most common human disorders are also significantly influenced by environmental factors, e.g., lifestyle), it is imperative that a large number of patients is recruited for the study so that most individuals share the same genetic susceptibility genes and mutations. This cohort of affected individuals is then matched with a cohort of unaffected, healthy controls. Here, it is important that these control individuals match the patient cohort in the distribution of age, sex, ethnicity, and potential environmental factors that may influence the development of the disease.

Once the case and control cohorts have been collected, the DNA samples can be used for SNP genotyping. Depending on the scope of the study, samples are either genotyped for SNPs in candidate genes that were preselected for the study or a genome-wide association analysis using a comprehensive SNP set across the entire genome will be performed. Published data to date primarily include candidate gene association analyses. A recent review by Newton-Cheh and Hirschhorn [59] discusses in detail the important considerations for the design of these association studies and the potential problems that can be encountered. The number of SNPs to be analyzed would determine the best genotyping platform to be used in the study. Clearly, candidate gene SNPs can be genotyped with common approaches for individual SNP genotyping or moderate multiplexing platforms. However, genome-wide association studies will require high-throughput approaches.

Although the recent efforts to elucidate the LD structure of the human genome (HapMap Consortium) promise to facilitate the selection of informative subsets of SNPs for these types of association studies, it remains to be seen whether whole genome association studies will help uncover the genetic determinants for such common diseases as diabetes, asthma, or cardiovascular disorders. Clearly, candidate gene studies have yielded several well-replicated associations, but they account only for a small portion of the overall genetic susceptibility. Hopefully, comprehensive association studies of these disorders will help uncover additional genes responsible for the disease susceptibility. These discoveries would significantly advance our ability to predict, diagnose, and hopefully treat these disorders in affected individuals.

6.1.1 INTRODUCTION

The human body is a veritable pharmacopia of useful protein drugs. After all, it is the collection of our own, endogenously produced enzymes, hormones, and antibodies that are responsible for maintaining homeostasis, stabilizing wounds, fighting infections, neutralizing toxins, keeping cancerous cells in check, and generally keeping us alive. It is only when we lose the function of certain enzymes, hormones,

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

or antibodies—or when our bodies are overwhelmed with some kind of trauma (blood loss, stroke, heart attack, massive infection, or heavy tumor burden)—that we need some supplementation to our natural protein drugs. The fact that our bodies or body fluids contain some kind of miraculous healing or "vital" substances was recognized even in ancient times by the Chinese, Moche Indians, Maasai, ancient Scythians, Gypsies, and early Christians when would-be warriors or the sick and sinful were encouraged to drink such body fluids as blood or urine to imbue health, healing, or strength. However, the general failure of these primitive protein cocktails was probably evident to most patients and many physicians especially by the Middle ages. Given the abysmal failure of oral protein delivery, Italian physicians, in the late 1400s began experimenting with a different approach, namely intravenous delivery via blood transfusions. The first recorded instance of a therapeutic blood transfusion was for the treatment of Pope Innocent VIII who fell into a stroke-induced coma in 1492 [1]. Although this effort ultimately failed, efforts to refine or improve blood transfusions from animals to humans or humans to humans as a way to treat wounds and other illnesses continued for another 300 years. The first therapeutically successful blood transfusion, and perhaps the first example of the successful use of a protein drug (albeit impure albumin), was performed in England by James Blundell in 1825 to treat a woman suffering from postpartum hemorrhaging [2]. By 1844 Blundell and his colleague Samual Armstrong Lane became the first to use blood (i.e., factor VIII) to treat a genetic disease—hemophilia [3]. Throughout the 1800s and early 1900s, blood transfusions became more refined (through blood typing and the use of aseptic conditions) and blood became a therapeutic protein product to treat wounds (albumin), infections (antibodies, antiglobulins), and other genetic disorders.

Obviously blood is not the only source of protein drugs. As far back as 1796 other sources of protein pharmaceuticals were beginning to be recognized. In particular, the work of Edward Jenner in developing an effective small-pox vaccine [4] could possibly be described as the first example of using protein drugs for prophylactic purposes. Keeping with the ancient theme of using "vital" body fluids for medical applications, Jenner used the fluid from cow-pox pustules as the source of his protein pharmaceutical (cow-pox viral coat proteins). In the 1870s Louis Pasteur extended Jenner's ideas by developing vaccines for cholera, anthrax, and rabies using deactivated bacterial cells or dried nerve tissues. Pasteur formulated the dried bacterial or viral protein components into injectable solutions. In this regard Pasteur was the first to introduce the concept of "synthetic" or *ex vivo* biological products as potential drugs. However the idea of working with a purified, active ingredient, especially with biological material, was still many years away. The principle of prophylactic vaccines, developed by Jenner and refined by Pasteur, was also extended to the development of "therapeutic vaccines" or antivenoms in the late 1800s. Antivenoms are generated using a method developed by Albert Calmette in 1895, which he devised to treat victims of cobra bites. Antivenoms are created by injecting a small amount of the targeted venom into animals such as horses, sheep, or rabbits. This leads to the production of different antibodies against the toxin. The mixture of antibodies is then harvested from the animal's blood and serves as the antivenom for a specified source venom.

Up until the mid-1800s the true source of the therapeutic powers of blood or the prophylactic powers of pustules or bacterial extracts was not known. Then in 1838

the concept of proteins was introduced by Jons Jakob Berzelius [5]. Berzelius argued that proteins (he is credited for creating the name) found in blood and bacteria were special organic substances that behaved or functioned as chemical compounds. This led to the realization that many different proteins existed in blood and other biological tissues and that they could potentially be isolated and treated as pure substances, just like all other chemical or small-molecule drug entities. However, it was not until 1922 that the technology to isolate therapeutically useful proteins was put to good use. Thanks largely to the work of four Canadian scientists (Banting, Best, Collip, and MacLeod), insulin became the first "pure" protein therapeutic to be used in the successful treatment of a human disease—diabetes. Before 1922, type I diabetes was a near-certain death sentence characterized by an agonizingly long and painful wasting process. The fact that it frequently afflicted adolescent children made it particularly devastating. Although the cause of diabetes was partially known by 1910, early efforts to use unpurified pancreatic extracts met with repeated failure and severe allergic reactions. The use of purified insulin, on the other hand, had absolutely stunning results. It is hard not to overstate the kind of spectacular recoveries observed among diabetic patients nor the effect that insulin, as a drug, had on the public as well as on the medical and pharmaceutical community. Indeed, the insulin "effect" not only saved the lives of millions of diabetics, but it essentially launched the modern concept of "pure" protein pharmaceuticals and laid the foundation to today's modern biotech industry.

Most of today's protein pharmaceuticals fall into 5 general classes: (1) hormones, (2) vaccines, (3) antibiotics, (4) antibodies, and (5) enzymes. Three of these classes, hormones, antibodies, and enzymes, are primarily used to treat noninfectious or endogenous diseases (i.e., genetic diseases or diseases of aging), whereas the remaining two classes, vaccines and antibiotics, are used to treat or prevent infectious or exogenous diseases (i.e., bacterial or viral infections). Interestingly all five drug classes were essentially identified or defined only in the past 80 years. Insulin, a hormone, was the first purified protein drug to be marketed (1922). Shortly after, in 1923, purified diptheria toxoid (a 58-kDa protein) was introduced, making it the first purified vaccine product [6]. The first purified peptide antibiotic, gramicidin S, was introduced in Russia in 1943 as a topical wound-healing agent. The first purified antivenoms or antitoxin antibodies were introduced in the 1950s and the first monoclonal antibody—OKT3 (muronomab or Orthoclone)—was approved for human use in 1986 [7]. The first purified enzyme to be approved for therapeutic use, Activase, was marketed in 1987. Interestingly, the first human recombinant protein used in disease management was also insulin (Humulin) [8], which was introduced in 1982 by Eli Lilly.

Up until 1982 all peptide and protein pharmaceuticals were isolated from "natural" sources, meaning they were purified from animal (or human) biofluids and tissues. Working with natural sources is exceedingly difficult, expensive, and can lead to the transmittance of undetected infectious materials (viruses, bacteria, prions) to patients. Because most proteins of pharmaceutical interest are relatively scarce, it was often necessary to process tens or hundreds of kilograms of tissue or fluid to produce a few milligrams of the desired product in pure form. For instance, up until the 1980s the preparation of sufficient human growth hormone (somatotropin) for a single treatment to combat dwarfism would require the extraction and homogenization of several adult human (cadaver) brains [6].

For the more abundant proteins (such as albumin) it is possible to find them in concentrations of about 35 g/L in selected tissues or biofluids [9]. This makes their isolation and purification relatively simple. However, many important protein pharmaceuticals are only found in concentrations of 1 or 2 pg/L. At such low concentrations, it is almost impossible to isolate and purify these compounds from the thousands of other proteins that are in the body. Furthermore, even if one wanted to produce enough material for commercial purposes, it would probably require the processing or homogenization of the entire world supply of cattle, pigs, or humans. Today most protein pharmaceuticals are produced through recombinant methods, including insulin, growth hormone, and most monoclonal antibodies. This allows large quantities of even the rarest protein to be purified and prepared under tightly controlled manufacturing conditions without the concerns over contamination with host viruses (HIV, HCV), toxins, or prions (that cause diseases such as CJD or BSE). Although mast protein drugs are biosynthetically produced (via cell culture), a small number of peptide pharmaceuticals (<20 residues) are produced chemically via automated peptide synthesis. These include Leuprolide (Eligard), Oxytocin (Oxytocin), Calcitonin (Miacalcin), and Abarelix (Plenaxis), for example. Peptides and proteins that continue to be isolated from natural sources include Menotropin (Repronex) and Hyaluronidase (Vitrase), for example.

Since the introduction of insulin in 1922, more than 110 distinct protein or peptide drugs have been approved for human use by the U.S. Food and Drug Administration (FDA) [10], with 50 being hormones, 2 being vaccines, 2 being peptide antibiotics, 26 being antibodies or antibody mixtures, and 17 being enzymes (see Tables 6.1-1–6.1-3). These peptide/protein pharmaceuticals range in size from less than 10 amino acids to over 1000 and may contain a variety of covalent modifications such as carbohydrate chains, D-amino acids, or amino acids with unusual side chains. More details about the structure and chemical composition of most protein pharmaceuticals can be found in subsequent chapters in this book as well as in the DrugBank database under its collection of biotech drugs [10]. According to the Biotechnology Industry Organization (www.bio.org), there are now more than 300 peptide and protein pharmaceuticals currently in clinical trials or under review. Just as with the FDA-approved biotech drugs, most of these newer products or potential products fall into the three major classes of endogenous or human-derived proteins: (1) hormones, (2) antibodies, and (3) enzymes. It is these three classes of pharmaceutically important proteins that are the focus of this chapter.

Beyond providing a historical perspective to proteins and protein pharmaceuticals, this chapter is intended to provide the reader with an overview of the general features and characteristics of pharmaceutically important hormones, antibodies, and enzymes. Together these three classes of protein therapies account for nearly three quarters of all approved biotech drugs and more than 90% of all biotech drug sales. In addition to providing a general outline about what hormones, enzymes, and antibodies are, this chapter will also provide the reader with specific examples and detailed descriptions of a few of the more important or historically interesting hormones, enzymes, and antibodies used today. The chapter is divided into five sections, an introduction to the history of protein pharmaceuticals, a general discussion about the advantages and disadvantages of protein pharmaceuticals, a detailed discussion on hormones, a detailed description of enzymes, and a detailed discussion on antibodies. Each section on hormones, enzymes, and antibodies

provides a working description or definition of class of these protein/peptide products; a general discussion on certain unique aspects of their formulation or delivery; several specific examples of important FDA-approved hormones, enzymes, or antibodies; and a brief discussion of some of the new enzymes, hormones, and antibodies that are under development or in clinical trials. A complete discussion concerning all aspects of hormones, enzymes, and antibodies is far beyond the scope of this chapter. Readers who are interested in learning more might want to consider reading several excellent books [11–13] or referring to the DrugBank database (http://redpoll.pharmacy.ualberta.ca/drugbank/) for more extensive biological, pharmaceutical, and biochemical data.

6.1.2 PROTEIN PHARMACEUTICALS

For a peptide or protein to be a useful drug, it must generally be water soluble, relatively stable, nonimmunogenic (i.e., identical or near identical to a human homologue), mostly monomeric, and causal or preventative to some disease process. Not all polypeptides match these requirements, and therefore, not all polypeptides are potentially suitable as drugs. Typically those that are not (yet) useful drugs are highly polymeric structural proteins such as tubulin, actin, or myosin. Equally impractical or improbable drugs are membrane-bound receptor proteins (G-protein-coupled receptors, laminins, etc.). These classes of proteins, which may account for as much as 60% of the human proteome, are usually most suitable as drug targets—not drugs. Certain other proteins, such as polymerases, histones, and ribosomal proteins, perform such vital functions that they are "essential" to life and so cannot generally serve as useful protein drugs either, although DNaseI (Pulmozyme) is a notable exception. Using these relatively simple criteria about what constitutes a viable drug versus a viable drug targets, it is possible to scan the human proteome and identify likely classes of potential protein drugs. When this is done one is typically left with three major groups of peptides or proteins: (1) hormones, (2) enzymes, and (3) immunological molecules (antibodies).

Peptide and protein pharmaceuticals are different from small-molecule drugs. For one, polypeptide drugs are generally much larger, ranging in size from 1000 daltons to more than 200,000 daltons (compared with <600 daltons for most small-molecule drugs). For another, the noncovalent structure or three-dimensional fold (i.e., the tertiary structure) of most polypeptides is absolutely critical to their function. This is in distinct contrast to small-molecule drugs, wherein their covalent or "primary" structure defines their function. Smaller polypeptides have relatively little tertiary structure or exhibit substantial tertiary structure only when bound to a target receptor. Larger (>40 residues) polypeptides generally have a stable, well-defined tertiary structure. As a general rule, polypeptides with less than 40 amino acids are called peptides, whereas those with more than 40 residues are called proteins. Typically most hormones are peptides (<40 residues), although some hormones such as somatotropin (human growth hormone) can be up to 200 residues in length. Many peptide hormones are actually fragments of larger precursor proteins or pro-proteins. Although most hormones are relatively small polypeptides, enzymes and antibodies are generally much larger. As a rule, most enzymes are between 200 and 800 residues in length, whereas most antibodies are typically

1200 residues in length, although smaller antibody fragments (Fabs, single-chain antibodies) can also be used as protein drugs.

Perhaps the most impressive and appealing quality about peptide and protein pharmaceuticals is their exquisite selectivity and specificity. Bioactive proteins target their receptors or bind their small-molecule ligands with a precision that matches a cruise missile. Almost no cross-reactivity to other targets or other receptor molecules is observed with most known hormones, enzymes, or antibodies. Additionally most protein drugs also exhibit very appealing pharmacokinetics and excellent bioavailability. These favorable pharmaceutical properties are not entirely unexpected. Indeed, the process of natural selection over hundreds of millions of years has evolved bioactive proteins such as hormones, enzymes, and antibodies to perform their functions in a fashion that is optimal to the health and viability of each organism. In contrast to so-called large-molecule (i.e., peptide and protein) drugs, almost no known small-molecule drug exhibits comparable selectivity or sensitivity. Perhaps the only small molecules that do are those drugs that are identical to the naturally occurring chemicals in the body (i.e., estrogen, testosterone, thyroxine, and epinephrine). Indeed, these small molecules likely coevolved with their target proteins.

The fact that polypeptides are large molecules means that far more functional and operational information can be chemically encoded into them than small molecules. In other words, there is much more room on a protein scaffold to add, remove, or substitute chemical moieties to change a given protein's specificity, bioavailability, kinetics, or function. This chemical flexibility can allow a protein chemist to engineer a potential or promising new protein drug into a more useful product. Indeed, many peptide and protein pharmaceuticals on the market today are engineered, via site-directed mutagenesis, or chemically modified to enhance their stability, selectivity, or efficacy. For example, the cytokine hormone Infergen is a "designed" interferon derived from a consensus alignment of bioactive mammalian interferon alpha sequences. This designed molecule was found to give the protein greater bioactivity. Another example is pegademase, a PEGylated version of the enzyme adenosine deaminase [14]. This protein is decorated with poly(ethylene glycol) (PEG) subunits covalently attached to exposed lysine side chains. This covalent chemical modification extends the *in vivo* half-life of the protein by a factor of 10 or more. Yet another example of an engineered or rationally designed protein is the hormone LisPro Insulin, a derivative of insulin in which Lysine 28 and Proline 29 have been interchanged [15]. This chemical change was found to enhance the activity and extend the lifetime of this form of insulin relative to natural insulin. Beyond these specific examples of engineered hormones and enzymes is a much larger collection of chimeric murine-human antibodies such as Infliximab, Rituximab, and Abciximab that have been designed to have murine variable domains and human constant domains. These chimeric features reduce the antigenicity of monoclonal murine antibodies and thereby greatly enhance the tolerance and half-life of these molecules.

Selectivity, specificity, and "programmability" are what make protein pharmaceuticals so attractive to today's pharmaceutical and biotech industry. As a result, enormous efforts are now going into the discovery, production, and FDA approval of dozens of new protein drugs. In 2005, the market capitalization of the biotechnology industry in the United States was estimated to be $311 billion. In 2004, 40

new protein pharmaceuticals (drug types, indications, or formulations) were approved by the (FDA)—more than in any prior year. With the completion of the Human Genome Project and the launch of many large-scale proteomic efforts [16, 17], the potential to find even more pharmaceutically useful hormones, enzymes, and antibodies will likely grow even further. How much further can it grow? The "universe" of endogenous protein drugs can be estimated by considering the size of the human proteome and the current diversity of functions or roles that have been identified to date. In particular, the approximately 25,000 genes identified in the human body probably code for around 40,000 different proteins (isozymes or splice variants) and up to 1,000,000 different posttranslationally modified variants, including chemically modified or cleaved proteins [18]. Current annotations suggest that approximately 3000 different human enzymes exist, along with over 150 different hormones. Given the number of enzymes and hormones available (which may be used for diseases requiring replacement therapy), this suggests that there could be at least 3500 antibody targets (which may be needed for antagonizing the unwanted effects of certain enzymes or hormones). If we include the number of known receptors (estimated to be 4000) for which antibodies may be targeted, then the number of potential, pharmaceutically important antibodies may be closer to 8000 molecules. Given that there are less than 400 protein drugs that are either approved or in the drug development pipeline, this rough calculation suggests we still have a long way to go before we exhaust the supply of potential endogenous protein drugs.

Although there is much to be optimistic about the future of protein pharmaceuticals, there are still many unique problems with their development, production, and delivery. Among the more obvious problems with protein drugs is the fact that they are much more delicate than small-molecule drugs. Proteins such as hormones, antibodies, and enzymes cannot normally be "compounded" or pressed into dry pills or emulsified or concentrated into tinctures. This type of conventional pharmaceutical manufacturing and formulation would destroy the activity of most protein pharmaceuticals. Similarly most peptide hormones, antibodies, and enzymes cannot be stored indefinitely at room temperatures in nonsterile containers; instead they must be kept in a cool, dark, aqueous, sterile environment for no more than a few weeks. These limitations to protein preparation and formulation have created a significant challenge to pharmaceutical chemists. Potential solutions to these problems are discussed in Chapter 4 of this book.

Yet another challenge in working with or producing peptide and protein drugs is their cost. Relative to small-molecule drugs, manufacturing costs for peptide and protein pharmaceuticals are enormous, with many protein drugs being priced at 10 to 1000 times the cost of a small-molecule drug (on a per-milligram basis). This price difference exists because most polypeptide drugs cannot be synthesized using classicl synthetic organic methods—they are simply too large and too complex for today's technology. Currently the only cost-effective method for producing most polypeptide hormones, antibodies, and enzymes is through recombinant gene expression in bacterial or mammalian cell culture. This is a time-consuming, low-yield (100 mg—10 g per liter) process that requires the use of large fermentor systems, carefully monitored growth conditions, and multiple purification steps.

Beyond the obvious problems of storage and production of protein pharmaceuticals lies one of the more discouraging facts about protein drugs: The body is not

a particularly friendly place for foreign proteins. Indeed, our bodies have developed a huge arsenal of tricks to quickly and efficiently dispose of proteins that are swallowed, ingested, or injected. For instance, proteins that are swallowed are immediately attacked by enzymes (amylases [19]) in the mouth, which are designed to remove the protective sugars that cover many proteins. Moving down the throat, these "naked" proteins are adsorbed and denatured by surface interactions with the mucosal cells. As the surviving proteins enter the stomach and small intestine, they are exposed to extremely acidic conditions (which instantly denature most proteins) and a host of acid-stable proteases that digest these denatured molecules into short, inactive peptides. Similarly, if a peptide or protein pharmaceutical is injected into the bloodstream, it may be attacked by antibodies or swallowed by T cells and cut into fragments. Alternatively, it may be adsorbed by albumins or lipoproteins and permanently removed from the circulation. Even if an injected protein survives these insults, a foreign protein may still be attacked by plasma proteases and demolished into tiny fragments. Foreign proteins are "ill treated" due to the design of our bodies to use proteins as a source of food (if ingested) or to identify pathogens (such as bacteria, viruses, and parasites) that have invaded our circulatory system. This makes most proteins "enemies" of the body, something to be digested or eliminated at every opportunity. Even for its own "friendly" proteins (i.e., the proteins needed for cellular functions), the body has established several mechanisms to turn over or eliminate these proteins every few days. This regular turnover prevents old proteins from malfunctioning and keeps tight control over regulatory proteins that need only be around for minutes or hours at a time. These finely tuned mechanisms, which have evolved over the past two billion years, make it very difficult for pharmaceutical companies to use protein drugs as injectables or oral consumables.

6.1.3 PEPTIDE AND PROTEIN HORMONE BIOPHARMACEUTICALS

A hormone is classically defined as a chemical messenger, either a small molecule or a large macromolecule, which is synthesized in an organ or tissue and then secreted into the circulatory system where it subsequently affects separate target organs whose cells bear an appropriate receptor. Hormone actions include the stimulation or inhibition of growth, the induction or suppression of programmed cell death (apoptosis), the modulation of the immune system, the regulation of metabolism, and the preparation for a new activity (e.g., fighting, fleeing, and mating) or phase of life (e.g., puberty, childbirth, and menopause). In many cases, one hormone may regulate the production and release of other hormones. Many hormones can be described as messengers serving to regulate the metabolic activity of an organ or tissue. Hormones also control the reproductive cycle of virtually all multicellular organisms.

Animal hormones essentially fall into four different chemical classes: (1) amine-derived hormones, (2) peptide/protein hormones, (3) steroid hormones, and (4) lipid or phospholipid hormones. Amine-derived hormones such as catecholamines and thyroxine are derivatives of the amino acids tyrosine and tryptophan. Peptide hormones including insulin, growth hormone, and vasopressin consist of polypeptides ranging in length from 5 to 200 residues. Steroid hormones such as estrogen

and testosterone are derived from cholesterol. The adrenal cortex and the gonads are primary sources for these hormones. Lipid and phospholipid hormones are derived from lipids such as linoleic acid and phospholipids such as arachidonic acid. For this chapter we are primarily concerned with peptide hormones.

The functional diversity of peptide/protein hormones is enormous. There are as many potential classes of these hormones as there are classes of hormonally regulated biological functions. If we also include potential antagonists to natural hormonal function (i.e., peptides that may bind competitively or noncompetitively to hormone receptors), we could double the number of classes. However we can generally group subcategories so that pharmaceutically important peptide hormones might be classified into the following broad conceptual categories:

1. Homeostatic regulators control basic physiological conditions such as blood glucose levels (insulin), water retention (vasopressin, desmopressin), or uterine muscle contractions (oxytocin).
2. Fertility regulators can be used to either inhibit or promote fertility. Although luteinizing hormone (LH) and follicle stimulating hormone (FSH) are regulated indirectly through the steroid hormone (estrogen and progesterone) levels to suppress fertility, direct introduction of the peptide hormones themselves is used to induce development and release of multiple ova.
3. Growth/division regulators may either include hormones regulating growth of the entire body (e.g., human growth hormone) or of a specific tissue type (e.g., erythropoeitin for hematopoeisis, palifermin for mucositis, or aldesleukin for lymphocytes). Some fertility hormones (e.g., leuprolide) may act indirectly as general or specific growth inhibitors.
4. Immunomodulatory hormones modulate the normal immune or inflammatory responses. This class can include hormones that upregulate the immune response (e.g., interferon) or that suppress it (e.g., cyclosporine).

If the definition of a hormone were expanded to include localized secreted or cell-surface signaling molecules, many other kinds of regulators would join this list, including molecules with roles in developmental fate specification and differentiation (e.g., netrins, semaphorins, and morphogens). Because the effects of such signals are highly localized, their use as effective therapeutic agents would require greater precision in administration than current systemic delivery methods. Table 6.1-1 provides a complete list of the peptide/protein hormones that are currently approved by the FDA. More details about some of these are provided below.

6.1.3.1 Examples of Hormone Biopharmaceuticals

Homeostatic Hormones. Insulin is produced by beta cells found in the islets of Langerhans that are dispersed throughout the pancreas. The islet cells constitute only 1% of total pancreatic tissue. Each islet contains about 3000 endocrine cells with a core of beta cells surrounded by other endocrine cells such as the glucagon-secreting alpha cells, the somatostatin-secreting delta cells, and the pancreatic polypeptide-secreting PP cells. The beta cells first synthesize a 109-amino-acid preproinsulin that is subsequently processed to an 86-amino-acid proinsulin. The

TABLE 6.1-1. FDA-Approved Protein/Peptide Hormone Pharmaceuticals

Generic Name	Chemical Name	Brand Name(s)	Description	Indication
Abarelix	acetyl-D-β-naphthylAla-D-4-chloroPhe-D-3-pyridylAla-L-Ser-L-N-methylTyr-D-Asp-L-Leu-L-N(e)-isopropyl-Lys-L-Pro-D-Ala	Plenaxis	Anti-Testosterone, Antineoplastic. Synthetic decapeptide antagonist to gonadotropin releasing hormone (GnRH)	Palliative treatment of advanced prostate cancer
Aldesleukin	Human interleukin 2 (modified)	Proleukin	Antineoplastic. Produced in recombinant *E. coli*. Nonglycosylated. N-terminal Ala deleted. Cys125Ser substitution.	adults with metastatic renal cell carcinoma
Anakinra	Human interleukin-1 receptor antagonist protein	Kineret	Antirheumatic, Immunomodulatory. Recombinant human interleukin-1 receptor antagonist. Produced in *E. coli*. 153 residues.	adult rheumatoid arthritis
Becaplermin	Human platelet-derived growth factor	Regranex	Topical anti-ulcer. Recombinant protein produced in the yeast, *Saccharomyces cerevisiae*. Homodimer.	topical treatment of skin ulcers (from diabetes)
Calcitonin, salmon	Salmon calcitonin	Miacalcin	Antihypocalcemic, Antiosteporotic. Synthetic peptide, 32 residues long formulated as a nasal spray.	osteoporitis
Cetrorelix	acetyl-D-3-(2′-naphtyl)-ala-D-4-chlorophe-D-3-(3′-pyridyl)-ala-L-ser-L-tyr-D-citruline-L-leu-L-arg-L-pro-D-ala-amide	Cetrorelix, Cetrorelixum, Cetrotide	Infertility Agent. Synthetic hormone blocks premature ovulation by antogonizing GnRH-stimulated LH release.	inhibition of premature LH surges in women undergoing controlled ovarian stimulation

Choriogonadotropin alfa	Human chorionic gonadotropin	Novarel, Ovidrel,; Pregnyl, Profasi	Fertility Agent. Has 2 subunits, alpha = 92 residues, beta = 145 residues, each with N-and O-linked carbohydrates.	female infertility
Darbepoetin alfa	Human erythropoietin	Aranesp	Antianemic. Human erythropoietin with 2 aa substitutions to enhance glycosylation. Produced in recombinant CHO cells.	anemia (from renal transplants or certain HIV treatment)
Denileukin diftitox	Diptheria toxin-Interleukin-2 fusion protein	Ontak	Antineoplastic. Recombinant diphtheria toxin fragments A and B (1–387) fused with interleukin-2 (1–133). Produced in *E. coli*.	cutaneous T-cell lymphoma
Desmopressin	1-desamino-8-D-arginine vasopressin	Concentraid; DDAVP, Stimate	Renal Agent. Synthetic modification of vasopressin. Deaminated and Arg8 is D not L.	primary nocturnal enuresis, diabetes insipidus, temporary polyuria and polydipsia
Desmopressin acetate	Desmopressin acetate	Stimate	Antidiuretic. Synthetic analogue of the natural pituitary hormone 8-arginine vasopressin (ADH). 3-mercaptopropionic acid replaces N-terminal Cys and D-Arg replaces Arg.	diabetes insipidus, prevention of polydipsia, polyuria and dehydration
Epoetin alfa	Human erythropoietin	Epogen, Epogin, Epomax, Eprex, NeoRecormon	Antianemic. Produced in recombinant CHO cells.	anemia (from renal transplants or certain HIV treatment)

TABLE 6.1-1. *Continued*

Generic Name	Chemical Name	Brand Name(s)	Description	Indication
Eptifibatide	N 6-(aminoiminomethyl)-N 2-(3-mercapto-1-oxo Pro-L-Lys-L-Gly-L-Asp-L-Try-L-Pro-L-Cys	Integrilin	Anticoagulant, Antiplatelet. Synthetic cyclic hexapeptide binds to platelet receptor glycoprotein and inhibits platelet aggregation.	myocardial infarction, acute coronary syndrome
Felypressin	2-(L-Phenylalanine)-8-L-lysine-vasopressin	Felipresina, Felipressina, Felypressin, Felypressine, Felypressinum	Renal Agent, Vasoconstrictor. Hemostatic. Synthetic analog of Lypressin (Lys-vasopressin) with more vasoconstrictor than antidiuretic action.	localizing agent for anesthetics
Filgrastim	Human granulocyte colony stimulating factor	Neupogen	Antineutropenic, Antiinfective, Immunomodulatory. 175 residues, expressed in *E. coli.*	Increases leukocyte production. Treatment of non-myeloid cancer, neutropenia, and bone marrow transplant.
Follitropin alfa/beta	Human follicle stimulating hormone	Gonal-F	Fertility Agent. Fertility Agent. Recombinant.Two non- covalently linked, non-identical glycoproteins with 92 and 111 amino acids.	female infertility
Follitropin beta	Human follicle stimulating hormone	Follistim	Fertility Agent. Recombinant. Two non-covalently linked, non-identical glycoproteins with 92 and 111 amino acids.	female infertility
Glucagon recombinant	Human Glucagon	GlucaGen, Glucagon	Antihypoglycemic Agent. 29 residue peptide hormone. Produced in *E. coli*.	severe hypoglycemia, also used in gastrointestinal imaging

Goserelin	pyro-Glu-His-Trp-Ser-Tyr-D-Ser(Bu^t)-Leu-Arg-Pro-Azgly-NH_2 acetate	Zoladex	Antineoplastic Agent. Synthetic hormone. Stops production of testosterone in men. Decreases production of estradiol in women.	breast cancer, prostate cancer, endometriosis
Insulin Glargine recombinant	Recombinant human insulin	Lantus	Hypoglycemic agent. Produced in *E. coli*. IDiffers from human insulin in that Asn21 is replaced by Gly and two Arg are added to the C-terminus of B chain.	diabetes (type I and II)
Insulin Lyspro recombinant	Human Insulin	Humalog, Insulin Lispro	Hypoglycemic Agent. Monomeric form of regular insulin hexamer. Absorbed more rapidly than regular insulin. Lsy28 and Pro29 swapped in B chain	diabetes (type I and II)
Insulin recombinant	Human insulin	Novolin R	Hypoglycemic Agent. 51 residues. Produced as 2 chains in recombinant *E. coli.* Chains linked chemically *in vitro*.	diabetes (type I and II)
Insulin, porcine	Porcine insulin	Iletin II	Hypoglycemic agent, Isolated from pro-insulin of pig pancreas. Forms hexameric structure.	diabetes (type I and type II)
Interferon alfa-2a	Human interferon alpha 2a	Roferon A	Antineoplastic, Antiviral. 165 residues. Produced in recombinant *E. coli*.	chronic hepatitis C, hairy cell leukemia, AIDS-related Kaposi's carcoma, chronic myelogenous leukemia

TABLE 6.1-1. *Continued*

Generic Name	Chemical Name	Brand Name(s)	Description	Indication
Interferon alfacon-1	Consensus sequence interferon alpha	Infergen	Antineoplastic, Antiviral, Immunomodulatory. Consensus sequence derived Interferon alpha, differs from human interferon alpha by 20 residues (88% identical to IFN alpha 2a)	hairy cell leukemia, malignant melanoma, and AIDS-related Kaposi's sarcoma
Interferon alfa-n1	Human interferon alpha	Wellferon	Antiviral, Immunomodulatory. Purified, natural glycosylated human interferon alpha. 166 residues.	venereal or genital warts caused by the Human Papiloma Virus
Interferon alfa-n3	Human interferon alpha (2a, 2b and 2c)	Alferon	Antineoplastic, Antiviral, Immunomodulatory. Purified, natural human interferon alpha. proteins (includes 2a, 2b and 2c)	hairy cell leukemia, malignant melanoma, AIDS-related Kaposi's sarcoma, laryngeal papillomatosis in children, some types of hepatitis
Interferon beta-1a	Human interferon beta	Avonex	Antiviral, Immunomodulatory. 166 residues, glycosylated. Produced in recombinant CHO cells. Primary sequence identical to natural human interferon beta.	relapsing/remitting multiple sclerosis. Also condyloma acuminatum.
Interferon beta-1b	Human interferon beta	Betaseron	Antiviral, Immunomodulatory. 165 residues. Cysteine 17 substituted with serine. Produced in *E. coli*, nonglycosylated.	relapsing/remitting multiple sclerosis
Interferon gamma-1b	Human interferon gamma-1b	Actimmune	Antiviral, Immunomodulatory. Produced from recombinant *E coli.* Purification by column chromatography.	chronic granulomatous disease, osteopetrosis

Lepirudin	Hirudo medicinalis hirudin (variant 1)	Refludan	Anticoagulants, Antithrombotic. Identical to natural hirudin except for substitution of leu for ile at N-terminal and absence of a sulfate group on tyr63. Produced in yeast cells.	heparin-induced thrombocytopenia
Leuprolide	5-oxo-pro-his-tryp-ser-tyr-leu-leu-arg-N-ethyl-pro	Eligard	Antineoplastic, analog of gonadotropin releasing hormone.	prostate cancer, endometriosis, uterine fibroids, premature puberty
Lutropin alfa	Human luteinizing hormone	Luveris	Fertility Agent. Recombinant human LH produced in yeast with 2 subunits, alpha = 92 residues, beta = 121 residues.	female infertility
menotropins	mixture of LH and FSH	Gengraf, Neoral, Restasis, Sandimmune	Immunomodulatory. Mixture of LH and FSH extracted from urine of postmeonopausal women.	transplant rejection, rheumatoid arthritis, severe psoriasis
Octreotide acetate	Octreotide acetate	Sandostatin LAR	Anabolic Agent, Hormone replacement. Acetate salt of cyclic octapeptide. Pharmacologic properties mimick somatostatin.	acromegaly and side effects from cancer chemotherapy
Oprelvekin	Human interleukin 11	Neumega	Coagulant, Thrombotic.	Increases reduced platelet levels due to chemotherapy
Oral interferon alfa	Human interferon alpha	Veldona	Antiinfective; Antineoplastic, Interferon alpha, 165 amino acids.	oral warts arising from HIV infection
Oxytocin	Oxytocin	Oxytocin, Pitocin, Syntocinon	Antitocolytic, Synthetic 9 residue cyclic peptide. Prepared synthetically to avoid possible contamination with vasopressin.	assist in labor, labor induction, uterine contraction induction

TABLE 6.1-1. *Continued*

Generic Name	Chemical Name	Brand Name(s)	Description	Indication
Palifermin	Human keratinocyte growth factor	Kepivance	Antimucositis. 140 residues long, expressed in *E. coli*. First 23 residues removed to improve stability.	mucositis (mouth sores)
Pegfilgrastim	PEGylated human granulocyte colony stimulating factor	Neulasta	Anti-infective, Antineutropenic, Immunomodulatory. 175 residues. Produced in recombinant *E. coli*.	non-myeloid cancer, neutropenia, bone marrow transplant
Peginterferon alfa-2a	PEGylated human interferon alpha 2a	Pegasys	Antineoplastic, Antiviral, Immunomodulatory. Covalent conjugate of recombinant alfa-2a interferon with single polyethylene glycol (PEG) chain. Produced in *E. coli*. 165 aa.	hairy cell leukemia, malignant melanoma, and AIDS-related Kaposi's sarcoma
Peginterferon alfa-2b	PEGylated human interferon alpha 2b	PEG-Intron	Antineoplastic, Antiviral, Immunomodulatory. 165 amino acids. Has a single amino acid substitution (Lys23Arg).	hairy cell leukemia, malignant melanoma, and AIDS-related Kaposi's sarcoma
Pegvisomant	PEGylated human growth hormone	Somavert	Anabolic Agent, Hormone replacement. Selectively binds to GH receptors on cell surfaces and blocks binding of endogenous GH.	acromegaly
Sargramostim	Human granulocyte macrophage colony stimulating factor	Leucomax, Leucine	Antineoplastic, anti-infective. Recombinant GM-CSF is expressed in yeast. 127 residue glycoprotein.	cancer and bone marrow transplant
Secretin, synthetic	Human secretin	Secremax, SecreFlo	Diagnostic Agent. Produced in the S cells of the duodenum in response to low local pH. Stimulates secretion of bicarbonate from liver and pancreas.	diagnosis of pancreatic exocrine dysfunction and gastrinoma

Sermorelin	Human growth hormone-releasing hormone fragment	Geref	Anabolic Hormone replacement. Acetate salt of an amidated synthetic 29-amino acid peptide from amino-terminal segment of the naturally occurring growth hormone-releasing hormone.	dwarfism, HIV-induced weight loss
Somatropin recombinant	Human growth hormone	BioTropin, Genotropin, Humatrope, Norditropin, Nutropin, NutropinAQ, Protropin, Saizen, Serostim, Tev-Tropin	Anabolic Agent, Hormone replacement. 191 residues. Produced in recombinant *E. coli*.	dwarfism, acromegaly, and prevention on HIV-induced weight loss
Thyrotropin Alfa	Human alpha thyrotropin	Thyrogen	Diagnostic. Heterodimeric glycoprotein with two noncovalently linked subunits identical to human pituitary TSH.	detection of residueal or recurrent thyroid cancer
Urofollitropin	Human follicle stimulating hormone	Fertinex, Metrodin	Fertility Agent. Purified from urine of postmenopausal women.	female infertility
Vasopressin	Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-Gly-NH2 (Cys linked by- S-S-bridge)	Pitressin; Pressyn	Antidiuretic, Vasoconstrictor. Nine amino acid peptide secreted from posterior pituitary. Binds receptors in collecting tubules of the kidney and promotes reabsorbtion of water.	enuresis, polyuria, diabetes insipidus, polydipsia, oesophageal varices with bleeding

A-chain and B-chain regions are connected by the C-peptide residues and by two disulfide bridges. Proinsulin is further cleaved by the Golgi apparatus before secretion, releasing the C-peptide (35 residues) from the two insulin chains (51 residues total) joined by disulfide bonds. Insulin is secreted into the blood by the beta cells and carried to its major target tissues in the liver, adipocytes, and muscles. Insulin binds to the insulin receptor tyrosine kinase localized in the plasma membrane of target cells leading to receptor autophosphorylation and a signal transduction cascade that is known to regulate more than 100 downstream genes.

Banting, Best, Collip, and MacLeod first isolated insulin in 1921 and demonstrated its therapeutic potential in treating type I diabetes (diabetes mellitus) in 1922 [20]. Before the development of recombinant forms of the hormone, it was isolated from bovine or porcine pancreata. Recombinant human insulin is produced in either *Escherichia coli* bacteria or *Saccharonlyces cerivisiae* yeast strains that have been genetically engineered. Active insulin consists of two peptide chains (called A and B) joined by disulfide linkages (Figure 6.1-1). The A chain is 21 amino acids long, whereas the B chain is 30 amino acids long. *E. coli* lack the protease necessary to cleave proinsulin, so A and B chains are either produced in separate cells, purified, and oxidized chemically to form the disulfide linkages, or full-length proinsulin is produced and cleaved in a separate *in vitro* proteolytic reaction (reviewed in Ref. 21). Insulin produced in *S. cerivisiae* is genetically modified so that A and B chains are linked directly or by a short synthetic sequence. The final product is converted into human insulin by a trypsin-mediated transpeptidation reaction carried out in an aqueous–organic solvent media, in the presence of excess threonine ester. Human insulin was the first animal protein to have been made in bacteria in such a way that its structure is absolutely identical to that of the natural molecule. Modifications to the original recombinant insulin have included reversing selected amino acid positions (insulin Lispro) and replacing and

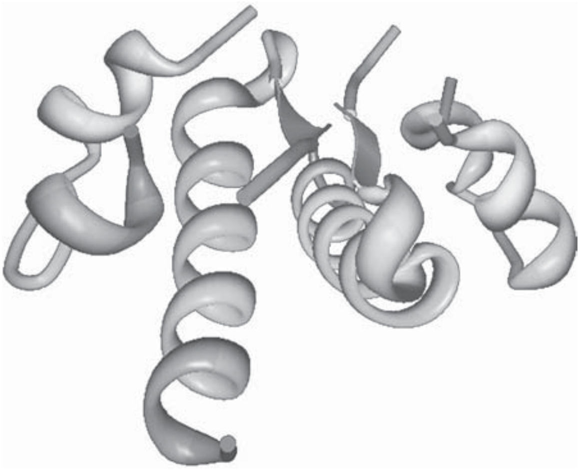

Figure 6.1-1. The x-ray crystal structure of a human insulin homodimer (A/B/C/D) at 1.5-Å resolution (PDB ID: *1ZEH*). Each component of the dimer is composed of a smaller chain (A/C of 21 residues) linked by disulfide bridges to a larger chain (B/D of 30 residues).

adding selected amino acids (insulin Glargine and Aspart). The purpose of these modifications is to improve the kinetics or duration of drug action.

Insulin is generally administered parenterally (subcutaneous injection), although many researchers and companies are developing alternative administration methods, i.e., oral, buccal, (Oral-lyn) or pulmonary (Exubera) [10]. These methods require greatly increased dosage in the case of buccal or pulmonary administration or additives to improve the bioavailability of orally administered insulin (including encapsulation, permeabilization, or chemical stabilization additives). No intestinally absorbed (oral) version of insulin has yet been proven effective and received FDA approval.

Another group of important homeostatic regulatory hormones are oxytocin and vasopressin. These two hormones are structurally related 9-mer oligopeptides produced in the hypothalamus and then transported along axons to the posterior pituitary where they are stored until they are secreted. Oxytocin and vassopressin are identical in sequence and structure except for residues three and eight; yet they have very different physiological effects. Oxytocin stimulates mammary milk secretion and contraction of uterine smooth muscle and likely plays a role in labor initiation. Vasopressin (also known as antidiuretic hormone—ADH) is a vasoconstrictor and reduces the water content of urine by increasing the reclamation of urinary water by the renal collecting duct. However, due to their structural similarity, there is a slight overlap of physiological response to these hormones; oxytocin has about 1% the antidiuretic potency of vasopressin, whereas vasopressin has about 15% the mammary secretion potency of oxytocin [11]. Both proteins are cyclic peptides with cysteines at positions one and six being joined by disulfide bonds, forming a six-residue ring structure with a flexible three-residue amidated carboxyl-terminal tail. Both hormones act through binding to specific receptors that are coupled to G-protein signal transduction pathways. G-protein activation leads to activation of inositol triphosphate and diacylglycerol, resulting in internal Ca^{2+} release and a MAP kinase cascade. The end result is phosphorylation of the myosin light chain leading to smooth muscle contraction. Oxytocin receptors are found in mammary myoepithelial and uterine smooth muscle cells, whereas vasopressin receptors are found predominantly in the cortical glomerular mesangial cells and medullary vascular smooth muscle cells of the kidney. In addition to stimulating contraction of vascular cells, vasopressin also causes translocation of aquaporin water channels to the apical surface of cells in the renal collecting duct. Traumatic or metastatic damage to the hypothalamus as well as rare hereditary disease can result in a lack of vasopressin, leading to the development of diabetes insipidus [11]. Those inflicted with this disease produce large amounts of dilute urine and must drink large amounts of fluid to replace what is lost.

Vasopressin is administered parenterally, but its synthetic analog, desmopressin acetate, can be administered by rhinal tube or orally, by tablet, for the treatment of diabetes insipidus [10]. Oxytocin and Vasopressin are manufactured through solid-phase synthesis [22, 23]. Antidiuretics are in fairly widespread use, having been prescribed in about 15% of all physician visits in the United Sates in 2002–2003 up from about 10% only 7 years before [24]. Oxytocin is used to induce labor by parenteral administration, either through subcutaneous or intravenous injection, or can be administered nasally to increase milk production in nursing mothers. Oxytocin induction of labor occurred in approximately 20% of births in the United States in 2003 [24].

Fertility Hormones. LH and FSH are heavily N-glycosylated glycoprotein dimers containing a common alpha chain of 92 amino acids and a unique 121 (LH) or 111 (FSH) residue beta chain. These hormones regulate human sex steroid production (LH) and gametogenesis (LH and FSH) in both males and females. They are expressed in a cyclic fashion by the pituitary gonadotrope cells. In males, for example, there is one LH pulse of consistent amplitude approximately every 90 minutes, but in females the amplitude and frequency of LH pulses varies throughout the ovarian cycle [11]. LH activates a seven-transmembrane G-protein-coupled receptor that is found primarily in the Leydig cells of the testes of males and in granulosa and theca cells in the female ovarian follicle. The FSH seven-transmembrane G-protein-coupled receptors are found only in Sertoli cells in the male testes or in granulosa cells in the female ovarian follicle. In males, LH induces the formation of testosterone in its target cells, whereas FSH induces production of androgen. In females, the complex cooperative activation of LH and FSH receptors regulates the levels of the primary sex steroids, progesterone, and estradiol. LH and FSH can be isolated from the urine of postmenopausal women, or they can be made in recombinant form by expression of transgenes in Chinese hamster (CHO) cells. LH and FSH are usually administered together to treat female infertility by stimulating ovulation and follicular maturation of the ovulated follicle into a corpus luteum. LH and FS (Lutropin—LH—or Repronex—combined LH and FSH) are administered parenterally. Of the approximately 6.7 million women with fertility problems in the United States in 1995, 35% were treated with some form of ovulation-inducing drug [25].

Growth Regulatory Hormones. Growth hormone (also known as somatotropin or somatropin) was first isolated in 1944 [11]. It is an anabolic hormone responsible for inducing cell division and controlling an individual's height. Growth hormone also increases calcium retention, strengthens and increases the mineralization of bone, increases muscle mass, induces protein synthesis, and stimulates the immune system. Mature growth hormone is a single-chain, nonglycosylated 191 residue polypeptide formed in the anterior pituitary. It is derived from a larger prohormone that includes a cleaved secretory signal peptide. In addition to the pituitary, growth hormone is also expressed at a much lower level in other tissues, including the central nervous system, mammary glands, gonads of both sexes, and hematopoietic and immune system cells. The growth hormone receptor was the first identified cytokine receptor and is an approximately 620-residue single-pass transmembrane protein that is highly glycosylated and ubiquitinated. A proteolytic fragment of the receptor, growth hormone binding protein, circulates throughout the bloodstream and increases the half-life of growth hormone by reducing its rate of degradation and clearing. The growth hormone receptor has been observed throughout the body in tissues as diverse as the gastrointestinal tract; the musculoskeletal system; the cardiorespiratory system; hematopoietic and immune systems; the central nervous system; integument, renal, and urinary systems; and the endocrine system. It is also found on cells of all major lineages in the developing fetus. However, in adults, it achieves its highest level of expression in the liver. A single growth hormone ligand binds to two receptors causing dimerization. This trimer, lacking its own kinase function, then recruits a member of the Janus tyrosine kinase family (JAK2) leading to activation of STAT-mediated gene transcription along with

activation of the Ras-Raf-MEK, phosphatidylinositol 3-kinase (PI 3-kinase) and protein kinase C pathways [26, 27]. As might be expected, this has diverse and widespread effects on physiology and morphology. The main effect is to stimulate both chondrocyte and osteoblast proliferation leading to longitudinal bone growth. In addition, muscle mass increase is favored as an increase in lipolytic activity in adipose tissue leads to a reduction in total fat. Growth hormone also affects differentiation within the central nervous system with consequent cognitive effects such as enhancement of long-term memory, learning, and rapid eye movement sleep, although only when administered at supraphysiological levels.

A reduction or loss of growth hormone production, an autosomal recessive disorder, leads to obvious signs of dwarfism as early as 6 months of age. Laron syndrome is a defect in the growth hormone receptor also leading to sharply reduced stature but is resistant to exogenous treatment with growth hormone [29]. By contrast, chronic overproduction of growth hormone can lead to acromegaly, a sometimes fatal condition due to resulting cardiovascular, cerebrovascular, respiratory, and metabolic diseases.

Recombinant human growth hormone for injection is produced in *E. coli*. The mature product is identical to the natural human hormone, although it is initially translated with a signal peptide that is cleaved by the cell as the peptide is synthesized and exported into the periplasm. Growth hormone production can also be increased through administration of semorelin acetate, the acetate salt of an amidated synthetic 29-amino acid peptide corresponding to the amino-terminal residues of human growth hormone releasing hormone [11]. By contrast overproduction of growth hormone leading to acromegaly can be treated by a PEGylated version of growth hormone, known as Pegvisomant [30]. This chemically altered version of growth hormone competitively binds to the receptors without activating them, thus interfering with the action of the elevated endogenous hormone.

Another example of a growth regulatory hormone is erythropoietin. Erythropoeitin (EPO) is a 166-residue cytokine, produced primarily by interstitial cells near the proximal tubular cells of the kidney. EPO stimulates erythropoiesis, the formation of red blood cells. The hormone was initially partially purified by Goldwasser and colleagues from the urine of anemic patients in 1977, and the cDNA was cloned by Lin et al. and Jacobs et al. in 1985 [31, 32]. The protein is highly N- and O-glycosylated, with up to 40% of its weight being carbohydrate. Each glycosylation chain is terminated with a sialic acid, which may also be incorporated into the chain, and the total sialylation affects both receptor-binding affinity and serum half-life (the latter is of greater importance in total EPO biological activity). Thus, the kidney sets the hematocrit (the percent of whole blood that is composed of red blood cells) at a normal value of 45% by regulating red cell mass through EPO production and plasma volume through excretion of salt and water [11, 33]. EPO released into the blood travels to the bone marrow and binds to its cell-surface receptor on erythroid-specific precursors to stimulate red blood cell production. Like the related cytokine, human growth hormone, the binding of erythropoietin to its cognate receptor leads to dimerization and subsequent recruitment of the JAK2 tyrosine kinase signal transduction pathways to stimulate erythrocyte proliferation and differentiation. EPO has been approved for the treatment of anemia associated with chronic renal failure, with chemotherapy in cancer patients, and anemia associated with surgery. EPO is also beneficial for treatment of anemia

associated with Zidovudine (e.g., AZT) therapy for patients infected with HIV. Because the functional protein must be correctly glycosylated posttranslationally, it is prepared from recombinant CHO cells expressing the erythropoietin precursor, including the 27-amino-acid signal peptide. A variant form (darbepoietin alpha) includes 2 amino acid substitutes that add N-glycosylation sites. The drug is currently only available for parenteral administration.

Immunomodulatory Hormones. Interferons constitute a family of species-specific vertebrate proteins (type I: IFN-α, IFN-β, IFN-ε, IFN-κ, and IFN-ω and type II: IFN-γ in humans) that confer general resistance to a broad range of viral infections, affect cell proliferation, and modulate immune responses [34]. Interferons were originally characterized in 1957 by Isaacs and Lindenmann as soluble proteins that induce antiviral activity in chicken cells. IFN-β and IFN-ω have only one functional copy each, but IFN-α is found in 13 different alleles producing 12 functional protein isoforms. The various IFN-α members each exhibit a distinct profile of antiviral, antiproliferative, and immunostimulatory effects, but variants of the IFNA2 gene (IFN-α2a, IFN-α2b, and IFN-α2c) provide the basis for most interferon therapeutics. Although the type I interferons invoke different cellular responses, they share a common dimeric receptor, IFNAR, which is found in low levels on the plasma membrane of all cell types. Each IFNAR subunit is composed of a single-pass transmembrane protein associated with a member of the JAK tyrosine kinase family (TYK2 for IFNAR-1 and JAK1 for IFNAR-2c). Upon binding of the ligand, the receptor dimerizes and cross-autophosphorylates the cytoplasmic receptor tails along with TYK2 and JAK1. This induces the phosphorylation and subsequent nuclear translocation of a STAT signaling complex and activation of gene-specific transcription [36]. It is not yet known how the many different species of IFN-α can lead to different cellular responses while acting through the same receptor, although data have indicated different ligands may have slightly different binding sites and may involve other receptors in the activated complex.

Parenteral administration of natural and recombinant interferons for the treatment of hairy cell leukemia, malignant melanoma, AIDS-related Kaposi's sarcoma, and a variety of viral diseases has been approved by the FDA. The type I IFNs exhibit a wide breadth of biological activities, including antiviral and antiproliferative effects as well as stimulation of MHC I antigen presentation and NK-cell activation. This makes them ideal for the treatment of many serious illnesses but can also result in undesirable side effects, especially at the high dosages normally employed. Oral administration of low-dose interferons has been studied in clinical trials but has not yet received approval for general use. Interferon-alpha was approved by the FDA on February 25, 1991 as a treatment for hepatitis C [37, 38]. In January 2001, the FDA approved PEGylated interferon-alpha. The PEGylated form is injected once weekly, rather than three times per week for conventional interferon-alpha.

6.1.3.2 The Future of Hormone Biopharmaceuticals

Research into new peptide hormone pharmaceuticals continues along several lines. Probably the most active area of research is into alternative delivery methods such as oral, nasal, buccal, transdermal, or pulmonary. All of these alternatives share issues of barrier penetration (whether mucosal or epidermal), protein stability, rate of clearance, and bioavailability.

The epithelial mucosa lining intestinal, buccal, nasal, and pulmonary tracts present significant barriers to protein or peptide hormone access to the circulatory system. Increasing the mucosal adhesiveness of therapeutic proteins delivered through the mucosa leads to an increase in the duration of residence at absorption sites. This is typically accomplished through encapsulation of the protein in micro- or nanoparticles made of mucoadhesive polymers [39, 40]. Increased duration in the mucosa also exposes the protein drug to increased extracellular proteolytic activity. Therefore therapeutic proteins and peptides can be chemically altered to reduce their susceptibility to proteases (e.g., in the intestine). Oral desmopressin acetate, for example, is partly protected against proteolytic degradation through amidation of the carboxyl-terminus, replacement of L-Arg with D-Arg and replacement of the amino-terminal residue with mercaptopropionic acid [41].

In addition to the mucosa, the epithelial cells also present a formidable barrier to the uptake of therapeutic proteins. A variety of strategies have been used to overcome this barrier, most notably through changing the hydrophobicity of the protein by the covalent attachment of lipophilic moieties. For example, the oral hexyl insulin monoconjugate 2 (HIM2) includes seven to nine units of PEG and a hexyl alkyl chain covalently attached to Lys29 and has proven safe and somewhat effective in controlling postprandial hyperglycemia in patients with type 1 diabetes mellitus during phase I/II clinical trials [42]. More recently, epithelial permeation enhancers, such as cationic or polymeric derivatives of the hydrophilic polysaccharide, chitosan, have proven effective in enhancing the effectiveness of oral [43], nasal [44], or pulmonary [39] administration of insulin or calcitonin in experimental settings. The precise mechanism by which these various permeant enhancers work is not yet understood, although, at least in the intestine, the modification of the tight junctions between cells in the intestinal epithelia is thought to be crucial [40].

In addition to novel delivery methods, several new peptide hormones with therapeutic potential have been recently identified. Ghrelin is a 28-residue, posttranslationally modified peptide that is secreted primarily from cells in the stomach and that has been implicated in the regulation of feeding behavior [11]. There is evidence that its orexigenic (appetite stimulating) activity is mediated, in part, by the hypothalamic hormone neuropeptide Y. Ghrelin is also the endogenous ligand for the growth hormone secretagogue receptor; it stimulates release of growth hormone from the pituitary independently of hypothalamic growth hormone releasing hormone. Repeated administration of Ghrelin has recently been shown to improve muscle mass and functional capacity in cachectic patients with heart failure or chronic obstructive pulmonary disease [45] and to alleviate chemotherapy-induced dyspepsia in rodents [46]. Leptin is an adipocyte-derived cytokine with an appetite-suppressing effect, likely mediated, in part, through neuropepetide Y. Along with adiponectin, another adipocyte-derived hormone, leptin may increase fat oxidation and promote insulin sensitivity via the AMP-activated protein kinase, thus reducing circulating fatty acids and triacylglycerol [47].

6.1.4 ANTIBODY BIOPHARMACEUTICALS

Antibodies or immunoglobulins are a class of disease-fighting proteins produced by B cells found in the lymphatic system or bone marrow. Antibodies are produced to

bind a specific antigen that has stimulated the immune system. Their selectivity and tunability to recognize and bind an almost infinite range of large- and small-molecule substrates is what makes antibodies so important to the immune system. Once bound, the antigen can be ingested and destroyed by other cells of the immune system, primarily macrophages. Each antibody consists of four polypeptides—two heavy chains and two light chains joined by disulfide linkages in a hinge region to form a “Y”-shaped molecule (Figure 6.1-2a). The arms of the Y are known as the antigen-binding fragments (Fab). The region of the heavy chain associated with the light chains in the Fab contains one variable domain and one constant domain. The light chains each contain one constant domain and one variable domain. The variable domains of both the light and the heavy chain are known collectively as the variable fragment (Fv), and each contains hypervariable regions (known as complementarity-determining regions–CDRs) that are primarily responsible for determining antigen recognition. The lower portion of the “Y,” consisting primarily of the heavy chains, is called the constant region. The constant region determines the mechanism used to destroy antigen. There are five classes of immunoglobulins (antibodies) in humans: IgM, IgG, IgE, IgA, and IgD. Most biopharmaceuticals are based on IgG.

Antibodies not only recognize and bind to antigens, but they also direct the process by which the antigens are eliminated or killed. These are called the effector function. The base of the heavy chain (called the constant fragment, Fc) is species-

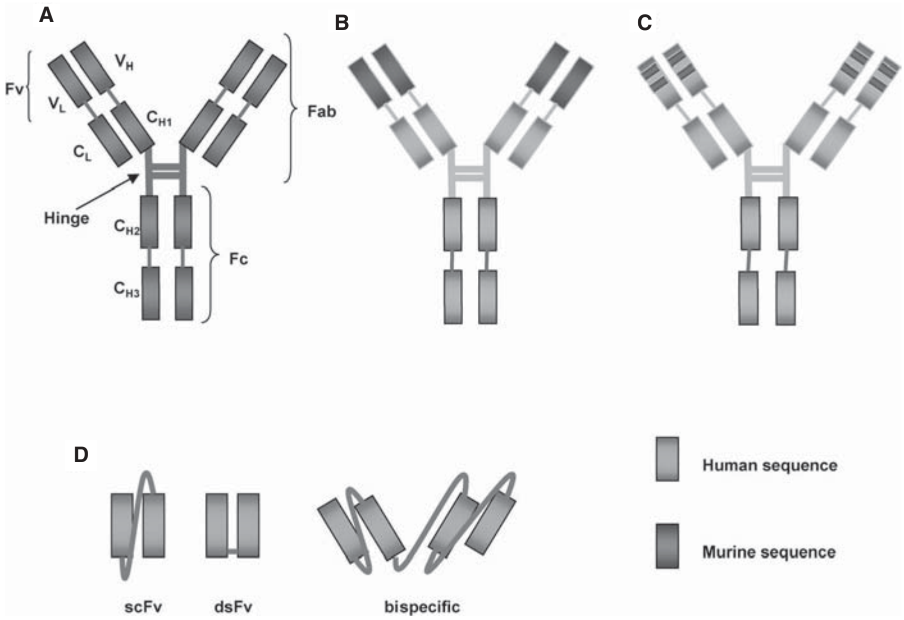

Figure 6.1-2. IgG antibodies and antibody fragments. (A) Murine IgG antibody showing variable (Fv), antigen-binding (Fab), and constant (Fc) fragments. Heavy and light chains are indicated by suffix H and L, respectively. (B) Chimeric IgG with murine Fv regions fused to human constant regions (C_L, C_{H1}, and Fc). (C) Humanized IgG with fused murine CDRs in Fv regions. (D) Antibody fragments. scFv—single-chain Fv; dsFc—disulfide-stabilized Fv; bispecific—two linked scFvs with different antigen recognition.

specific and mediates effector functions, including antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC). In ADCC, antibodies bind to Fc receptors on the surface of natural killer (NK) cells or macrophages, and trigger phagocytosis or lysis of the targeted cells. In CDC, antibodies kill the targeted cells by triggering the complement cascade at the cell surface. IgG is most efficient in inducing both ADCC and CDC and, therefore, is most suitable for use as a therapeutic molecule.

The first monoclonal antibody (mAb) tested in 1986 as a therapeutic in humans was a murine antibody, Muromonab (OKT3) [6]. Despite the high expectations of mAb therapy, OKT3 failed as a good treatment for transplantation rejection, primarily as a result of severe human anti-murine antibody response in patients. The second mAb marketed for therapeutic use in humans, Abciximab (ReoPro), required nearly 9 years of development to produce a chimeric Ab with mouse Fab and human Fc regions [48]. Since that time, more than 27 recombinant antibody therapeutics have been approved by the FDA, accounting for 24% of all approved protein/peptide therapeutics (Table 6.1-2) The current scheme for classifying mAbs is based on variation in their structure (Figure 6.1-2b–d).

1) Standard mAbs are produced by fusing murine cultured melanoma cells with isolated immune-reactive spleen cells to produce hybridoma fusions. These hybridomas are assayed *in vitro* for reactivity to the selected antigen and clones of single reactive cells are grown by intraperitoneal injection into naïve mice. Thus, all reactive cells from a single mouse result from a single reactive clone, and hence, the resulting antibodies are called monoclonal.
2) Fc-humanized mAbs are the result of genetic engineering to replace the murine Fc with human Fc in the melanoma cell lines [49].
3) An alternative approach to producing humanized Abs is to graft murine CDRs and a few structural residues from the heavy chain into a human IgG heavy chain [50]. In combination with the normal mouse light chain produced by the hybridoma, this CDR-grafting leads to the development of Daclizumab (Zenapax) in 1997. Instead of generating CDRs in whole animals by antigen immunization, they can also be selected by panning combinatorial phage libraries with recombinant Fabs [51]. Adalimumab (Humira) was the first therapeutic antibody developed with this technique in 2002. Yet another strategy for producing humanized Abs immunizes transgenic mice engineered to express human IgG against the selected antigen [52, 53]. Several therapeutic mAbs derived from such transgenic "humanized" mice are in late-phase clinical trial, including Panitumumab, an anti-EGFR Ab for the treatment of advanced metastatic colorectal cancer.
4) Recombinant bacterial techniques, coupled with the recognition that the entire antibody is not always required, have led to the formation of many therapeutic antibody fragments (Figure 6.1-3d). Whole IgG molecules are about 150 kDa, and subsequently, they diffuse into tissue slowly and are cleared from the body slowly as well. These characteristics make them poor candidates in diagnostic imaging or radiotherapy applications. The Fv region is the smallest portion of the Ab that maintains its antigen specificity, and it is small enough to be easily expressed in *E. coli*. Single-chain Fvs (scFvs) are fusion proteins containing both heavy and light variable regions connected

TABLE 6.1-2. FDA-Approved Antibody Pharmaceuticals

Generic Name	Chemical Name	Brand Name(s)	Drug Category	Indication
Abciximab	Chimeric human-murine (anti CD41) Ab	ReoPro	Anticoagulant, Antiplatelet. Fab fragment of chimeric human-murine monoclonal antibody binds to the glycoprotein lIb/IlIa receptor of human platelets and inhibits aggregation.	myocardial infarction, adjunct to percutaneous coronory intervention, unstable angina
Adalimumab	Humanized anti-TNF antibody	Humira	Antirheumatic, Immunomodulatory. Created using phage display technology. Has human-derived heavy- and light-chain variable regions and human constant regions. It is produced by recombinant DNA technology in a mammalian cell expression system.	for treatment of rheumatoid arthritis
Alefacept	Human LFA-3/IgG1 fusion protein	Amevive	Immunomodulatory, Immunosuppresant. Dimeric fusion of extracellular CD2-binding portion of leukocyte function antigen-3 linked to the Fc (hinge, CH2 and CH3 domains) portion of human IgG1. Produced in recombinant CHO cells.	moderate-to-severe chronic plaque psoraisis
Alemtuzumab	Humanized anti-CD52 antibody	Campath	Antineoplastic. Humanized mAb specific to lymphocyte antigen (cell surface glycoprotein,CD52). IgG1 with human variable framework and constant regions and murine CDRs. Produced in CHO cells.	B-cell chronic lymphocytic leukemia

Antithymocyte globulin	Rabbit anti-thymocyte globulin	Atgam, Thymoglobulin	Immunomodulatory. Polyclonal antibody depletes T cells responsible for acute organ rejection in transplant patients.	renal transplant rejection
Arcitumomab	AntiCEA antibody	CEA-Scan	Diagnostic, Imaging Agent. Fab fragment of murine IgG1 mAb IMMU-4 (also called NP-4 with specificity for carcinoembryonic antigen (CEA) covalently labeled with Technitium 99.	imaging colorectal tumors
Basiliximab	Chimeric murine/human anti-CD25 antibody	Simulect	Immunomodulatory, Immunosupressant. Blocks IL-2R alpha on surface of activated T lymphocytes. Produced by mouse myeloma cell line. Contains human heavy- and light-chain constant regions and murine heavy- and light-chain variable regions.	kidney transplant rejection
Bevacizumab	Humanized anti-VEGF antibody	Avastin	Antiangiogenesis, Antineoplastic. Contains human framework regions and the murine anti-VEGF CDRs. Produced in recombinant CHO cells.	metastatic colorectal cancer
Capromab	Murine anti-7E11 antibody	ProstaScint	Imaging Agent. Murine IgG1 mAb conjugated to linker chelator peptide group for indium attachment.	diagnosis of prostate cancer and detection of intra-pelvic metastases
Cetuximab	Humanized anti-EGFR antibody	Erbitux	Antineoplastic. Epidermal growth factor receptor binding Fab. Has variable regions of murine EGFR mAb for the N-terminal portion of human EGFR with human IgG1 heavy- and kappa light-chain constant (framework) regions.	metastatic colorectal cancer

TABLE 6.1-2. *Continued*

Generic Name	Chemical Name	Brand Name(s)	Drug Category	Indication
Daclizumab	Humanized anti-CD25 antibody	Zenapax	Immunomodulatory, Immunosupressant. Humanized IgG1 Mab that binds to the human IL-2R (anti-CD25). Composite of 90% human (IgG1 constant plus variable framework regions of the Eu myeloma Ab) and 10% murine Ab (CDR) sequences.	renal transplant rejection
Digibind	Anti-digoxin antibody fragment	Digibind	Sheep antibody Fab fragment specific to Digoxin.	digitoxin overdose or digitalis glycoside toxicity
Efalizumab	Humanized anti-CD11a antibody	Raptiva	Immunomodulatory, Immunosupressant. Humanized IgG1 anti-CD11a mAb. Produced in recombinant CHO cells.	psoriasis
Etanercept	Human tumor necrosis factor receptor fusion protein	Enbrel	Antirheumatic, Immunomodulatory. Dimeric fusion protein consisting of extracellular ligand-binding portion of human p75 TNFR linked to IgG1 Fc portion lacking CH1 domain. Produced by recombinant DNA technology in CHO cells.	severe adult and juvenile rheumatoid arthritis
Gemtuzumab ozogamicin	Humanized chimeric anti-CD33 antibody	Mylotarg	Antineoplastic. Recombinant humanized IgG4 conjugated with cytotoxic antitumor antibiotic, calicheamicin. Binds to cell-surface CD33 antigen. Produced in mammalian cell culture.	acute myeloid leukemia
Ibritumomab	Murine anti-CD20 antibody	Zevalin	Antineoplastic. Indium conjugated murine IgG1 anti-CD20 mAb. CD20 antigen is found on the surface of normal and malignant B lymphocytes. Produced in recombinant CHO cells.	non-Hodgkin's lymphoma

Immune globulin	Human antibodies	Flebogamma, Gamunex	Anti-infective, Immunomodulatory. Mixture of IgG1 and other Abs derived from human plasma via Cohn fractionation. 70.3% IgG1, 24.7% IgG2, 3.1% IgG3, and 1.9% IgG4.	immunodeficiencies, thrombocytopenic purpura, Kawasaki disease, gammablobulinemia, leukemia, bone transplant
Infliximab	Chimeric mouse/human anti-TNF-alpha antibody	Remicade	Immunomodulatory, Immunosuppresants. TNF-alpha binding antibody. Chimeric Ab composed of human constant and murine variable regions. Produced by a recombinant cell line cultured by continuous perfusion	Crohn's disease, psoriasis, rheumatoid arthitis and ankylosing spondylitis
Muromonab	Murine anti-CD3 antibody	Orthoclone OKT3	Immunomodulatory, Immunosuppressant. Purified murine (mouse) mAb, directed against CD3 (T3) receptor on the surface of T lymphocytes. Cultured from murine ascites. 93% monomeric IgG2a.	prevention of organ rejection
Natalizumab	Humanized anti a4 integrin antibody	Tysabri, Antegren	Immunomodulatory. Humanized IgG4 mAb produced in murine myeloma cells. Contains human framework regions and murine anti-a4 itegrin CDR.	multiple sclerosis
Omalizumab	Humanized anti-IgE antibody	Xolair	Anti-Asthmatic, Immunomodulatory. Recombinant humanized IgG1 mAb binds to human IgE. Produced by recombinant CHO cells.	allergy-induced asthma

TABLE 6.1-2. *Continued*

Generic Name	Chemical Name	Brand Name(s)	Drug Category	Indication
Palivizumab	Humanized anti-RSV antibody	Synagis	Antiviral. Humanized mAb (5% murine) directed to an epitope in the A antigenic site of the F protein of respiratory syncytial virus (RSV). Produced by a stable murine myeloma cell line.	respiratory diseases caused by respiratory syncytial virus
Rituximab	Chimeric murine/human monoclonal anti-CD20 Ab	Rituxan	Antineoplastic. Chimeric murine/human monoclonal anti-CD20 Ab. Contains murine light- and heavy-chain variable region sequences and human constant region sequences. C20 is found on the surface of normal and malignant B lymphocytes.	B-cell non-Hodgkins lymphoma (CD20 positive)
Satumomab Pendetide	Murine anti-TAG72 antibody conjugated with Indium 111	OncoScint	Imaging Agent. Tumor associated glycoprotein mAb conjugated with Indium 111 for radioimaging colon tumors.	diagnosis of extrahepatic malignant cancers
Tositumomab	Murine anti-CD20 antibody	Bexxar	Antineoplastic. Murine IgG2 anti-CD20 mAb. Produced in cultured mammalian cells. Can be covalently linked to radioactive Iodine 131.	non-Hodgkin's lymphoma
Trastuzumab	Humanized anti-HER2 antibody	Herceptin	Antineoplastic. A recombinant humanized mAbbinds to the extracellular domain of human EGFR. Produced in CHO cell culture.	HER2-positive metastatic breast cancer

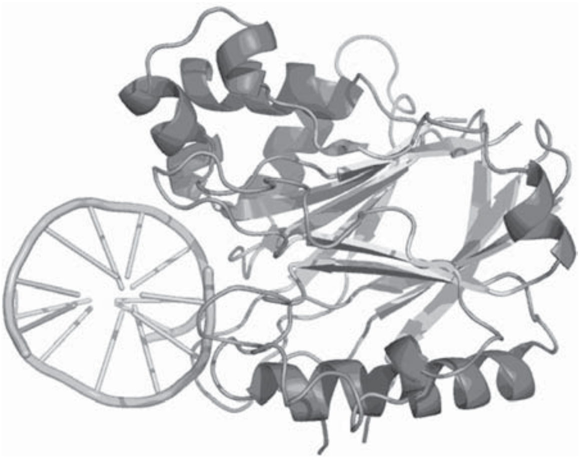

Figure 6.1-3. The x-ray crystal structure of DNase I in the presence of the palindromic d(GCGATCGC) DNA fragment at 2.0-Å resolution (PDB ID: *2DNJ*).

through a short peptide linker. Disulfide-stabilized Fvs (dsFvs) connect the two variable regions through engineered cysteine disulfide linkages. Diabodies are homodimers of scFvs that are covalently linked by a short peptide linker so that the V domains are forced to make intermolecular complexes. Bispecific Fvs are fusions of two complete Fv regions with a different antigen specificity. Variations on these themes incorporating part of the constant region are also possible.

6.1.4.1 Examples of Antibody Biopharmaceuticals

Muromonab (Orthoclone OKT3) is a purified murine monoclonal antibody specific to the CD3 receptor on the surface of human T cells (T lymphocytes). Used in organ transplant prophylaxis, Muromonab is administered parenterally. It has been effective in reversing corticosteroid-resistant acute rejection in renal, liver, and cardiac transplant recipients. Muromonab binds to the epsilon subunit of the surface glycoprotein CD3 that is associated with the T-cell receptor. It seems to kill CD3 positive cells by inducing Fc mediated apoptosis, antibody mediated cytotoxicity, and complement-dependent cytotoxicity. Immediately after administration CD3-positive T lymphocytes are abruptly removed from circulation, most likely by NK-mediated cytoxicity directed toward the T cells themselves [54] or by inducing T-cell apoptosis [55]. The OKT3-dependent reduction in alloreactive T lymphocytes severely downmodulates transplant rejection. However, because OKT3 contains the mouse Fc regions, its application led to several unfortunate side effects, including acute cytokine overstimulation, flu-like symptoms, and, in rare cases, pulmonary edema, central nervous system disorders, or an anaphylactic reaction to the murine Fc (reviewed in Ref. 56.)

Abciximab (ReoPro) was the first partially humanized antibody approved for therapeutic use. It was produced from transgenic murine melanoma cells containing human heavy-chain genes so that the resulting Fab fragment is a chimera of human and mouse Ab fragments. Abciximab binds to the glycoprotein lIb/IlIa

receptor (a member of the integrin family of adhesion receptors and the major platelet surface receptor involved in platelet aggregation) and competitively inhibits fibrinogen-mediated platelet aggregation and clot formation [57]. Thus it is used in the treatment of myocardial infarction, unstable angina, and as an adjunct to percutaneous coronary intervention. Because the constant regions of the Fab fragment are derived from a human gene, side effects such as those observed with Muromonab are dramatically reduced. Nevertheless, in rare cases, acute profound thrombocytopenia can occur after Abciximab administration leading to a recommendation to monitor platelet count in patients within 11 to 21 hours after treatment [58].

Daclizumab is a humanized IgG mAb that binds to the human IL-2 receptor (anti-CD25). Daclizumab is a composite of human (90%) and murine (10%) antibody sequences. The human sequences were derived from the constant domains of human IgG1 and the variable framework regions of the Eu myeloma antibody [59]. The antibody is produced by expression in a mammalian cell line. The murine sequences were derived from the complementarity-determining regions of a murine anti-CD25 antibody [50]. Daclizumab competitively inhibits the cytokine IL-2 from binding to its CD25 receptor and phosphorylating the IL-2R beta and gamma-chains. This leads to an inhibition of downstream STAT activator genes and a subsequent immunosuppressive effect [60]. Early evaluations of clinical effectiveness of Daclizumab have been promising with reduced side effects relative to OKT3.

Adalimumab (Humira) is an anti-TNF antibody used in the treatment of rheumatoid arthritis. Elevated levels of TNF are found in the synovial fluid of rheumatoid arthritis patients and play an important role in both the pathologic inflammation and the joint destruction that are hallmarks of the disease. Adalimumab binds specifically to TNF-alpha and blocks its general cytokine effects through its interaction with the p55 and p75, thereby reducing TNF-induced inflammation and halting joint destruction. Adalimumab also lyses surface TNF expressing cells *in vitro* in the presence of complement. It was the first FDA-approved antibody therapeutic created using phage display technology [48] resulting in an antibody with human-derived heavy- and light-chain variable regions and human IgG constant regions. Adalimumab is produced by recombinant DNA technology in a mammalian cell expression system from which it is purified and administered by subcutaneous injection. Like other drugs that block TNF, use of Adalimumab has been associated with reactivation of previous serious infections such as tuberculosis, sepsis, and fungal infections. Patients with active infections should not be treated with Adalimumab.

6.1.4.3 The Future of Antibody Biopharmaceuticals

The development of future therapeutic antibodies revolves around several central issues: (1) further humanization to reduce unwanted Fc-based immune responses, (2) generation of novel CDRs against selected targets, and (3) selection of novel therapeutic Ab targets. Humanization of mAbs has been extensively reviewed elsewhere [61, 62]. A leading focus of recent activity is the use of transgenic mice that have been engineered by a combination of modified traditional transgenic

techniques, yeast artificial chromosome (YAC) technology, and microcell-mediated chromosome transfer. The use of these techniques is required due to the large size of the immunoglobulin gene clusters; the human heavy-, λ-light-, and κ-light-chain loci (located on chromosomes 14, 22, and 2, respectively) span over a megabase each. In addition, murine native light- and heavy-chain regions are deleted in these heavily engineered mice to reduce the production of murine antibodies. Several mAbs produced from these mice are currently under development, including Zanolimumab (anti-CD4 for treatment of cutaneous and peripheral T-cell lymphoma [63]), Panitumumab (anti-epidermal growth factor receptor (EGFR) for treatment of advanced metastatic colorectal and other cancers [64]), and Denosumab (anti-receptor activator of nuclear factor kappa B ligand (RANKL)—a key mediator of the resorptive phase of bone remodeling—for treatment of osteoporosis, rheumatoid arthritis, and cancer with skeletal metastasis [65]).

We have discussed techniques using combinatorial phage libraries to pan for CDRs responding to therapeutic targets. In addition, libraries of novel CDRs can be displayed on the surface of *E. coli* or *S. cerevisiae* or produced *in vitro*, using ribosome display or semi- or fully synthetic antibody libraries (reviewed in Ref. 48). Libraries can be based on CDRs of inoculated or näive individuals and extract variable domains from IgG or IgM regions by polymerase chain reaction (PCR) and subsequent cloning into expression vectors for display (e.g., in phage or *E. coli*). Although naïve libraries (those that have been derived from nonimmunized individuals) have greater complexity than libraries from inoculated individuals, they also tend to have reduced expression and increased toxicity in *E. coli*. *In vitro* methods circumvent these issues and permit harsher selection conditions that may lead to the production of higher affinity antibodies. Phage display is the only technology that has been developed sufficiently that it can be used commercially, and several therapeutic antibodies produced using this approach are in various stages of development, including Mapatumumab (an agonistic mAB that activates the TNF receptor apoptosis induced ligand (TRAIL-R1) to induce apoptosis in multiple types of cancer cells), Metelimumab (anti-TGF-β1 for treatment of sclerodoma), and AbThrax (anti-*Bacillus anthracis* Protective Antigen prevents anthrax from inducing toxin-mediated cell death).

Although novel therapeutic targets continue to be sought routinely, antibody development has mainly been focused on traditional cell-surface and extracellular antigens. Development of novel potential therapeutic targets is dependent on discoveries from fields as diverse as cell biology, cancer biology, microbiology, and developmental genetics. Recently, attention has been focused on the development of antibody derivatives, called intrabodies, that are directed toward intracellular targets [66]. The reducing environment found within the cells makes it difficult for most antibodies to form the disulfide bonds necessary for molecular stability. Intrabodies are formed from a subset of naturally occurring immunoglobulin frameworks that are capable of supporting a variety of antigen-binding structures inside this reducing environment. Alternative methods for discovering intrabodies involve screening scFvs, yeast surface display, phage display, intracellular antibody capture, and directed modifications to the Fc region to improve molecular stability in the cell. Experimental intrabodies that bind H-RAS and block oncogenic transformation of NIH 3T3 cells have recently been developed from scFvs [67] as have anti-angiogenic adenoviral-delivered scFvs [68].

6.1.5 ENZYME BIOPHARMACEUTICALS

Enzymes are produced by living organisms and function as biological catalysts in specific biochemical reactions of substrates. Enzymes accelerate reactions usually through stabilization of a reactive intermediate at their active site, the place where the reaction occurs. The enzymes, themselves, may be chemically altered during the reaction but are restored to their initial state by its completion. Enzymes are critical to the functioning of most cellular systems as most essential metabolic or catabolic reactions would occur too slowly, or would lead to different products without enzymes. Because of their importance, the mutation, overproduction, underproduction, or deletion of a single critical enzyme can lead to severe disease. For example, mucopolysaccharidosis type VI (or Maroteaux–Lamy syndrome), is a lethal syndrome that develops when patients are deficient in an enzyme called N-acetylgalactosamine 4-sulfatase (galsulfase) and, thus, cannot degrade glycosaminoglycans sufficiently. These compounds accumulate in various tissues leading to permanent, progressive cellular damage affecting an individual's appearance, physical abilities, organ and system functioning, and, in most cases, mental development [69].

More than 3000 human enzymes have been identified and named. Typically the suffix-*ase* is added to the name of the substrate (e.g., lactase is the enzyme that catalyzes the breakdown of lactose) or the type of reaction (e.g., DNA polymerase catalyzes the assembly of DNA). However, this is not always the case, especially when enzymes modify multiple substrates. For this reason, enzymes are formally named and classified based on the recommendations of the Nomenclature Committee of the International Union of Biochemistry, which assigns an Enzyme Commission (EC) number and a formal name. There are six main classes of enzymes: oxidoreductases (EC 1), transferases (EC 2), hydrolases (EC 3), lyases (EC 4), isomerases (EC 5), and ligases (EC 6). Most enzyme pharmaceuticals in current use belong to the hydrolase class such as galsulfase and agalsidase. These enzymes are involved in the hydrolysis (i.e., cleaving) of various bonds. However, there are also examples of pharmaceutical enzymes that belong to oxidoreductases, for example, rasburicase. Some enzymes are highly specific to certain substrates, such as adenosine deamidase, making them ideal drug candidates. On the other hand, some enzymes have wide specificities, such as vitamin A esterase, making these less desirable for drug development.

The potential utility of enzymes as pharmaceuticals was noted many decades ago, and since then, nearly two dozen enzymes have been developed to treat a variety of diseases. Almost all enzyme therapies developed to date are used to deal with a loss of function defect (a mutation that diminishes activity, a low level of production, a deletion). Hence, most enzyme drugs are used as enzyme replacement therapies (ERT) for relatively rare, inborn errors of metabolism (IEMs). As a result, many enzyme therapeutics fall under the FDA's Orphan Drug Designation. However, a few enzyme therapies can also be used to treat much more common conditions such as cancer, heart attacks, and stroke. In the United States, the first enzyme to receive FDA approval was a tissue plasminogen activator called alteplase. This protein, which is now commonly used to treat strokes, was introduced in 1987 as Activase. Since then at least 16 other enzyme drugs have been introduced into the marketplace. Some of these are described in more detail below and in Table 6.1-3.

TABLE 6.1-3. FDA-Approved Enzyme Pharmaceuticals

Generic Name	Brand Name(s)	Indication	Description
Agalsidase beta	Fabrazyme	Fabry's disease	Recombinant human α-galactosidase A. The mature protein is composed of 2 subunits of 398 aa. Protein is glycosylated and produced by CHO cells.
Alglucerase Imiglucerase	Ceredase Cerezyme	Gaucher's disease	Human β-glucocerebrosidase or β-D-glucosyl-N-acylsphingosine glucohydrolase. 497 aa protein (59.3 kDa) with N-linked carbohydrates. Alglucerase is prepared by modification of the oligosaccharide chains of human β-glucocerebrosidase. The modification alters the sugar residues at the nonreducing ends of the oligosaccharide chains of the glycoprotein so that they are predominantly terminated with mannose residues.
Alteplase	Activase	Acute myocardial infarction, acute ischemic stroke, and acute pulmonary emboli	Human tissue plasminogen activator, purified, glycosylated, 527 aa purified from CHO cells.
Anistreplase	Eminase	Acute pulmonary emboli, intracoronary emboli, and myocardial infarction	Human tissue plasminogen activator, purified, glycosylated, 527 residues purified from CHO cells. Eminase is a lyophilized formulation of anistreplase, the p-anisoyl derivative of the primary Lys-plasminogen-streptokinase activator complex (a complex of Lys-plasminogen and streptokinase). A p-anisoyl group is chemically conjugated to a complex of bacterial-derived streptokinase and human plasma-derived Lys-plasminogen proteins.
Asparaginase	Elspar	Acute lymphocytic leukemia & non-Hodgkin's lymphoma	L-asparagine amidohydrolase from *Escherichia coli.*
Collagenase	Santyl	Chronic dermal ulcers & severe skin burns	The enzyme collagenase is derived from fermentation of *Clostridium histolyticum.*

TABLE 6.1-3. *Continued*

Generic Name	Brand Name(s)	Indication	Description
Dornase alfa DNase	Dilor Lufyllin Neothylline Pulmozyme	Cystic fibrosis	Recombinant human deoxyribonuclease I. Delivered by aerosol mist. The protein is produced by genetically engineered CHO cells containing DNA encoding for the native human protein, DNase I. 260 aa.
Hyaluronidase	Vitrase	For increase of absorption and distribution of other injected drugs, for rehydration and diabetic retinopathy	Highly purified sheep hyaluronidase for injection into the vitreous cavity of the eye.
Laronidase	Aldurazyme	Mucopolysaccharidosis	Human recombinant α-L-iduronidase, 628 aa (mature form), produced by recombinant DNA technology in CHO cells. Laronidase is an 83 kDa glycoprotein. The nucleotide sequence is identical to a polymorphic form of human α-L-iduronidase. It contains 6 N-linked oligosaccharide modification sites.
Pancrelipase	Cotazym Pancrease Ultrase Zymase	Cystic fibrosis, chronic pancreatitis, and pancreatic duct blockage	Protein mixture isolated from porcine or bovine pancreas, sometimes called pancreatin. Contains 3 enzymes: amylase, lipase, and protease (chymotrypsin).
Pegademase	Adagen	Severe combined immunodeficiency disease	Bovine adenosine deaminase derived from bovine intestine that has been extensively PEGylated for extended serum half-life.
Pegaspargase	Oncaspar	Acute lymphoblastic leukemia	PEGylated L-asparagine amidohydrolase from *Escherichia coli*. PEGylation substantially (factor of 4) extends the protein half-life.
Rasburicase	Elitek	Hyperuricemia	Rasburicase (34.1 kDa) reduces elevated plasma uric acid levels due to tumor lysis (from chemotherapy). It catalyzes the oxidation of uric acid into an inactive and soluble metabolite (allantoin).

Reteplase	Retavase	Acute pulmonary emboli, intracoronary emboli, and myocardial infarction	Human tissue plasminogen activator, purified from CHO cells, glycosylated, 355 aa. Retavase is considered a “third-generation” thrombolytic agent, genetically engineered to retain and delete certain portions of human tPA. Retavase is a mutant of human tPA formed by deleting various aa’s present in endogenous human tPA. Retavase contains 355 of the 527 aa of native human tPA (aa 1–3 and 176–527), and retains the activity-related kringle-2 and serine protease domains of human tPA. Three domains are deleted from retavase—kringle-1, finger, and EGF.
Streptokinase	Streptase	Acute evolving transmural myocardial infarction, pulmonary embolism, deep vein thrombosis, arterial thrombosis or embolism, and occlusion of arteriovenous cannulae	A purified preparation of a bacterial protein from group C (β)-hemolytic *Streptococcus*.
Tenecteplase	TNKase	Myocardial infarction and intracoronary emboli	Tenecteplase is a 527 aa glycoprotein developed by introducing the following modifications to the cDNA for natural human tPA: Thr_{103} to Asp_{103}, Asp_{117} to Gln_{117} (both within the kringle 1 domain), and the tetra-Ala substitution at aa 296–299 in the protease domain.
Urokinase	Abbokinase	Pulmonary embolism, coronary artery thrombosis, and *IV* catheter clearance	Low-molecular-weight form of human urokinase that consists of an A chain of 2 kDa linked by a SH bond to a B chain of 30.4 KDa. Recombinant urokinase plasminogen activator.

6.1.5.1 Examples of Enzyme Biopharmaceuticals

Dornase alfa (DNase I; EC 3.1.21.1) was introduced over a decade ago as an optional drug to treat cystic fibrosis (CF). Cystic fibrosis is an autosomal, recessive, hereditary disease that affects the lungs, sweat glands, and the digestive system, causing chronic respiratory and digestive problems. It is caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) protein and is the most common fatal autosomal recessive disease in Caucasians. Approximately 1 in 25 individuals of European descent is a carrier of a CF mutation. Dornase breaks down the built-up sputum in the lungs of affected individuals through the digestion of the accumulated extracellular DNA from the breakdown of neutrophils that collect due to the local inflammation of the lungs [70]. As the drug has a short duration of action, it is administered continuously through daily inhalation by a nebulizer or a compressor system. This treatment benefits about 40% of patients. The drug is usually well tolerated, although some side effects such as chest pain and skin rashes, have been reported [71]. The three-dimensional structure of DNase I in the presence of a short DNA segment is illustrated in Figure 6.1-3.

Galsulfase (Aryplase) or N-acetylgalactosamine 4-sulfatase (ARSB; EC 3.1.6.12) is a hydrolase drug used in the treatment of mucopolysaccharidosis (MPS) type IV (or Maroteaux–Lamy syndrome), a lysosomal storage disease. Patients suffering from this lethal syndrome are deficient in Galsulfase expression leading to a block of the degradation of glycosaminoglycans, which causes an accumulation of these compounds in various tissues [69]. Galsulfase treatment is well tolerated, although some patients develop antibodies against the enzyme. However, these enzyme-specific antibodies generally decrease significantly in these patients after about a year and a half of treatment [72]. Another drug has been available for the treatment of MPS type I since 2003. This disease is caused by a deficiency in α-L-iduronidase (laronidase; Aldurazyme; EC 3.2.1.76) [73]. Treatment with laronidase for the milder forms of MPS type I has been shown to be safe, well tolerated, and effective. No significant side effects are associated with the administration of this enzyme-drug, although most patients develop antibodies against the enzyme; however, with time the antibody titers subside [74]. Injection of laronidase must be done on a weekly basis [73].

Agalsidase (Fabrazyme) is used in the treatment of Fabry disease, a lethal inborn error of metabolism disorder in which patients lack lysosomal hydrolase α-galactosidase A (αGalA; EC 3.2.1.22). This enzyme is involved in the breakdown of glycosphingolipids leading to the accumulation of α-galactose in tissues and plasma [75]. This accumulation can lead to skin lesions, febrile episodes, and burning sensations in the extremities. Death in early adulthood is usually due to renal failure because of proteinuria induced hypertension. The bimonthly injection of agalsidase-α (Replagal) or agalsidase-β (Fabrazyme) alleviates the severe pain associated with this condition. The cost of these drugs can exceed $170,000 per year.

Pegademase (adenosine deaminase; EC 3.5.4.4) is a PEGylated enzyme used for treating patients with adenosine deaminase (ADA) deficiency [76] and suffering from a form of severe combined immunodeficiency syndrome (SCID), a disease that occurs in about 1/50,000 births. SCID patients have a severely crippled immune system and cannot clear or recover from the mildest microbial or viral infections.

SCID patients, if untreated, usually die within 1 year due to severe, recurrent infections such as chronic diarrhea, ear infections, recurrent pneumonia, and profuse oral candidiasis. The ADA deficiency leads to an accumulation of purine metabolites, in particular dGTP, which are cytotoxic to lymphoid stem cells. Restoration of normal ADA levels removes the dGTP and allows the lymphoid stem cells to propagate. Pegademase is administered intravenously, stored at 4°C, and should never be frozen [77].

Imiglucerase (alglucerase) is used in the treatment of type 1 Gaucher disease (GD), a lysosomal storage disorder due to a deficiency of glucocerebrosidase (EC 3.2.1.45). This enzyme deficiency leads to the accumulation of glucosylceramide in cells [78]. Imiglucerase has been used to treat Gaucher disease for the past decade and is given intravenously. Its application leads to a marked improvement in the clinical manifestation of the disease [79]. However, this drug cannot reverse all effects of Gaucher disease, such as fibrotic and necrotic tissue damage [80]. The drug is well tolerated and has few side effects. The most common side effect is antibody generation to imiglucerase [81]. However, the excellent safety profile of imiglucerase enables patient self-administration and prevents the morbidity associated with the disease.

Although most enzyme therapies are used to treat relatively rare metabolic or genetic disorders, some enzymes are used to treat much more common afflictions such as heart attacks and stroke. Tissue plasminogen activators (tPA; EC 3.4.21.68) are intravenously administered fibrinolytic agents that are used in reperfusion for the treatment of acute ischemic stroke [82]. It has been shown that the use of tPAs such as reteplase (Retavase), tenecteplase (TNKase), alteplase (Activase), and anistreplase (Eminase) within 3 hours post-stroke-onset affords at least an order of magnitude more benefit to patients than aspirin, the only other beneficial drug for this condition. About one third of patients treated with intravenous fibrinolytic therapy exhibit an improvement poststroke [83]. Furthermore, tPAs are also used in the treatment of acute myocardial infarction [84]. Tenecteplase is known to have a long half-life; therefore, a single bolus injection is sufficient for treatment [85]. The half-life of reteplase is even longer allowing its administration as a double-bolus injection. However, this increased half-life seems to be only useful in reducing the number of injections, as it provides no additional health benefits to the patient [86]. Streptokinase (Streptase; EC 3.4.99.0) is another thrombolytic agent that, in some instances, has been shown to be more effective than tPAs [87]. Lastly, urokinase (Abbokinase; EC 3.4.21.73) is another type of thrombolytic agent that activates plasminogen through another mechanism and is used in the treatment of pulmonary embolisms.

Several enzyme therapies are also used in the treatment of cancer. For instance, rasburicase (uricase; Elitek; EC 1.7.3.3) is used in the treatment of hyperuricemia due to tumor lysis syndrome (TLS). This is a potentially life-threatening condition that is associated with rapidly developing tumors, such as those found in lymphoma and leukemia, in patients undergoing chemotherapy. The incidence of hyperuricemia in these patients is close to 20% [88]. Uricase is an interesting enzyme, because it is found in most mammals, with the exception of humans, where the gene contains a nonsense mutation [89]. Rasburicase is well tolerated, has a very fast onset of action, and is administered intravenously once a day. However, the enzyme cannot be used on patients with glucose-6-phosphate dehydrogenase deficiency [90]. The

PEGylated formulation of uricase is less immunogenic and has a longer half-life than its "naked" form [89].

Asparaginase (EC 3.5.1.1) is an example of another enzyme-based anticancer therapy. Asparaginase, derived from *E. coli*, is frequently used in the treatment of acute lymphoblastic leukemia [91]. Asparaginase works by depriving leukemic cells of L-asparagine. Asparaginase hydrolyzes the amino acid L-asparagine to L-aspartic acid and ammonia. Most human tissues do not require L-asparagine because it can be synthesized from L-glutamine by the action of asparagine synthase (AS). However, acute lymphoblastic leukemia cells generally have very low levels of AS and cannot upregulate the AS gene during conditions of L-asparagine depletion. Asparaginase is an effective way of depleting L-asparagine from the body, and this depletion results in selective cell death of those cells that cannot make L-asparagine. Asparaginase has a relatively short half-life (10–20 hours). However, PEGylated asparaginase has a half-life that is 10–15 times longer. PEGylated-asparaginase (Pegaspargase) was developed in the 1970s and 1980s. The drug has undergone extensive testing and seems to retain its antileukemic effectiveness while allowing less-frequent administration than the native compound. Although the actual cost to patients for Pegaspargase is greater than that of multiple injections of other Asparaginases, the reduced need for physician visits and treatment of complications of therapy may make overall treatment costs considerably less than that of the conventional Asparaginases.

Also some drug formulations contain more than one enzyme. For example, pancrelipase or Zymase contains amylase (for processing starch), lipase (for breaking down fats), and chymotrypsin (a protease) in various combinations. This protein mixture is isolated from porcine or bovine pancreatic tissues and is sometimes called pancreatin. This enzyme cocktail is sold to help digestion in people who do not produce enough of their own digestive enzymes. Such a condition can arise due to pancreatic disfunction caused by pancreatitis, cystic fibrosis, or pancreatic cancer.

6.1.5.2 The Future of Enzyme Biopharmaceuticals

The field of enzyme therapy is not static. New enzymes are being developed and tested to treat a variety of diseases or conditions all the time. Some of the most active work has been in the area of lysosomal storage diseases. Indeed there are now several enzyme pharmaceuticals that are entering phase II and phase III trials to treat several fatal or debilitating syndromes associated with sugar metabolism or sugar catabolism. One example is acid maltase, which is associated with a rare, fatal condition called Pompe's disease. Pompe's disease, also known as infantile glycogen storage disease type 2 (GSD-II), or acid maltase deficiency, results from a genetic deficiency of the acid maltase enzyme, a protein that normally breaks down glycogen (sugar stored in cells). In the absence of acid maltase, glycogen accumulates to toxic levels in cardiac and skeletal muscles, causing the muscles to waste away. Early experiments with acid maltase on several newborns with Pompe's disease indicated good success, particularly with those with residual acid maltase activity [92]. Several other lysosomal storage diseases are also being investigated with enzyme replacement therapy, including Hurler's disease and Maroteaux–Lamy syndrome. Hurler's disease is characterized by a deficiency of α-iduronidase activ-

ity that causes accumulation of dermatan sulfate and heparin sulfate in patients. This leads to stiff joints, reduced range of motion, restrictive pulmonary disease, sleep apnea, and other problems with the eyes, liver, joints, and skeleton. Recent clinical trials with α-iduronidase ERT have shown significant improvement in some patients, especially with their range of motion, flexibility, and reduced sleep apnea (reviewed in Ref. 93). Maroteaux–Lamy syndrome is caused by the accumulation of excessive quantities of dermatan sulfate because of a deficiency of the enzyme N-acetylgalactosamine-4-sulphatase (arylsulfatase B). An ERT trial has recently been conducted with recombinant arylsulfatase B given once every week. In this trial, urinary glycosaminoglycans were reduced, walking ability improved, the range of shoulder motion increased, and joint pain lessened [72]. However, several adverse reactions were also noted and all patients developed antibodies to arylsulfatase.

Not all enzyme therapies are likely to be successful, at least not until better methods for formulating and delivering enzymes are developed. One central challenge to almost all ERTs is the delivery of the proteins to the right tissues. For example, among the lysosomal storage diseases, new and improved formulation and delivery technologies need to be developed to deliver therapeutic enzymes effectively to cardiac muscle and kidney in Fabry's disease, skeletal muscle in patients with Pompe's disease, and to joint tissues and structures in patients with Hurler's disease and Maroteaux–Lamy syndrome. Improved tissue targeting would no doubt help many other enzyme therapeutics used to treat cancer, heart attacks, and strokes.

Another challenge with ERT is the enormous cost and the sometimes questionable benefits or small improvements to patient quality of life. For some IEMs, the rarity of the disease means that production costs will always remain high. For Gaucher's disease, in which ERT has been the most effective, the annual cost of ERT ranges from $40,000 to 320,000 per patient. The cost of ERT for Fabry's disease is about $160,000 per year. Even for more common disorders such as cancer, heart attacks, and stroke, the costs of enzyme-based drugs are sometimes observed as too high. In fact, similar cost–benefit debates have swirled around the issue of tPA versus aspirin and heparin treatments for stroke for more than 15 years [94]. In some cases, the enzyme drug is determined to be very cost-effective. In other cases it is not. Certainly as the market size grows for some enzyme therapies, the costs will inevitably drop. Likewise as formulations are improved and delivery mechanisms are enhanced, it is likely that the cost–benefit balance will change markedly.

6.1.6 CONCLUSIONS

Pharmaceuticals based on natural and recombinant proteins have proven their therapeutic value. Whether for hormone or enzyme replacement therapies or to block or inhibit other protein signals, pharmaceutical proteins exhibit exquisite selectivity and specificity in their targets. Over 100 proteins have been approved by the U.S. Food and Drug Administration since their inception and many more are currently in various phases of development. Despite their potency, many issues hinder the widespread use of protein pharmaceuticals. Proteins require special

(expensive) preparation techniques, usually involving recombinant engineering and expression in cell culture followed by lengthy and costly purifications. They must be stored and shipped under special conditions as they are susceptible to denaturation and degradation by proteolysis. The barriers to easy oral administration and bioavailability are formidable, as the body has many natural defenses to exogenous proteins. Nevertheless, although there are many hurdles to be overcome, protein biopharmaceuticals are certain to see continued rapid development and growth because their potential for providing a more specific and potent therapeutic approach is unparalleled.

6.2.1 INTRODUCTION

The protein pharmaceuticals such as human growth hormone and insulin have been known for years. However, in the past decade, an increased number of protein

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.
Copyright © 2007 John Wiley & Sons, Inc.

products have come on the market and into the development pipeline as a result of the following reasons.

6.2.1.1 Recombinant DNA Technology

Advances in recombinant technology alleviated the problem of protein production and its purity. Through the process of recombinant DNA technology and use of nonhuman cell lines, human proteins can be manufactured free of viral contamination. This process enables production of large quantities of proteins previously difficult to obtain from human sources. Further isolation of protein from human sources is associated with a high risk of viral contamination. One such example, plasma derived clotting factor VIII isolated from human blood, resulted in transmission of viral diseases such as hepatitis and AIDS [1, 2].

6.2.1.2 Specificity and Potency

Protein products are specific as they are identified based on their mechanism of action. Further, protein products are attractive because of their potency, as only μg quantities or a few thousand IU are required to exert the pharmacological effect.

6.2.1.3 Molecular Medicine

The term molecular medicine is defined as understanding disease at the molecular level. For example, the deficiency of factor VIII causes a bleeding disorder, Hemophilia A [3]. Given the accomplishments made in the area of human genome and the emergence of proteomics, functional proteins that have important therapeutic value have been developed, and more will be identified in the future.

6.2.1.4 Therapeutic, Subunit Vaccines

Protein and peptide antigen-based vaccines are safe. The search for safe, single-shot vaccines against infectious and other diseases is a major focus of current research. Several peptide-and protein-based antigens are at different stages of development.

However, the protein therapeutics have unique handling and development requirements relative to the small organic molecule-based drugs and pose exclusive challenges for the formulation scientist. The formulation and delivery issues of therapeutic proteins can contribute to difficulties in pharmaceutical development such as

- Stability (in vivo and in vitro)
- Immune toxicity
- Pharmacokinetics / pharmacodynamics-related problems

Formulation strategies, such as addition of specific functional excipients, freeze-drying, protein engineering, and delivery strategies, have been used to improve the stability and circulation half-life and reduce immunogenicity, which in turn improve

therapeutic efficacy of protein drugs. This chapter will focus on formulation and delivery strategies of therapeutic proteins.

6.2.2 STABILITY OF THERAPEUTIC PROTEINS

As a result of the complex structure of the proteins, formulation of protein therapeutics pose unique difficulties as it is susceptible to physical and chemical instabilities. The complexity develops from the hierarchical nature of its structure: primary, secondary, tertiary, and quaternary structures. Primary structure is the amino acid sequence of the polypeptide chains; secondary structure refers to local-ordered conformation; tertiary structure deals with the spatial arrangement of secondary structural elements (often referred as global fold); and the quaternary structure is the spatial arrangement of subunits. In general, chemical instability is related to primary structure of the protein, whereas physical instability is associated with the global fold or 3D structure of the molecule. The common problems encountered for protein products are listed in Table 6.2-1.

6.2.2.1 Chemical Instability

Chemical instability refers to covalent modifications of the molecule that result in a new chemical entity. Some amino acids in the protein are chemically labile and undergo degradation to form a new chemical entity. The chemical reactions that affect the proteins are as follows:

Deamidation. The side chain of amide linkage in a Gln or Asn residue is hydrolysed to form a free carboxylic acid that gives mixtures of peptides in which the polypeptide backbone is attached via an alpha-carboxyl linkage (Asp/Glu) or is attached via beta carboxyl linkage (iso-Asp/Glu) [4]. The key step in the reaction is the formation of a five- or six-membered cyclic imide structure [5], and this degradative reaction most often occurs at a higher rate at the sequence Asn-Gly.

Oxidation. Oxidation is an important chemical degradation pathway for several proteins and can occur during all steps of its pharmaceutical development. The amino acids that are labile to oxidation are Met, His, Cys, Trp, Phe, Tyr, and Pro. Met has been identified as one of the most easily oxidized amino acids in proteins

TABLE 6.2-1.

Chemical Instability	Physical Instability
Hydrolysis	Denaturation
Deamidation (Gln and Asn)	Adsorption to surfaces
Oxidation (His, Met, Cys, Trp, and Tyr)	Aggregation
Proteolysis	Precipitation
Incorrect disulfide formation (Cysteine)	
Racemization	
Beta elimination	

[6, 7]. Free radicals generated by metal ion catalysis and photo or thermal degradation of buffer or other excipients can accelerate the oxidative degradation reactions.

Beta Elimination. The beta elimination can occur in amino acids that have beta side chains. The amino acids that are labile for beta elimination are Cys, Ser, Thr, Phe, and Lys [6]. The rate of this degradative reaction is influenced by pH, temperature, and presence of metal ions. The beta elimination of Cys leads to incorrect disulfide formation, as this reaction produces thiols [6].

Incorrect Disulfide Formation. This reaction occurs in neutral and alkaline pH conditions. Under such conditions, deamidation also occurs. The thiols (formed by beta elimination) can promote the disufide bond formation [8]. In an acidic environment, sulfenium ion promotes the incorrect disulfide bonds [9]. Proteins with scrambled disulfide bridges have been shown to yield native structure by incubating the protein with small amounts of mercaptoethanol or Cys.

Racemization. All amino acids except Gly are chiral and are subjected to base catalyzed racemization. This reaction leads to the formation of nonmetabolizable D-enantiomers and is often associated with loss of activity.

The chemical instability studies are often performed in simulated pharmaceutical stress conditions such as pH shifts or thermal stress conditions in the presence and in the absence of metal ions or buffer salts. The degradative products are analyzed by sequencing techniques such as mass spectrometry, HPLC techniques, and by employing specific enzymatic assays.

6.2.2.2 Physical Instability

Physical stability refers to changes in the higher-order structure (secondary and above) and is manifested as aggregation, precipitation, and surface adsorption [10]. Proteins, because of their complex structure and global fold, undergo physical instability [11]. In the global fold, the exposure of the hydrophobic groups is minimized, and this conformation is required for optimal biological activity of the protein. Denaturation is a molecular process that disrupts the global fold of the molecule.

Denaturation. Denaturation refers to an alteration in the global fold of the molecule (i.e, a disruption in tertiary and frequently secondary). The global fold of the molecule can be altered by environmental conditions that are encountered in pharmaceutical development of proteins, including changes in temperature, pH, pressure, and concentration of denaturing agents such as surfactants. This molecular process is generally associated with inactivation of the protein. Denaturation of the protein may also be followed by additional phenomena of physical degradation such as surface adsorption, aggregation, or precipitation.

Aggregation. The existence of I (folding intermediate) states in several proteins leads to the inactivation of the protein by aggregation. Moderate amounts of stress can generate I states, which retains secondary structure but tertiary structural

features such as intramolecular contacts are lost [12]. These intermediates associate to form large aggregates.

Precipitation. Precipitation is the macroscopic manifestation of aggregation. It has been observed that the formation of finely divided precipitate of insulin occurs on the walls of the container [13]. The precipitation of proteins is also observed during the manufacturing stages. Upon expression in recombinant systems, many proteins form aggregates called inclusion bodies [14].

Surface Adsorption. Adhesion of proteins to surfaces is a well-known phenomenon. The denatured or I states of the protein expose hydrophobic domains. This exposure promotes the binding of the protein to the walls of the container and other surfaces it comes in contact with. It has been well documented that insulin binds to surfaces of delivery pumps, to glass and plastic containers, and to the inside of the intravenous bags [15].

6.2.2.3 Formulation and Delivery Approaches to Overcome Instability

The risk of chemical instability can be assessed from the primary sequence of the protein. The sequence containing labile amino acids such as Asn-Gly and Met would be indicative of potential instability issues. The rate of chemical reactions that alter the primary sequence of the protein is higher in solution conditions and can limit the shelf-life of protein therapeutics. As the mobility of reactants is minimized in the solid state, freeze-drying is often attempted to improve the stability [16]. In such instances, physical instability is a major issue to be dealt with. Freeze-drying, also termed as lyophilization, is a dessication process in which the solvent (usually water) is first frozen and then is removed by sublimation in a vacuum [17]. In other words, the protein in solution is frozen, producing discrete ice and solute crystals. The solid ice is sublimed. Controlled heating desorbs any of the tightly bound water.

Three steps constitute the freeze-drying process [17].

- Freezing
- Primary drying (sublimation) to remove bulk, free water
- Secondary drying (desorption) to remove structured, more tightly bound water

To prevent denaturation/unfolding of the protein during the harsh freeze-drying process, excipients are added, including bulking agents, suitable buffers for pH and osmotic adjustment, cryoprotectants, protein structure stabilizers, and phase-state modifiers (glass transition temperature modifiers) [17, 18]. As a result of the potency of therapeutic proteins, a low concentration of the protein is commonly used, which may lead to loss of therapeutic ingredients during freeze-drying [17]. To prevent protein loss, bulking agents such as mannitol, glycine, lactose, and sucrose are added to increase the bulk mass. These bulking agents can also be used as cryoprotectants and to increase the collapse temperature, thereby improving product stability [18]. Cryoprotectants stabilize the proteins during the freezing and drying/storage process and improve the collapse temperature. The collapse temperature

is closely linked to product temperature, which in turn, determines the storage temperature [16]. It is generally desired to store the product at room temperature, or 4–8°C, and, thus, excipients combined with a bulking agent that increases the glass (product) temperature are desired. Many informative review articles on freeze-drying are available [16–18].

The screening of protein structure stabilizers for long-term stability is generally achieved by performing folding/unfolding studies in solution conditions. As a first step to perform solution studies, a reasonable quantity of the protein is required. As protein folding is a complex but interesting area of research, this section of formulation development involves basic research. It is essential that suitable analytical, spectroscopic, and thermal methods are developed to investigate the protein folding [19, 20]. In addition, solubility, buffer and pH conditions, and biochemical properties such as size, charge, and PI are determined. Acceptable buffers can be obtained from FDA guidelines and generally regarded as safe (GRAS) list. Commonly used buffers include phosphates, acetates and carbonates, lactates, ascorbates, and citrates. Addition of sodium chloride and other salts should also be investigated as these buffers and salts can increase the stability of a protein.

It is a common practice to employ thermal stress and pH changes to unfold the protein [21, 22], as these are often encountered during the pharmaceutical development of protein drugs. A pH range of 5 to 7 is desired for formulation development [23]. Temperature-dependent studies yield thermodynamic information such as Tm and ΔG and the stability of the protein. To determine the Tm and ΔG, a simple two-state model for unfolding is assumed [24, 25].

$$N \Leftrightarrow D$$

The equilibrium constant for the unfolding is given by

$$K = [D]/[N]$$

The Gibbs free energy changes can be deduced from the equilibrium constant using the formula $\Delta G = (G_D - G_N) = -RT\ln K$, where R is the gas constant and T is the absolute temperature. The Tm and ΔG are determined by spectroscopic methods [circular dichroism (CD), fluorescence, second derivative ultraviolet absorption spectroscopy] or by thermal methods (Differential Scanning Calorimetry, DSC) [20]. The aggregation of the protein is monitored using gel filtration, by light-scattering measurements, analytical ultracentrifugation, and field flow fractionation techniques.

The spectroscopic methods allow the estimation of [D] and [N] at any temperature. At the melting temperature Tm, the ΔG is zero and ΔS is equal to ΔH/Tm where [D] and [N] are equal. The measured free energy is typically 5–20 Kcal/mol. Thus, the unfolding of the protein decreases the stability. A strategy to screen for excipients involves compounds that increase the Tm and prevent aggregation and surface adsorption. The above rational strategy has been used to identity excipients for acidic fibroblast growth factor [21].

The existence of intermediate states complicates this simple approach. The reversible denaturation or unfolding step can be followed by the formation of irreversible inactivated forms of the protein (I). The inactivated forms are chemical

reaction (intermolecular disulfide bridges, intermolecular beta strands), aggregation, dissociation of oligomers to monomers, adsorption to surfaces, and incorrect refolding.

$$N \Leftrightarrow D \rightarrow I$$

K is the equilibrium constant that defines $N \Leftrightarrow D$ transition and thermodynamic stability. k is the rate constant for the irreversible transition from $D \rightarrow I$ and provides information regarding the long-term stability. Although the equation shows the inactivation after denaturation, the inactivation can proceed from the native state through the formation of intermediate states [26].

It has been observed for several proteins that the intermediate structures are formed as the protein unfolds from N state to D state [26]. As the protein unfolds, protein loses tertiary structure and, frequently, secondary structure. In some instances, the secondary structure remains intact while the tertiary structure is lost [12], which is clear from spectral studies that measure loss of secondary and tertiary structural changes. One spectroscopic technique that is sensitive to tertiary structure (e.g., fluorescence) would detect changes, whereas other techniques that are sensitive to secondary structures (e.g., far UV CD) do not show any spectral changes. This molecular property is defined as molten globule or structured intermediate [12]. These intermediates expose hydrophobic domains, and thus promote aggregation or surface adsorption.

The mechanisms of protein aggregation and stability are further complicated by the existence of aggregation-prone states in the unfolding of the protein that mimics the native state. Proteins subjected to thermal stress can aggregate from the fully unfolded state, but partially unfolded states have more frequently been implicated in aggregation processes; an example of the latter is the transition to molten globule states, in which proteins retain the majority of their secondary structural features while losing most of their tertiary structure. Such partially unfolded states have more exposed apolar regions and are more prone to aggregation than native or unfolded conformations. For proteins such as interferon gamma (IFN-γ) [27] and granulocyte colony stimulating factor (GCSF) [28], it has been clearly demonstrated that extensive unfolding or formation of molten globule states is not a prerequisite for aggregation and can occur even under solution conditions that are considered to be physiological. Rather, aggregation seems to occur from an expanded state that more resembles the native protein than substantially disrupted structures. In many such cases, the rate-limiting step is not the generation of extensively unfolded states. In the case of rhIFN-γ, aggregation has been shown to occur through the formation of a transiently expanded conformational species, whose surface area is greater than the native state by only 9% [27]. Similarly, native rhGCSF has been shown to aggregate through the formation of a monomeric transition state in which the surface area increase was only 15% [28]. The role of such small conformational fluctuations and their effect on long-term stability has received considerable attention recently.

The large therapeutic proteins, such as factor VIII, are often organized into distinct domains that play a critical role in their structure and function [29, 30]. The folding/unfolding behavior of these individual domains, and the interactions between them, may coordinate various functions in multidomain proteins.

Furthermore, the modular assembly of multidomain proteins often results in complex unfolding characteristics and the existence of intermediate species, which may lead to physical instability including a tendency to aggregate. In the case of rFVIII, neither complete unfolding of the protein nor the generation of partially unfolded states of the protein appears to be a prerequisite for the protein to aggregate. Rather, aggregation appears to involve subtle conformational changes in the C2 domain encompassing the lipid-binding region [31]. The excipients that bind to this domain have been developed as a formulation excipient that promotes the stability [31, 32].

Another complication that can impact the protein folding and stability is the irreversibility and "kinetic" aspects of protein folding. If kinetic components exist, they can interfere with the excipient screening process. It has been observed that the unfolding of rFVIII after thermal perturbation of the protein leads to irreversible aggregation [32, 33]. Based on thermal denaturation studies of multidomain proteins like phosphoglycerate kinase (PGK) and thermolysin, Sanchez-Ruiz et al. demonstrated that irreversible denaturation defies analysis by standard equilibrium methods and suggested that the unfolding may be a kinetically controlled process [34, 35]. It is a general practice to acquire the unfolding profile at different heating rates to determine the Tm. If Tm is found to be a function of the heating rate, it is important to develop excipients to minimize this kinetic contribution to protein instability. Such heating rate dependency on unfolding transitions has also been observed for other proteins including IFN-γ, Immunoglobulin G (IgG), and streptokinase [30, 36, 37].

In general, the heating rate dependence of protein thermal structural perturbations can be understood in terms of the Lumry–Eyring model [38], as shown below. According to this framework, a reversible unfolding step is followed by an irreversible event:

$$N \underset{k2}{\overset{k1}{\rightleftarrows}} U \xrightarrow{k3} A \qquad \text{(scheme 6.2-1)}$$

where A is the final (aggregated) state of the native protein N, irreversibly arrived at from the reversible altered form U. In this scheme, the first-order kinetic constants for each reaction j are represented by k_j, which varies with temperature according to the Arrhenius equation. If $k_3 >> k_2$, then all of U will be converted into A, and the process can be represented by the simpler kinetic scheme as discussed in detail by Sanchez-Ruiz et al. [34]:

$$N \xrightarrow{k} A \qquad \text{(scheme 6.2-2)}$$

This scheme represents the limiting case of the Lumry–Eyring model consisting of only two populated states, the native (N) and the final aggregated state (A). This scheme predicts that k is a first-order kinetic constant that varies with temperature, as given by the Arrhenius equation. Based on this simple kinetic model, T_m should vary with heating rate (ν) according to the equation:

$$\ln(\nu/T_m^2) = \ln(AR/E_a) - E_a/RT_m$$

where A is the frequency factor, E_a is the activation energy of the unfolding step, and R is the gas constant. Therefore, a linear plot of ln (ν/T_m^2) versus $1/T_m$ should

indicate a first-order reaction with slope of $-E_a/R$. The activation energy (E_a) for factor VIII was found to be ~535 KJ/Mole (~128 Kcal/Mole) and compares well with the E_a associated with the two transitions observed for the multidomain protein IgG [E_a for the two transitions were reported to be 456 KJ/mole (~109 Kcal/mole) and 692 KJ/mole (~165 Kcal/mole)] [30]. Thus, analysis of the data in terms of kinetic scheme 6.2-2 suggests that, under the experimental conditions used in this study, the rate-controlling step in the aggregation of rFVIII may be a unimolecular reaction involving protein conformational changes. Based on our antibody binding assays, we believe that the conformational changes involve at least the lipid-binding region, 2303–2332 of the C2 domain [31]. O-phospho-L-serine (OPLS) is known to bind to the lipid-binding region in the C2 domain [31]. The addition of ligand capable of binding to this region inhibited conformational changes and interfered with the aggregation process.

It is important to study the protein folding at different concentrations of the protein once the selection of excipients is narrowed [39], which is critical for scale up and for proteins such as monoclonal antibody products where higher doses are desired. The kinetic aspects of protein folding and concentration-dependent aggregation could potentially lead to instability. Overall, equilibrium unfolding is often used to screen excipients for the development of protein formulations. However, minor conformational changes that resemble the native state can lead to aggregation interfering with the equilibrium unfolding measurements. In addition, use of higher protein concentrations can accelerate the kinetically controlled aggregation process [39]. Thus, formulation development requires the characterization of minor conformational changes or aggregation prone states and their kinetics. Previous findings on the molecular details of the aggregation prone state of rFVIII and their kinetics [32] have contributed toward the rational design of a rFVIII-phosphoserine (PS) complex with improved physical characteristics [31].

6.2.3 IMMUNOLOGICAL PROPERTIES OF PROTEIN THERAPEUTICS

6.2.3.1 Immunogenicity of Proteins

Proteins and peptides are more immunogenic than conventional xenobiotics, and they are more prone to evoke immunotoxicity reactions (Table 6.2-2). The immunotoxicity is usually manifested in the form of a humoral immune response involving the formation of antibodies [40–42]. The antibodies can abrogate the efficacy of the administered protein by neutralizing its activity [41–43] or by altering its pharmacokinetics, thus complicating the dose-response relationships. The risk of generating an immune response is dictated by a host of product-specific factors such as product origin, molecular structure, impurities/degradation products, and formulation [44]. Proteins of animal or microbial origin can invariably be expected to elicit an immune response as they will be recognized as foreign proteins (neoantigen) triggering a classic immune response involving the B and T cells [45]. Human proteins, expressed in microbes such as *Escherichia Coli* can be immunotoxic because of lack of glycosylation [46], which can expose immunogenic neoepitopes with the possibility of epitope spreading leading to immune responses against conserved regions in the long term. Even proteins of human origin, when

TABLE 6.2-2.

Therapeutic Protein	Detected Incidence of Anti-product Antibody
OKT3	~80%
Remicade	10–57%
Roferon	20–50%
Proleukin (interleukin-2)	47–74%
Betaferon	44%
Advate	15–30%
Bone morphogenic protein-7	13–38%
Enbrel (TNF receptor / anti-TNF IgG)	16%
Thrombopoietin	≤10%
PEGylated-MGDF	0.5–1.6%

administered to humans, genetically deficient of the respective protein, will trigger a classic immune response as the patients are not immunotolerant to the protein. The above is illustrated by the observations in patients having severe forms (negligible endogenous protein production) of Fabry's disease [47], an X-linked deficiency of α-galactosidase A enzyme or Hemophilia A, where almost 30% of the patients develop antibodies upon therapy with the respective protein [48, 49]. Proteins used as therapeutic agents to supplement endogenous proteins (e.g., erythropoeitin, IL-2) have the potential of immunotoxicity because of the breaking of immune tolerance to self proteins. The breaking of immunotolerance to self proteins results more because of product-related factors (impurities, degradation products, and formulation excipients) [50] and dosing regimens employed for therapy [51].

A major challenge faced by a protein formulation scientist is the inability to predict or asses the risk of immunotoxicity of the final product. The prediction of immune response requires a comprehensive consideration of protein structure, putative genetic background of the patient population, the formulation excipients, as well as frequency and route of administration [44]. The ability to asses the potential of immunotoxicity of a protein therapeutic is mainly hampered by the lack of predictive *in vitro* or *in vivo* models. Animal models, widely used in preclinical drug testing, cannot predict immune responses in humans because of issues of immunotolerance and basic differences in the structure and function of the immune system that may not be readily translated across species. Mouse models have been the foundation for the majority of the work done toward understanding immune responses. However, when it comes to prediction of immunotoxicity of therapeutic proteins, significant discrepancies in adaptive and innate immunity preclude any extrapolation to humans. Nevertheless, animal models can still be used to conduct preclinical immunotoxicity studies, provided one appreciates all the caveats associated with use of such animal models. Evidence suggests that nonhuman primates and transgenic/knockout mice models may be useful for predicting the relative immunogenicity of protein therapeutics and assessing the risk of immunotoxicity [52, 53].

As mentioned above, several product-related factors can influence the immunogenicity of protein therapeutics. The impact of trace impurities and excipients used

in the formulation on the immunogenicity of the protein relative to the pure native protein should be evaluated in relevant animal models (nonhuman primates or transgenic/knockout mice) very early during the development cycle. Close attention should be paid to the impact of excipients and impurities on the structure of the protein. Structural changes can promote formation of neo-epitopes, which can initiate immune response in tolerant individuals followed by epitope spreading and thus resulting in immunotoxicity. The methods used to detect immune responses should be extremely sensitive to detect even small amounts of antibodies in the animal models, as even small amounts of inhibitory antibodies observed in animal models may indicate the potential for significant immunotoxicity in humans. Further, cellular basis for generation of the immune response should be thoroughly investigated in the animal models with the emphasis on mechanism. The above information can greatly enhance our ability to anticipate and devise strategies to prevent or minimize immunotoxicity issues in humans early on during the product development cycle. Aggregates are one of the major degradation products formed in protein therapeutics. Both chemical and physical degradation can give rise to the formation of aggregates. It is generally believed that the aggregates can enhance the immunogenicity of therapeutic protein preparations [44]. Although the presence of aggregates in protein preparations can influence its immunotoxicity, the generalization of the above statement may not be appropriate. Several studies with aggregates of various proteins have shown that aggregates do not always enhance the development of antibodies [54]. Aggregation can be associated with structural changes of the protein. The mechanism (physical or chemical) causing the aggregation of the protein dictates the structural features of the aggregated protein. These structural changes can significantly alter the epitope repertoire of the aggregated protein relative to the monomeric protein, thereby altering its properties as an immunogen [55]. Additionally, the altered structure can also change the processing of the immunogen by the endosomal proteases in the antigen-presenting cells, which is essential for presentation by the major histocompatibility complex [55]. Hence, to understand the risk of immunotoxicity associated with the administration of aggregates, one needs to have the explicit understanding of the correlation between structure and immunogenicity. Aggregates that retain the structure of the native protein are more likely to cause immunotoxicity. However, aggregates that do not retain the structure of the protein should not be considered safe as the exact immunotoxicological consequences are not known and should be investigated.

Individuals having a genetic predisposition for generating an immune response against a therapeutic agent are unlikely to benefit from the prior knowledge generated during the preclinical immunotoxicity testing. However, methods and techniques identifying their genetic predisposition will greatly benefit this subset of patients as alternatives can be explored early or before initiating therapy. *In vitro* systems using dendritic cells and B-cells isolated from patients need to be developed and hold promise as an individualized immunotoxicity screening method before initiating therapy.

6.2.3.2 Formulation and Delivery Considerations to Reduce Immunogenicity

Although the mechanism is not clear, immunodominant epitopes in the protein sequence and aggregates or impurities in the protein product can facilitate the

immunogenicity of the protein. Immunodominant epitopes (linear or conformational) are subunits of the protein that are most easily recognized by the immune system and can evoke a specific immune response [56, 57]. Proteins having these immunodominant epitopes when administered in humans do run the risk of breaking tolerance. Additionally, in humans who are intolerant to a given protein, the immunodominant epitopes are most likely to evoke the immune response. A strategy used to reduce immunogenicity of a protein is to identify the immunodominant regions in the protein and replace them with innocuous sequences while retaining the original structure and function of the protein. An example of the above approach is the development of hybrid porcine/human FVIII molecule in which the immunodominant regions in the human molecule were replaced with less immunogenic regions of the porcine FVIII [58]. The above strategy has the potential for development of protein molecules that are less immunogenic by virtue of their design.

Another strategy used frequently to reduce immunogenicity of protein molecules by tampering with its basic chemistry is the use of "pegnology." The term signifies the science of attaching polyethylene glycol polymer chains to specific residues in the protein molecule, thereby influencing its properties of immunogenicity and circulation half-lives of the parent protein molecule. The mechanism by which the pegylation of the protein molecule can reduce immunogenicity is the shielding of specific immunodominant epitopes. The shielding phenomenon prevents the recognition of specific epitopes by B-cells, thereby preventing initiation of an immune response. Adagen (pegylated form of adenosine deaminase) and Oncaspar (Pegylated asparaginase) are examples of pegylated proteins currently in clinical use where immunogenicity has been reduced relative to the parent protein by pegylation. Another desirable property of pegylation is that it usually reduces the clearance of the protein molecule, which serves a dual purpose as it increases the circulation half-life of the protein molecule, thereby reducing the frequency of administration. Hence, the overall affect of pegylation is an improved therapeutic protein.

6.2.4 PHARMACOKINETICS AND PHARMACODYNAMICS

It is generally accepted that the successful development of new therapeutic entities is strictly dependent on their pharmacokinetic/pharmacodynamic properties. The classic PK concepts can be successfully applied to large molecules, leading to optimization of the dosing regimen to achieve the desired pharmacological effect. However, the pharmacokinetic scientists usually encounter challenging difficulties in interpreting the concentration-time profiles for the protein drugs, partly because of the limitations of the detection systems in terms of lower accuracy and precision of the bioassays. Moreover, the presence of endogenous proteins in some instances and the low bioavailability and the rapid elimination from the systemic circulation in others will further decrease the ability to determine the true levels of therapeutic proteins. The recent advances in immunoassays and mass spectrometry analysis improved our ability for quantification. However, caution should be taken when analyzing data from immuno-/radio-labeled assays or LC/MS, because of the inability of those methods to discern between active and inactive protein molecules (native state vs. proteolytic fragments/denaturated states). Extensive review arti-

cles on the subject of validation of bioanalytical methods are available in the literature [59].

6.2.4.1 Formulation and Delivery Approaches to Overcome PK Issues

The lack of protein stability within the gastrointestinal tract leads [60] to the administration of therapeutic biomolecules through the parenteral routes. Among those, the i.v. route grants complete bioavailability, a rapid distribution within the blood with achievement of high drug concentrations [61]. On the other hand, the s.c. and i.m. administration of therapeutics protein is very appealing based on the possibility of an increase in residence time because of slow absorption from the injection site [44]. Hence, efforts are being made to develop new strategies for alternative parenteral routes. The extent of absorption from the interstitial space varies from case to case and is dependent on the extent of proteolytic degradation at the injection site. In many instances, the proteolytic degradation is a saturable process and an increase in the therapeutic dose usually translates to increased bioavailability [62]. However, a higher dose might break the tolerance level and lead to undesired immunological properties, as discussed in the previous section. Hence, to exploit the advantages offered by parenteral routes other than i.v., a need exists to design improved, novel methodology or delivery vehicles that would limit the proteolytic degradation and prevent the rapid elimination from the systemic circulation.

PEGylation. Poly (ethylene glycol) (PEG) is a nontoxic, highly soluble polymer [63] that can be linked to a protein via several chemical modifications. This approach includes attaching PEG to ε-amino (lysine), thiol (cysteine), and hydroxyl (tyrosine, serine) groups or carbohydrate moieties (glycoproteins) as well as at the N- or the C-terminal of peptides and proteins [64]. The foundation of this technology resides in the steric hindrance factor induced by the bulky covalently attached polymer. For instance, the covalent linkage of PEG to protein surfaces leads to shielding of putative immunodominant epitopes that will directly affect the antibody recognition process [65]. Apart from the improved immunological properties, the shielding factor exerted by the PEG alters the accessibility of proteolytic enzymes [66]. It is also responsible for a decrease in receptor-mediated endocyotsis with a subsequent decrease in clearance. In addition, the net increase in hydrodynamic radius (two or three water molecules—tightly bound per ethylene glycol monomer) will lead to a decrease in renal clearance, further improving the pharmacokinetic properties of the therapeutic proteins and peptides [67].

The prolonged circulation time, in turn, reduces the frequency of administration that can further reduce the adverse immune response and can maximize the pharmacological effects [44].

PEGylation of asparaginase (Oncaspar) resulted in greater than 96% reduction in the incidence of detectable immunogenicity [68]. In a phase III study involving 2000 patients, a native interferon induced antibodies in 14.5% of recipients in contrast to only 1.5% of patients receiving PEGlyated derivative. In addition, the renal filtering was reduced by ~100-fold for PEG-interferon relative to the unpegylated one. Thus, PEGylation seems to be a promising strategy for reducing immunogenecity and for reducing the frequency of dosing.

Historically, the first generation of PEG derivatives targeted the labile, solvent-accessible amino groups present either at the N-terminal or on the side chain of positively charged amino acid residues [68]. Lysine is one of the amino acids commonly found on protein surfaces. Hence, it was relatively easy to covalently couple PEG or other molecules at this position. However, the high occurrence of lysine in proteins was also responsible for a high degree of heterogeneity in the first generation of PEGylated proteins. Therefore, both Oncaspar [68] and Adagen [69] (PEG adenosine deamidase) suffered from this design flaw. However, the use of different PEGylated isomers received FDA approval as long as data was provided to support batch-to-batch reproducibility.

The second generation of PEG derivatives were merely designed to overcome the heterogeneity concerns present in the first generation of PEGylated proteins. To accomplish PEGylation at specific positions, the novel PEG reagents took advantage of the subtle differences in the pKa of α and ε amino groups present on the side chains of amino acid residues [70]. Another successful approach was to target the thiol group of cysteine residues that are rarely occurring on proteins surfaces and, hence, should lead to a more homogeneous population of PEG derivatives [71].

However, despite those advances in PEG technology, several issues still plague the formation of PEGylated derivatives. The PEGylation approaches are limited by substantial loss of specific activity of the protein, leading to inconsistent therapeutic effects. It is worthwhile to mention that new strategies are being developed to address the loss of biological activity and function. In this line, Peleg-Shulman et al. [72] adopted a reversible PEGylation approach in the case of interferon $\alpha 2$, in which the PEG derivative undergoes limited hydrolysis under physiological conditions. The advantage of the reversible PEG-interferon lies in the fact that the released interferon can penetrate the tissue effortlessly and therefore exert its biological function. On the other hand, the PEG derivative retains its PEGylation advantages in terms of PK parameters such as the long circulation half-life.

To maintain the protein bioactivity, other valuable technologies incorporate a blocking step of the active site before PEGylation through the use of ligands/enzyme inhibitors. Those inhibitors can be free in solution or bound to a solid phase, facilitating the subsequent removal procedure of free PEG.

Altogether, the PEGylation approaches presented herein have been successful to small proteins that, overall, have a limited number of active sites on the surface. Such approaches might not be applicable to all proteins, particularly for the larger ones. It is too early to speculate whether those limitations might be responsible for the low anti-PEG antibody response evoked following administration in humans of PEG-uricase [73].

Lipid Structures as Drug Delivery Vehicles. Liposomes and lipid-based nanoparticles can act as a sustained release system for protein drugs. The formulation of Interferon Gamma in negatively charged liposomes [74] increases the residence time of the protein by approximately 19 times upon s.c. administration. Further, liposomal formulation of factor VIII improves physical stability, reduces immunogenicity, and prolongs the circulation time of factor VIII (unpublished results). Liposomes can be PEGylated to further extend their blood circulation time. Compared with classic liposomes, PEGylated vesicles show increased half-

life, decreased plasma clearance [75], and a shift in distribution in favor of diseased tissues. PEG is incorporated into the lipid bilayer of the liposome, forming a hydrated shell that protects it from destruction by proteins. Pegylated liposomes are also less extensively taken up by the reticuloendothelial system [76] and are less likely to leak drug while in circulation. This approach of PEGylation avoids the covalent modification of the protein and the complication developing from these modifications.

In addition, liposomes can act as protein stabilizers that reduce the protease degradation and improve the physical stability (unpublished data, [62]). The aggregation promoted by the existence of intermediate states is a common problem. As these intermediate structures expose hydrophobic domains, the addition of liposomes at critical stages of the protein unfolding stabilize the protein against aggregation and help to refold the protein to native conformation. This property is referred to as chaperones, and the use of chaperones as a formulation excipient has not received considerable attention. Another mechanism, lipidic particles, can stabilize the protein by competing with the aggregation kinetics. For example, protein inactivation after the unfolding step is controlled by a kinetic process. Lipidic particles can interfere with this aggregation step. We have shown in our laboratory that the aggregation of factor VIII is kinetically controlled and undergoes irreversible denaturation [32]. However, in the presence of lipidic particles, the recovery of factor VIII upon refolding is much higher compared to free factor VIII.

PLGA Microspheres. Polymers such as PLGA microspheres have been used as delivery vehicles for peptides. In this delivery system, the peptide is embedded in a polymer matrix [77]. Two biodegradable polymeric systems are currently approved by FDA for use, Lupron [78] and Zoladex [79]. Several peptide drugs have been formulated in the biodegradable polymers. These PLGA polymers have been shown to release the peptide over the period of 1 to 3 months, which alleviates the pain caused by daily injections and improves the patient's compliance [78]. The monomers lactic and glycolic connected by ester bonds undergo ester hydrolysis that releases the peptide [77]. The peptide encapsulation is performed in methylene chloride. Such harsh conditions denature protein molecules but are acceptable for peptides. The microsphere encapsulation provides sustained release of IL-12 at the tumor site and avoids systemic toxicity associated with the administration of IL-12 [80]. However, there is substantial loss of activity.

6.3.1 INTRODUCTION

Recombinant DNA technology produced many protein drugs in large scale and many important protein drugs like erythropoietin (EPO) for anemia-associated diseases, granulocyte-colony stimulating factor (G-CSF) for leucopoenia, and insulin for diabetes are now clinically available [1–3]. In addition, peptide hormones like leuprolide [an agonist of luteinizing hormone-releasing hormone (LHRH)] are also clinically used. However, these peptide/protein drugs are unstable because of hydrolytic degradation in the body [4]. Peptide/protein drugs also have a barrier for their administration because of low absorption efficiency. Therefore, their is parenteral preparation, *main dosage form* in which case intravenous (i.v.) or subcutaneous (s.c.) injection is used. After i.v. injection of these drugs, the administered drug molecules are completely available to the systemic circulation (i.e., bioavailability (BA) is 100%). On the other hand, BA becomes lower when these drugs are injected s.c. or i.m. In some protein drugs like interferon gamma, BAs after s.c. and i.m. injection are greater than 100% (i.e., 200% and 300%, respectively [5–7]. Furthermore, it is recognized that protein drugs whose mole-

cular weight is larger than about 20 kDa are absorbed into the systemic circulation via lymphatic route. As a result, a large T_{max} value is obtained, when peak serum or plasma drug level appears after administration; for example, T_{max} is approximately 8 h for s.c.-injected EPO. After the serum drug level reached its maximum level, C_{max}, serum drug concentration decreases. In the case of organic compound drugs, the elimination process is composed of hepatic metabolism and renal excretion pathways. However, for peptide/protein drugs, we must consider the hydrolytic degradation process because of poor tolerability of these drugs to endogenous hydrolytic enzymes. Therefore, the elimination half-life of peptide/protein drugs is generally shorter than that of organic compound drugs. To increase the stability of peptide/protein drugs, several approaches have been performed and second-generation peptide/protein drugs have been developed and launched on the market [4], including PEGylated protein drugs (i.e., pegylation) and attachment of polyethylene glycol (PEG) to protein molecules. In the case of PEG-EPO, the administration frequency has decreased to once per week as compared with three times per week for the conventional EPO preparations; although almost the same serum EPO levels are obtained in the two types of EPO preparations. Most of the current peptide/protein drugs are injectable, and there is great commercial potential for delivery systems that use alternative administration routes like the pulmonary route and the nasal route, as suggested from insulin new dosage forms. In these cases, the pharmacokinetic profile of the peptide/protein drugs shows a completely different pattern as compared with that obtained after i.v. injection.

In this section, the pharmacokinetics of clinically important peptide/protein drugs, such as insulin, EPO, G-CSF, interferon, growth hormone, leuprolide, desmopressin, and antibodies, are described in relation to their administration routes and formulations (i.e., dosage forms).

6.3.2 INSULIN

6.3.2.1 Background

The finding of insulin in 1922 by Ranting and Best is one of the greatest discoveries in the history of medicine [8], and now it has been already proven that adequate control of blood glucose delays or prevents the progression of diabetic complications. To achieve the suggested targets for glycemic control necessary to reduce the incidence of diabetic complications, it has been established that a more intensive insulin regimen requiring multiple insulin injections is required for patients with type 1 diabetes mellitus. From a patient's point of view, however, noninvasive insulin delivery systems have been required for a long time. Indeed, a major limitation for advancing to intensive insulin therapy is that the only viable way to administer insulin is through injection. Several other methods of insulin delivery are now available or in development, including: continuous subcutaneous insulin infusion by a wearable infusion pump; total or segmented transplantation of a pancreas; transplantation of isolated islet cells; implantation of a programmable insulin pump; oral, nasal, rectal, and transdermal mechanisms of insulin delivery; insulin analogs; implantation of polymeric capsules that give continuous or time-pulsed release of insulin; and implantation of a biohybrid artificial pancreas, which uses

encapsulated islets [9]. Many of these methods of insulin delivery are aimed at achieving a more physiological means of delivery of the insulin, at improving glycemic control, and, hopefully, at minimizing the secondary complications of diabetes.

On the other hand, during the nearly 80 years of insulin therapy, insulin preparations have undergone dramatic changes in their purification, production, and formulation. Despite these changes, and despite the development of different injection regimens and delivery systems, normalizing glycemic control still has not been adequately achieved. Recently, specific amino acid substitutions of the β-chain of the insulin molecule by recombinant DNA techniques have resulted in insulin analogs that have different pharmacokinetic properties than currently available insulins [10]. Some of these insulin analogs appear to have less variation in absorption than conventional insulins [11], and analogs have been developed with both very rapid [12] and delayed absorption [11]. Those analogs with a very rapid absorption may be useful in better mimicking the physiological insulin profiles seen postprandially than currently available native insulins [11]. All of these advances have been accomplished through protein engineering to produce insulin analogs with a decreased tendency for self-association (monomeric insulin), which in turn increases the subcutaneous absorption of these insulins [13]. These monomeric insulin analogs have been found to have a faster onset of action and are better able to reduce postprandial glucose excursions than conventional human insulin preparations, which subcutaneously become hexamers and slow absorption [14]. These insulin analogs, especially the monomeric types, appear to be less immunogenic and antigenic [13] where the pharmacokinetic aspects of human insulin and an analog insulin of aspart and lispro are described. In addition, other delivery options for insulin besides subcutaneous administration, such as transdermal and nasal approaches, are described.

6.3.2.2 Pharmacokinetics of Human Insulin after Intravenous Administration

In the 1970s, pork insulin had been widely used for the treatment of diabetics. In the 1980s, biosynthetic and recombinant DNA technology came to be introduced. In 1981, Halban et al. [15] compared the biologic potency of pancreatic human insulin with that of biosynthetic human insulin, which was manufactured by recombinant DNA techniques in bacteria, after intravenous injection in rats. The metabolic clearance rates of A14-mono-^{125}I-insulin (pork) were found to be similar to those observed for semi-synthetic [^{3}H]insulin (pork), being 20.8 ± 0.8 mL/min/kg and 23.6 ± 1.0 mL/min/kg, respectively. On the other hand, the metabolic clearance rates for A14-mono-^{125}I-biosynthetic human insulin was 24.6 ± 2.2 mL/min/kg, which was significantly higher than the value for A14-mono-^{125}I-pork insulin. In addition, the specific activity of the pancreatic human insulin was 32 U/mg, whereas that for biosynthetic human insulin was 27 U/mg. These values were not significantly different but were higher than the value for pancreatic pork insulin (25 U/mg). Biosynthetic human insulin is thus no less active than pork insulin in rats, and possibly somewhat more active. Moreover, in 1987, Brogden and Heel [16] reviewed that human insulin, whether produced by recombinant DNA techniques (biosynthetic, insulin crb) or enzymatic modification of porcine insulin (semi-synthetic, insulin emp) is equivalent in biological activity to porcine insulin after intravenous administration. There were no differences in the pharmacokinetic profiles among

them. However, slight differences between human and porcine insulin in hypoglycemic activity after subcutaneous injection appear to be related to differences in absorption and are unlikely to be of major clinical importance.

Turnheim and Waldhausl [17] characterized pharmacokinetic aspects of recombinant human insurin in human. After intravenous injection, the plasma concentration of insulin declines with at least two exponentials. Inslin distributes rapidly from the intravascular space to tissue compartments with a distribution half-life of 2.4 min, whereas insulin disappears slowly with an elimination half-life of 50–130 min, which is reflecting the elimination from the interstitial fluid and the tissues that use insulin. Total body clearance of insulin, which is the result of metabolic degradation, ranges between 700 and 800 mL/min. The sites of degradation are primarily the liver (hepatic insulin clearance: 320–400 mL/min) and the kidneys (renal insulin clearance: 190–270 mL/min); hence, insulin disposal depends on the function of these organs. The apparent volume of distribution for insulin is approximately equal to the extracellular space. Insulin kinetics appears not to be altered in diabetes mellitus, except in cases with insulin antibodies or in insulin-resistant patients, in which insulin removal may be retarded.

6.3.2.3 Pharmacokinetics of Human Insulin after Subcutaneous Administration

There is a continuing search for improved insulin formulations to imitate the physiological pattern of insulin secretion as closely as possible, and thereby to minimize the complications of diabetes mellitus. The major advances achieved to date are in the area of human insulin analog synthesis resulting from the introduction of recombinant DNA techniques and in improved delivery systems that use noninvasive or minimally invasive modes of administration. Usually, insulin is administered subcutaneously to control blood sugar levels in type 1 and type 2 diabetics. There are plenty of insulin pharmaceutics, and insulin's physico-chemical differences provide different profiles in the insulin pharmacokinetics after subcutaneous injection. Kang et al. [18], investigated absorption mechanisms of insulins with different physico-chemical properties after subcutaneous administration in humans. Based on a single-blind randomized comparison study of seven healthy male volunteers 22–43 years of age, equimolar dosages of ^{125}I-labeled forms of soluble hexameric 2 Zn^{2+} human insulin and human insulin analogs with differing association states at pharmaceutical concentrations (AspB10, dimeric; AspB28, mixture of monomers and dimers; AspB9, GluB27, monomeric) were administred. The initial fractional disappearance rates for the four insulin preparations were 20.7 ± 1.9 (hexameric soluble human insulin), 44.4 ± 2.5 (dimeric analog AspB10), 50.6 ± 3.9 (analog AspB28), and 67.4 ± 7.4%/h (monomeric analog AspB9, GluB27). The absorption of the dimeric analog was significantly faster than that of hexameric human insulin, and the absorption of monomeric insulin analog AspB9, GluB27 was significantly faster than that of dimeric analog AspB10. There was a negative linear correlation between association state and the initial fractional disappearance rates ($r = -0.98$, $p < 0.02$). A log-linear scale analysis for the elimination of insulin showed that only the monomeric analog had a monoexponential elimination. On the other hand, two phases in the rates of absorption were identified for the dimer and three for hexameric human insulin. The fractional disappearance rates calculated by log-linear

regression analysis were monomer 73.3 ± 6.8%/h; dimer 44.4 ± 2.5%/h from 0 to 2 h and 68.9 ± 3.5%/h from 2.5 h onward; and hexameric insulin 20.7 ± 1.9%/h from 0 to 2 h, 45.6 ± 5.0%/h from 2.5 to 5 h, and 70.6 ± 6.3%/h from 5 h onward. The author concluded that the lag phase and the subsequent increasing rate of subcutaneous soluble insulin absorption can be explained by the associated state of native insulin in pharmaceutical formulation and its progressive dissociation into smaller units during the absorption process.

6.3.2.4 Pharmacokinetics of Rapid-acting Insulin Analog after Subcutaneous Administration

By the end of the 1980s, to accommodate postprandial hyperglycemia, monomeric insulin formulations, insulin lispro (the Lys-Pro analog) and insulin aspart (the Asp-Pro analog) had been developed for clinical use [19, 20] (Figure 6.3-1).

Formulations including insulin lispro have a rapid rate of absorption after subcutaneous injection and, therefore, have to be administered at meal time. Their residence time is also about two fold shorter than regular human insulin, minimizing the risk of the excessive hypoglycemic effect that characterizes regular human insulin formulations. Becker et al. compared the pharmacokinetics and pharmacodynamics of insulin lispro with regular human insulin after subcutaneous injection in obese subjects in a single-dose, randomized, double-blind, cross-over euglycemic clamp study [21]. Insulin lispro had more rapid-acting profiles than regular human insulin. Fractional glucose infusion rate (GIR)-area under the curve (AUC) of the GIR curve and maximum GIR were greater for insulin lispro compared with regular human insulin. Time to 20% (early glucose disposal) and 80% (bulk of activity) of total GIR-AUC were shorter for insulin lispro than regular human

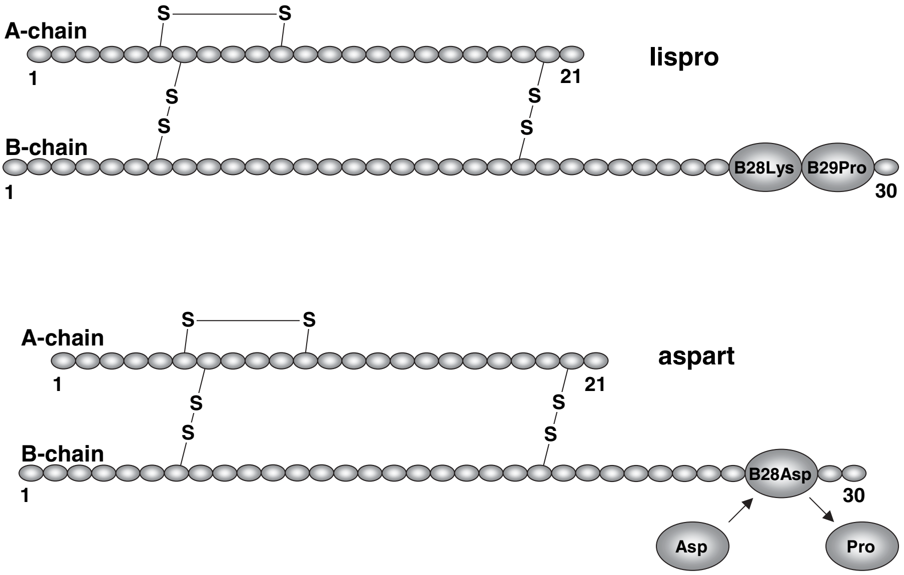

Figure 6.3-1. Schematic presentation of primary structure of human insulin lispro and aspart.

insulin, which was corroborated by more rapid and shorter residing pharmacokinetic profiles of insulin lispro than regular human insulin, evidenced by shorter times to 20% of total AUC of insulin, C_{max} of insulin, and mean residence time. On the other hand, Osterberg et al. compared the pharmacokinetics and pharmacodynamics of insulin aspart with regular human insulin in healthy subjects in a cross-over trial. There were statistically significant differences between most of the human insulin and insulin aspart pharmacokinetic parameters, including the sigmoidicity of the time-course of absorption (1.5 for human insulin vs. 2.1 for insulin aspart), elimination rate constant (0.010 min^{-1} vs. 0.016 min^{-1}, respectively). In addition, the pharmacodynamic model parameters were mostly not different, except for the rate of insulin action (0.012 min^{-1} vs. 0.017 min^{-1}, respectively) [20]. Moreover, Homko et al. compared insulin levels and actions in patients with type 1 diabetes after subcutaneous injection of insulin analogs, aspart and lispro [22]. Both insulin analogs produced similar serum insulin levels (250–300 pmol/l) at approximately 30 min and disappeared from serum after approximately 4 h. Insulin aspart and lispro had similar effects on glucose and fat metabolism. Effects on carbohydrate metabolism (glucose uptake, glucose oxidation, and endogenous glucose production) peaked after approximately 2–3 h and disappeared after approximately 5–6 h. Effects on lipid metabolism (plasma free fatty acid, ketone body levels, and free fatty acid oxidation) appeared to peak earlier (at approximately 2 h) and disappeared earlier (after approximately 4 h) than the effects on carbohydrate metabolism. The author concluded that both insulin aspart and lispro are indistinguishable from each other with respect to blood levels and that they are equally effective in correcting abnormalities in carbohydrate and fat metabolism in patients with type 1 diabetes.

6.3.2.5 Other Formulations of Human Insulin

Inhaled Insulin. Subcutaneous insulin has been used to treat diabetes since the 1920s; however, despite a number of different formulations, intensive insulin therapy with multiple daily injections has not gained widespread clinical acceptance. Great efforts have been made in searching for noninvasive administration modes of insulin that will avoid the need for parenteral administration of subcutaneous injection. Attempts to find effective, well-tolerated, nonenteral routes for delivering insulin began in the 1920s, and, over the years, have included ocular [23], buccal [24], rectal [25], vaginal [26], oral [27], nasal [28] and uterine [29] delivery systems, where various enhancers or formulations have been tested to increase the bioavailability of insulin from each route. Until recently, it was believed that insulin delivered noninvasively was associated with a bioavailability that was too low to offer a realistic clinical approach. However, progress in the pharmaceutical approach of insulin suggests that inhaled insulin is an effective, well-tolerated, noninvasive alternative to subcutaneous regular insulin.

Oral inhalation of insulin potentially offers noninvasive treatment and better glycemic control in diabetes by virtue of its apparently faster absorption into the systemic circulation compared with subcutaneous injection. However, the pharmacokinetics of inhaled insulin in the human lung has yet to be fully clarified because of the complexity of insulin-glucose physiology and the difficulty in approximating the inhaled dose. In 2004, Sakagami conducted a meta-analysis of

insulin pharmacokinetics in the lung after oral inhalation of insulin in humans [30], where, based on the data from well-controlled clinical studies of inhaled insulin published in the literature, a physiologically realistic insulin-glucose kinetic model was derived. The model defined the first-order absorption ($k_{a,L}$) and parallel non-absorptive loss ($k_{mm,L}$), the latter primarily occurring via metabolism and mucociliary clearance in the lung with two systemic compartments. The significant estimate for $k_{a,L}$ was found to be from 0.020 to 0.032 h^{-1}, effectively unchanged across doses (from 0.3 to 1.8 IU/kg), formulations (powder vs. liquid), and subjects (healthy vs. diabetic), suggesting passive diffusive absorption of insulin from the lung. In contrast, the values for $k_{mm,L}$ were much larger (from 0.5 to 1.6 h^{-1}) and decreased with increasing inhaled dose. From this perspective, the author considered that a dose-dependent saturable lung metabolism regulates the value of $k_{mm,L}$, alongside mucociliary clearance. As a result, the absolute bioavailability of insulin through the oral inhalation ranged from 1.5% to 4.8%.

Henry et al. [31] evaluated the AERx insulin Diabetes Management System (AERx iDMS) to the deep lung for systemic absorption, which was an aerosol of liquid human insulin produced by Aradigm (Hayward, CA). This study examined the effects on pulmonary function, pharmacokinetics, and pharmacodynamics of inhaled insulin in asthmatic and nonasthmatic subjects without diabetes, where a total of 28 healthy and 17 asthmatic subjects were enrolled in a two-part, open-label trial. The area under the time versus concentration curve (AUC) of insulin after inhalation showed significantly greater value for healthy subjects than for asthmatic subjects, whereas no difference was observed for maximum concentration in the two groups. In addition, a greater reduction of serum glucose level was observed in healthy subjects. Moreover, asthmatic subjects had greater intra-individual variations in insulin AUC, maximum concentration values, and glucose levels than healthy subjects. In this report, the author concluded that, after inhaling insulin using the AERx iDMS, asthmatic subjects absorbed less insulin than healthy subjects, resulting in less reduction of serum glucose.

The rationale behind developing a pulmonary drug delivery system is to ensure that insulin powder is delivered deep into the lungs, where it is easily absorbed into the bloodstream, in a handheld inhalation device. More recently, Nektar Therapeutics (formerly Inhale Therapeutic Systems) has developed a pulmonary drug delivery system for insulin [32]. This device converts the insulin powder particles into an aerosol cloud for the patient to inhale. The inhaler requires no power source, and the clear chamber ensures that the patient knows immediately when all the insulin has been inhaled. In addition, Nektar Therapeutics is using its Advanced PEGylation technology to develop a dry powder-inhaled polyethylene glycol (PEG) formulation for delivering peptides efficiently across the lungs and to promote prolonged serum concentration of the peptide. PEGylation is designed to increase the size of the active molecule and ultimately improve drug performance by optimizing pharmacokinetics, increasing bioavailability, and decreasing immunogenicity and dosing frequency. The investigation has begun with inhaled, long-acting (PEGylated) insulin, and is funded by Pfizer.

Intranasal Insulin. Insulin administered nasally has considerable potential for the treatment of both type 1 and type 2 diabetes. Using enhancers or novel delivery systems such as adequate bioadhesive microspheres, it is believed that the low bioavailability of simple formulations of insulin can be greatly improved [33].

Therefore, several efforts on developing the nasal delivery system of insulin with nontoxic and nonirritant properties have been done.

In 1992, Drejer et al. [31] investigated the pharmacokinetics of intranasal insulin containing a medium-chain phospholipid (didecanoyl-L-alpha-phosphatidylcholine) as absorption enhancer in 11 normal volunteers. Intranasal insulin was absorbed in a dose-dependent manner with a mean plasma insulin peak 23 ± 7 min after administration. Mean plasma glucose nadir was seen after 44 ± 6 min, 20 min after intravenous injection. Moreover, intranasal administration of insulin resulted in a faster time-course of absorption than subcutaneous injection, and the bioavailability for the nasal formulation was 8.3% relative to an intravenous bolus injection when plasma insulin was corrected for endogenous insulin production estimated by C-peptide.

On the other hand, there are negative opinions on the nasal delivery of insulin. In 1995, Hilsted et al. evaluated metabolic control and safety parameters (hypoglycemia frequency and nasal mucosa physiology) in 31 insulin-dependent diabetic patients treated with intranasal insulin in an open, cross-over randomized trial [35]. Serum insulin concentrations increased more rapidly and decreased more quickly during intranasal as compared with subcutaneous insulin administration. Metabolic control deteriorated, as assessed by hemoglobin A1c concentrations, slightly but significantly after intranasal as compared with subcutaneous insulin therapy. The bioavailability of intranasally applied insulin was low; therefore, intranasal insulin doses were approximately 20 times higher than subcutaneous doses. The frequency of hypoglycemia was similar during intranasal and subcutaneous insulin therapy, and nasal mucosa physiology was unaffected after intranasal insulin. The author concluded that because of low bioavailability and a high rate of therapeutic failure, intranasal insulin treatment was not a realistic alternative to subcutaneous insulin injections.

In the early twenty-first century, nanoparticles based on nanotechnology have altered the direction of investigation in the drug delivery system. Nanoparticles, an evolvement of nanotechnology, are increasingly considered as a potential candidate to carry therapeutic agents safely into a targeted compartment in an organ, particularly a tissue or a cell [36]. In 2002, Dyer et al. investigated effects of chitosan-formulated nanoparticles on the insulin pharmacokinetics and pharmacodynamics as a nasal drug delivery system [37]. The nasal absorption of insulin after administration in chitosan nanoparticle formulations and in chitosan solution and powder formulations was evaluated in rats and in conscious sheep. Insulin-chitosan nanoparticle formulations produced a pharmacological response in the two animal models, although in both cases the response in terms of lowering the blood glucose levels was less than that of the nasal insulin-chitosan solution formulation. The insulin-chitosan solution formulation was found to be significantly more effective than the complex and nanoparticle formulations. The authors concluded that chitosan nanoparticles did not improve the nasal absorption.

6.3.3 ERYTHROPOIETIN

6.3.3.1 Background

Erythropoietin (EPO), a glycoprotein hormone with a molecular mass of 30 KDa, is mainly synthesized by the kidney in response to hypoxia. Serum EPO

concentrations in humans normally range from 6 to 32 U/L [38]. The plasma half-life of EPO is reported to range from 2 to 13 hours, with a volume of distribution close to plasma volume. As expected for a large sialoglycoprotein, less than 10% of EPO is excreted in the urine [39]. EPO is known to stimulate the proliferation and differentiation of erythrocytic progenitors in the bone marrow, leading to reticulocytosis and increased erythrocyte numbers in the blood [38].

Recombinant human EPO (rHuEPO) has proven beneficial for treating renal anemia as well as anemia of other chronic disorders, including autoimmune diseases, malignancies, and AIDS. Evidence from clinical trials indicates that anemia associated with cancer chemotherapy generally responds well to a standard rHuEPO regimen of 150 IU/kg subcutaneous (s.c.) three times per week [40, 41]. Several dosage recommendations have been made for surgery patients depending on the type of surgery and practicality of an autologous blood donation program. In patients scheduled for major orthopedic surgery, three weekly 600 IU/kg s.c. doses of rHuEPO, with the last one on the day of the surgery, have been suggested [42]. Goldberg et al. present here pharmacokinetic/pharmacodynamic (PK/PD) modeling from four comparable, placebo-controlled, parallel-group studies in healthy subjects who were administered single rHuEPO doses of 300 to 2400 IU/kg as well as multiple doses of 600 IU/kg/wk and 150 IU/kg/tiw for 4 weeks.

Clinical trials of recombinant product began in Seatle and London in 1986, and its efficacy was established at an early stage [43–46]. The early studies confirmed that intravenously administered EPO was highly effective in correcting the anemia of end-stage renal failure in hemodialysis. The intravenous route was, however, clearly impractical for patients maintained on continuous ambulatory peritoneal dialysis (CAPD) who had no ready vascular access, which necessitated an examination of the intraperitoneal and subcutaneous routes of administration, and several pharmacokinetic studies have compared these in CAPD patients [47, 48]. These three routes of erythropoietin administration are the only ones to have been investigated either from a pharmacokinetic or a therapeutic point of view. Although Storring et al. [49] and Charles et al. [50] compared the two forms of rHuEPO (i.e., EPO-alpha and EPO-beta), they reported that the volume of distribution after intravenous EPO-beta compared with EPO-alpha and that delayed subcutaneous absorption of EPO-beta compared with EPO-alpha. They believed the pharmacokinetic differences were caused by their glycosylation.

6.3.3.2 Pharmacokinetics of Erythropoietin in Healthy Subjects

Intravenous administration in the dialysis center has been practical and effective for patients undergoing hemodialysis [51, 52], but impractical for patients without vascular access who are receiving peritoneal dialysis. Studies of subcutaneous administration showed lower but more sustained peak plasma EPO concentrations (C_{max}) than occurred using the intravenous route. The efficacy of subcutaneous administration supports the concept of a sustained minimal effective EPO concentration. High C_{max} values after intravenous administration appear unnecessary; the dose response relationship seen with intravenous administration most likely correlates with serum EPO concentrations maintained above a minimal effective level.

Flaharty et al. presented data on the pharmacokinetics of EPO in healthy normal subjects [53]. To assess phamacokinetics to human recombinant erythropoietin

(EPO-beta), single intravenous doses (10, 50, 150, and 500 IU/kg) were administered at monthly intervals to 16 healthy subjects in a two-panel, placebo-controlled, double-blind ascending-dose trial. A 1000-IU/kg dose was subsequently administered in an open manner. EPO concentrations were detemined in serum by radioimmunoassay. Mean EPO apparent half-lives ranged fiom 4.42 to 11.02 hours. The apparent volume of distribution was between 40 and 90 mL/kg, consistent with plasma water, and the apparent clearance values ranged from 4 to 15 mL/kg/hr, with both parameters having the highest values at the 10-IU/kg dose level. Clearance tended to decrease as a function of dose. The use of EPO in healthy individuals will have clinical relevance if EPO is found to be effective for use in autologous transfusion programs. Although EPO was well tolerated in this study, clinical trials in patients with end-stage renal disease have shown adverse effects, including hypertension, seizures, and thrombocytosis, related to the increase in erythropoiesis. These effects are not expected in normal subjects, but careful monitoring should be performed if EPO is used in repeated doses in healthy subjects.

Salmonson et al. [54] also described the pharmacokinetics of rHuEPO after intravenous and subcutaneous administration of 50 U/kg to six healthy male volunteers. The calculated mean values for volume of distribution at steady state and clearance after an i.v. dose were 76 ± 33 mL/kg and 12.0 ± 3.0 mL/h/kg, respectively. Serum concentrations of rHuEPO peaked at 13.0 ± 6.0 h after the s.c. dose and the bioavailability over 72 h was 36 ± 23%. The mean residence time and half-life of rHuEPO were 6.2 ± 1.0 and 4.5 ± 0.9 h after i.v. and 46 ± 18 and 25 ± 12 h after s.c. administration. They found that the serum concentration time profiles after i.v. adminisitaration followed a mono- or bi-exponential decline, and the elimination after s.c. dose was described by a mono-exponential decline.

McMahon et al. [55] reported a double-blind, placebo-controlled study of the pharmacokinetics and safety of multiple doses of rHuEPO 150 or 300 U/kg, either by i.v. bolus or s.c. in normal male subjects, which demonstrated that rHuEPO had a dose-related effect on the hematocrit independent of the route of administration, and that multiple doses of rHuEPO had no direct pressor effects. When rHuEPO was injected by i.v. route, a mono-exponential decrease in serum EPO level was observed for 18 to 24 hours postdose. Absorption of s.c.-injected rHuEPO occurred more slowly with relatively low serum EPO levels being maintained for 48 hours. As a result of the prolonged elevation in serum EPO concentrations with s.c. injection, with injections every 48 hours, s.c. resulted in higher preinjection serum EPO concentrations than with i.v. injection of the same dose.

Moreover, Ramakrishnan et al. [56] described the pharmacokinetic and pharmacodynamic modeling of rHuEPO after single and multiple doses in healthy volunteers. A one-compartment model with limited distribution and nonlinear elimination characterizes the data from the i.v. dosing. Most of the rHuEPO after s.c. dosing was rapidly absorbed within 2 to 3 days by zero-order rate constant. A dual-absorption model (fast zero-order and slow first-order inputs) with nonlinear disposition characterized the pharmacokinetics of s.c. rHuEPO. A similar pharmacokinetic model describes the time-course of plasma concentrations of rHuEPO on monkeys [57]. On the other hand, Cheung et al. [58] demonstrated the pharmacokinetics of rHuEPO after single s.c. doses of 300, 450, 600, 900, 1200, 1350, 1800, and 2400 IU/kg and in multiple s.c. dose regimens: 150 IU/kg three times a week for four weeks and 600 IU/kg once per week for four weeks in open-label,

randomized placebo-controlled studies in healthy volunteers. The absorption rate of rHuEPO after s.c. administration was independent of dose, whereas clearance was dose-dependent, in which it decreased with increasing dose. In an advanced investigation, Cheung et al. [59] further described the comparison of the pharmacokinetics administered s.c. once weekly (qw), 150 IU/kg, and three times weekly (tiw), 40,000 IU. The C_{max} values for serum rHuEPO qw were six times and AUC values three times that of the tiw regimen. Subsequent study reported by Krzyzanski et al. [60] showed that a phamacokinetic and pharmacodynamic (PK/PD) model for rHuEPO in healthy subjects was developed to describe the time profiles of changes in serum rHuEPO and the pharmacological responses of percent reticulocytes, total red blood cell counts, and hemoglobin after single and multiple subcutaneous administration of rHuEPO. Data used is the same data as Wing Cheung et al. [59]. A dual-absorption model (fast zero-order and slow first-order inputs) with linear disposition kinetics was used to characterize the pharmacokinetics of erythropoietin after subcutaneous administration. Flip-flop kinetics was apparent in the pharmacokinetics as the absorption rate was slower ($ka = 0.7\ day^{-1}$) than the elimination rate ($CL/Vd = 1.2 - 9.2\ day^{-1}$).

6.3.3.3 Pharmacokinetics of Erythropoietin in Patients

rHuEPO is established as an effective therapeutic agent for anemia in patients undergoing long-term hemodialysis. After an intravenous dose of EPO 24 to 240 U/kg, serum clearance was 0.66 ± 0.42 L/h; terminal elimination half-life was 6 to 9 h and did not change after repeated doses given for more than two months [61]. In hemodialysis patients, the pharmacokinetics of rHuEPO was studied by Brockmöller et al. [62]. They investigated in 12 patients under chronic hemodialysis on a thrice weekly intravenous rHuEPO treatment. The pharmacokinetics of rHuEPO was also assessed after a subcutaneous injection during the initial period and during maintenance treatment. After the first i.v. dose, plasma EPO concentrations were best described by a mono-exponential disposition function with a mean (±s.d.) elimination half-life of 5.4 ± 1.7 h. The volume of distribution was 70 ± 5.2 mL/kg, and the clearance was administered intravenously as 10.1 ± 3.5 mL/h/kg. After three months of continuous therapy, the plasma half-life of rHuEPO decreased by 15% (mean half-life during steady state: 4.6 ± 2.8 h), while mean clearance and volume of distribution remained constant. On the other hand, the absorption of rHuEPO after s.c. injection was prolonged and flip-flop kinetics applied. The extent of systemic availability of the s.c. dose ranged from 28% to 100% (mean 44%).

Gladziwa et al. [63] described the pharmacokinetics of rHuEPO after long-term therapy in patients undergoing hemodialysis and hemofiltration. In 17 patients with end-stage renal disease (ESRD), studies were performed in three groups to assess pharmacokinetics during the intertreatment interval and during hemofiltration and dialysis treatment. After an intravenous bolus injection of EPO 150 U/kg, the half-life was 7.7 h, steady-state volume of distribution was 0.066 L/kg, and total plasma clearance was 5.4 mL/min. The mean steady-state serum concentration during multiple-dose administration was 656 U/L. The drug was not eliminated by hemofiltration or dialysis. Therefore, long-term treatment of ESRD patients with EPO does not significantly alter the pharmacokinetic profile of the drug. EPO dosage adjustment or substitution after hemofiltration and dialysis is not necessary. On the

other hand, peritoneal dialysis (PD) has gained recognition worldwide as an alternative to hemodialysis in the management of patients with end-stage renal disease. The most common is continuous ambulatory peritoneal dialysis (CAPD) in which most patients perform four to five exchanges daily. As the peritoneal catheter provides direct access to the peritoneum, intraperitoneal drug administration has become widely used for the administration of certain drugs. The instillation and drainage of PD fluids contribute to the total body clearance of drugs, in which peritoneal clearance is low. Taylor III et al. [67] reported the pharmacokinetic studies after rHuEPO administration to patients receiving PD. Intraperitoneal (i.p.) drug administration, via a PD catheter, produces a concentration gradient between the peritoneal and vascular compartments, favoring drug absorption. Absorption is enhanced if the plasma concentration of drug is low relative to the concentration of drug in the peritoneal fluid. Lymphatics draining the diaphragm contribute to the absorption of albumin and dextrans from the peritoneum and may be important in the absorption of protein drugs or other large-molecular-weight compounds like rHuEPO. The pharmacokinetic parameters observed in patients undergoing CAPD following i.v. and s.c. administration are similar to those determined for hemodialysis patients [65, 66]. s.c. adminisitration was found efficacious in several studies of PD patients [67–71], and allows reduction of the dose of EPO to 50–60% of the i.v. dose. i.p. administration is convenient and circumvents any pain associated with s.c. administration. In several studies, EPO was administered i.p. 1 L to 2 L of dialysate and allowed to dwell for varying time periods [72–75]. Low absorption of EPO from the peritoneal cavity is seen if dialysate is present. Hematological response similar to those observed with either s.c. or i.v. administration were seen following i.p. administration using this technique, but substantially higher doses were required [76–78]. Other investigators have reported poor efficacy, although this may result partly from the low doses administered [79, 80]. Based on these observations, the i.p. administration of EPO in large volumes of dialysate appears prohibitively costly to achieve the desired results. An improved bioavailability was observed in humans after administration of undiluted EPO 400 U/kg followed by an 8-hour dry dwell [81]. A greater than nine fold increase in bioavailability was observed with dry administration, compared with diluting the dose in 2-L dialysate followed by an 8-hour dwell. The dry-dose administration area under the concentration-time curve (AUC) approached that seen with s.c. dosing. Ateshkadi et al. [82] administered EPO 100 U/kg IP to eight patients undergoing CAPD using a 4-hour dry dwell followed by an infusion of 2-L dialysate that was allowed to dwell for 6 hours. The i.p. EPO serum-concentration time profiles were similar to those observed with s.c. administration, with a mean bioavailability of 11.4% compared with 22.8% for s.c. administration. Ongoing studies are examining the pharmacokinetics and efficacy of administration using an 8-hour dry dwell. Single-dose pharmacokinetics of EPO were studied in pediatric dialysis patients [83, 84]. EPO appears to be better absorbed and more rapidly cleared in children than it is in adults. Differences in the volume of distribution of EPO have also been noted between children and adults. These differences may be result of methodological differences between studies or true physiological differences relating to the plasma volume or tissue distribution of the drug. A recent study of i.p. administration in five children on continuous cycling peritoneal dialysis (CCPD) suggests that this route is safe and efficacious [85].

6.3.3.4 Erythropoietin Formulation

Humoral factors and cytokines are glycosylated with variable numbers of carbohydrate chains, each of which has variable carbohydrate structures. Although the biological function is typically determined by the protein component, carbohydrate can play a role in molecular stability, solubility, *in vivo* activity, serum half-life, and immunogenicity. The sialic component of carbohydrate, in particular, can extend the serum half-life of protein therapeutics. One aspect of glycoengineering is to introduce N-linked glycosylation consensus sequences into desirable positions in the peptide backbone to generate proteins with increased sialic acid-containing carbohydrate, thereby increasing *in vivo* activity because of a longer serum half-life [86].

DarbEPO alfa (DA) is a hyperglycosylated analog of recombinant human erythropoietin (rHuEPO) generated by glycoengineering. This rHuEPO is used to treat the anemia associated with chronic kidney disease and cancer. The discovery that the sialic acid-containing carbohydrate content of rHuEPO was directly proportional to the serum half-life and *in vivo* bioactivity [87] led to the hypothesis that additional carbohydrate on rHuEPO might further enhance *in vivo* activity. DA contains two additional N-linked glycosylation sites and has increased *in vivo* activity and prolonged duration of action because serum half-life is increased three fold above rHuEPO [88, 89], which allows for less frequent dosing with subsequent increased convenience for the patient and caregiver and improved patient compliance.

Allon et al. [90] investigated the pharmacokinetics of darbEPO alfa and rHuEPO after repeated intravenous dosing in patients with chronic kidney disease receiving hemodialysis. Overall, 47 patients were randomized to receive darbEPO alfa administered once weekly or three times weekly or EPO administered three times weekly for up to 52 weeks. Pharmacokinetic profiles were measured during weeks 1 and 12. The terminal half-life of darbepoietin alfa was 17.8 hours, which was approximately two to three times longer than that of EPO (6.3 hours). The clearance of darbepoietin alfa (2.00 mL/h/kg) was approximately four times slower than those of EPO (8.58 mL/h/kg). They conclude that darbepoietin alfa can be administeredless frequently than EPO in patients with chronic kidney disease receiving hemodaialysis.

Lerner et al. [91] also studied the pharmacokinetics of darbepoietin alfa in pedisatric patients with chronic kidney disease (CKD). Twelve patients 3–16 years of age with CKD were randomized and received a single 0.5 μg/kg dose of darbepoietin alfa administered i.v. or s.c. After a 14- to 16- day washout period, patients received an identical dose of darbepoietin alfa by the alternate route. After i.v. administration, the mean clearance of darbepoietin alfa was 2.3 mL/h/kg with a mean terminal half-life of 22.1 h. After s.c. administration, absorption was rate limiting, with a mean terminal half-life of 42.8 h and a mean bioavailability of 54%. Comparison of these results with those from a previous study of darbepoietin alfa in adult patients [89] indicated that the disposition of darbepoietin alfa administered i.v. or s.c. is similar in adult and pediatric patients, although absorption may be slightly more rapid in pediatric patients after s.c. dosing.

6.3.4 GRANULOCYTE-COLONY STIMULATING FACTOR (G-CSF)

6.3.4.1 Background

Colony stimulating factors (CSFs) as well as hematopoietic growth factors are a group of glycoproteins regulating the survival, proliferation, and differentiation of hematopoietic progenitor cells as well as the function and activation of the mature cells. The CSFs are produced by a variety of cells and range in molecular mass from 14 to 90 kDa. Recently, these factors have been purified, cloned, and produced through recombinant DNA techniques. The recombinant factors have been shown to have biologic properties and actions that are similar to the naturally occurring factors. The availability of quantities of the recombinant factors has resulted in their introduction into clinical trials and into the market.

The pharmacokinetics of CSFs has been evaluated widely in animals and in man. Early studies, however, used impure or poorly characterized fractions and the interpretation of these results is difficult. With the availability of recombinant proteins, these limitations were overcome and definitive studies have been completed. In general, the biologic effects of these factors can be quantitated by measuring the effects on the target hematopoietic cell population, which has provided a basis for relating the pharmacokinetic profile of the factor to the pharmacodynamic response. As clinical trials and the therapeutic applications of these factors are expanded, the knowledge and understanding of the pharmacokinetics of the drug will be critical to guide the clinician in the choice of dosing routes and schedule.

The generation of granulocytes from immature hematopoietic progenitor cells depends on the presence of several hormone-like glycoproteins. CSFs are acidic glycoproteins required for the survival, proliferation, and differentiation of hematopoietic progenitor cells [92–95]. Granulocyte-colony stimulating factor (G-CSF) was identified because it induced differentiation in a murine myelomonocytic leukemic cell line and stimulated granulocyte colony formation by normal progenitor cells [96]. The hematopoietic actions of this regulator are restricted exclusively to cells of neutrophilic granulocyte lineage [97–99]. Murine and human G-CSFs have been purified from various sources [96–98] and the genes encoding human and murine G-CSF have been isolated [100–102]. This factor supports the growth and proliferation of relatively late granulocyte progenitor cells already committed to the neutrophil lineage and enhances the function and activation of mature neutrophils [103, 104]. This factor has also been cloned and expressed in both bacterial cells and mammalian cells [104, 105].

Characterization of the gene encoding G-CSF has led to the production of this protein by recombinant DNA techniques. The recombinant form of human G-CSF, rhG-CSF, is also capable of supporting the formation of granulocytic colonies from committed precursor cells. The availability of large quantities of molecularly homogeneous and biologically active human G-CSF by recombinant DNA technology has made it possible to explore the use of human G-CSF as a therapeutic agent. rhG-CSF shows broad species cross-reactivity with respect to its characteristic biologic response, a rapid and dose-dependent neutrophilia. The potential clinical applications for rhG-CSF include myelorestoration after bone marrow

transplantation, mitigating chemotherapy-induced neutropenia, boosting host defense against infections, and augmenting effecter cell purpose [106].

6.3.4.2 Pharmacokinetics of G-CSF in Animals

Cohen et al. [107] also reported biexponential clearance of *E. coli*-derived rhG-CSF administrated intravenously to hamsters; the α and β serum half-lives were 0.5 and 3.8 hr, respectively (all data were normalized to the amount recovered at 5 min after injection). Tanaka and Kaneo [108] reported the pharmacokinetics of rhG-CSF (KRN8601) in male Sprague-Dawley rats at a dose of 5 μg/kg as a preclinical investigation. The serum concentrations of rhG-CSF were monitored using a specific sandwich enzyme immunoassay. For i.v. administration, the serum concentration-time curve showed a rapid disappearance of rhG-CSF from the systemic blood with a mean residence time (MRT) of 1.34 hr. For s.c., i.m., and i.p. administration, lower peak serum levels were observed; but after 2 to 3 hr, rhG-CSF levels were higher than those for i.v. administration with the MRTs of 3.92, 2.90, and 3.54 hr, respectively. Moreover, Tanaka et al. [109, 110] examined the influence of dose level and route of administration on the pharmacokinetics of *E. coli*-derived G-CSF after i.v. administration to Sprague-Dawley rats at doses of 10 or 100 μg/kg. Biexponential plasma clearance was noted after an i.v. dose of 100 μg/kg; the half-lives at distribution phase (α) and elimination phase (β) were 25 and 102 min, respectively. In addition, the total body clearance of rhG-CSF in the rat after i.v. administration showed an approximate 30% decrease from 80 to 56 mL/h/kg as the dose was increased from 1 to 10 μg/kg; no further decreases in the total body clearance were noted up to 100 μg/kg. However, the volume of distribution calculated was equivalent at each dose. For the serum concentration profiles of rhG-CSF after extravascular administration, an i.m. injection gave slightly faster absorption kinetics of rhG-CSF from the injection site into systemic blood than did s.c. and i.p. injections [108]. After s.c. administration, biological effects were noted at 2 h and were sustained for 36 h, suggesting rapid absorption. Peak serum concentrations were seen at approximately 2–3 h postdose. The calculated bioavailability of the subcutaneous dose was approximately 78%. There were nonproportional increases in the AUC value; a 100-fold increase in the dose resulted in a 164-fold increase in the AUC. Bioavailability after subcutaneous dosing ranged from approximately 50% to 70%. The results of this study suggested that two mechanisms may be involved in the clearance of G-CSF. One pathway is saturated at low concentrations and represents high-affinity, low-capacity receptor-mediated uptake by target cells (neutrophils). The other mechanism represents clearance by nonspecific pathways such as renal excretion.

In multiple-dose studies, rhG-CSF was injected into animals by i.v. and s.c. at 5 μg/kg/day for 7 days [108]. When the serum concentration-time profiles on day 7 after multiple dosing of rhG-CSF were compared with single dosing, the AUC after i.v. multiple dosing decreased by 17.4%. However, the half-lives and the volume of distribution were not significantly different between single and multiple dosing groups. In addition, the AUC after s.c. multiple dosing decreased by 25.6% without significant differences in the bioavailability and observed maximum serum concentration of rhG-CSF. These results showed that the clearance of rhG-CSF increased after multiple dosing, although the mechanism of increased clearance was not apparent.

Moreover, Tanaka et al. reported the effect of sex differences and hepatic or renal failure on the pharmacokinetics of rhG-CSF in the rats. After i.v. and s.c. administration of rhG-CSF to male and female Sprague-Dawley rats at a dose of 5 and 100 μg/kg, area under the concentration versus time curve and elimination half-lives of rhG-CSF in female rats were smaller than those for male rats. The volume of distribution of rhG-CSF in female rats was not significantly different from that in male rats. After s.c. administration, the values of AUC, MRT, and half-lives of elimination phase in female rats were smaller than those for male rats. In the *in vitro* biological activities of rhG-CSF using [^{3}H]thymidine uptake assay in cultures of bone marrow cells obtained from male and female rat femur, female rat bone marrow cells showed a similar dose-response profile to rhG-CSF to that of male rat bone marrow cells. The effect of rhG-CSF administration in rats was a specific activity on the neutrophil lineage with an increase of neutrophils in peripheral blood. On the other hand, the *in vivo* effects of rhG-CSF after i.v. and s.c. adrninistration to male and female rats at 5 and 100 μg/kg doses, namely the neutrophil count in female rats, was similar to that in male rats in the early period; however, the neutrophil count in female rats was lower than that in male rats 24 h after administration. These results indicate the sex differences in pharmacokinetics and the *in vivo* effects of rhG-CSF as well as the close relationship between pharmacokinetics and the *in vivo* effects of rhG-CSF [111]. In rats with experimental renal and hepatic failure, the total body clearance of rhG-CSF after i.v. administration at a dose of 10 μg/kg was 44.48 mL/h/kg in sham-operated rats compared with 9.429 mL/h/kg in bilaterally nephrectomized rats. In sham-operated rats, the elimination half-life of rhG-CSF at β phase was 1.51 h, and it increased to 5.33 h after nephrectomy. In contrast, the volumes of distribution were identical in both rats. In rats with acute renal failure induced by uranyl nitrate, the total body clearance and volume of distribution were identical to those of control rats, but the elimination half-life at β phase was slightly shorter. In 70% hepatectomized rats, the clearance of rhG-CSF decreased from 42.08 mL/h/kg to 31.93 mL/h/kg, and similar half-lives were observed in rats in both the sham-operated and hepatectomized groups. However, the volume of distribution decreased after hepatectomy. In rats with hepatic failure induced by CCl_4, the pharmacokinetic changes were similar to those observed in hepatectomized rats. These results suggest that renal clearance makes a major contribution to total body clearance compared with hepatic clearance [112].

6.3.4.3 Pharmacokinetics of G-CSF in Humans

In the early period, the pharmacokinetics of *E. coli*-derived rhG-CSF as part of phase I and II clinical trial was evaluated by Layton et al. [113]. The protein was administered by i.v. or s.c. routes at dose levels of 3 to 30 μg/kg. The elimination half-life after i.v. dosing was 1.4 h at a dose of 1 μg/kg, and increased to 4.2 h at a dose of 60 μg/kg. These results indicated saturation mechanisms in the total body clearance at doses greater than 10 μg/kg. When a continuous s.c. infusion was performed for 5 days, steady state was not achieved and there was a rapid reduction in serum G-CSF levels during the last 2 days of administration. Neutrophil levels increased during this period, and these results were interpreted as neutrophil receptor-mediated regulation of G-CSF uptake and degradation. The peak levels

of G-CSF after initiation of s.c. dosing were achieved at 6h, and these levels were maintained for up to 16h. When high doses of melphalan were coadministered with G-CSF, the neutrophil levels did not increase and serum G-CSF levels remained constant.

For the pharmacokinetics of rhG-CSF in humans, it has been reported that the absorption and clearance of rhG-CSF follow first-order kinetics without any apparent concentration dependence [114]. When rhG-CSF was administered by 24-h constant i.v. infusion at a dose level of 20μg/kg, the mean serum concentration achieved 48ng/mL. Constant i.v. infusion for 11 to 20 days produced steady-state serum concentrations over the infusion period. Subcutaneous administration of rhG-CSF at doses of 3.45 and 11.5μg/kg resulted in peak serum concentrations of 4 and 49ng/mL, respectively. The mean value of volume of distribution was 150mL/kg. The elimination half-life was 3.5h after either i.v. routes or s.c. routes, with a clearance rate of 0.5–0.7mL/min/kg. The administration of a daily dose for 14 consecutive days did not affect the half-life.

More recently, Hayashi et al. reported the results of pharmacokinetic and pharmacodynamic (PK/PD) analysis for rhG-CSF (lenograstim) after s.c. administration [115]. A total of 72 adult healthy volunteers were administered 1μg/kg of rhG-CSF. There was no correlation between the maximal plasma concentration (C_{max}) and an increase in peripheral neutrophil count, whereas a negative correlation between AUC and this increase was observed. It is considered that the mechanism of this phenomenon is probably based on the correlation between the elimination rate constant (ke) and neutrophil increase, because the ke probably has a close relationship with uptake by neutrophil and its progenitor the G-CSF receptor. Indeed, a volunteer with higher ke showed a greater increase in neutrophil count. Therefore, AUC is proportional to the rhG-CSF remainder, that is, the proportion that is not consumed in the course of increasing the neutrophil count. From this perspective, the bioavailability calculated from the AUC is unlikely to indicate the absorbed amount. A two-compartment pharmocokinetic model with zero-order absorption and first-order elimination provided a good curve fit, suggesting that the absorption process is not a first-order process but is a zero-order process.

As the clearance of rhG-CSF is known to decrease with a rise in dose and is known to be saturable, the average clearance after i.v. administration will be lower than that after s.c. administration. Therefore, the apparent absolute bioavailability with subcutaneous administration calculated from the AUC ratio is expected to be a conservative estimate. In a second study by Hayashi et al., the estimation of rhG-CSF absorption kinetics after s.c. administration with a nonlinear elimination pharmacokinetic model using a modified Wagner–Nelson method was studied [116], and the results of the bioequivalency study between two rhG-CSF formulations with a dose of 2μg/kg were described. The apparent absolute bioavailability for s.c. administration was 56.9% and 67.5% for each formulation, and the ratio between them was approximately 120%. The true absolute bioavailability was, however, estimated to be 89.8% and 96.9%, respectively, and the ratio was approximately 108%. The absorption pattern was applied to other doses, and the values of predicted clearance for s.c. and i.v. administrations were then similar to the values for several doses reported in the literature. Using this pharmacokinetic model, the underestimation of bioavailability was around 30%, and the amplification of difference was 2.5 times, from 8% to 20%, because of the

nonlinear pharmacokinetics. The neutrophil increases for each formulation were identical, despite the different bioavailabilities. Therefore, it is considered that there is an upper limit to the transfer rate of rhG-CSF from subcutaneous tissue to blood, and that the amount eliminated through the saturable process, which indicates the amount consumed by the G-CSF receptor, was identical for each formulation.

Wang et al. also reported the PK/PD relationship of the granulopoietic effects of r-metHuG-CSF (filgrastim) in healthy volunteers through a population pharmacokinetic approach [117]. Healthy male volunteers were enrolled into a four-way crossover clinical trial. Subjects received four single doses of r-metHuG-CSF (375 and 750 μg for i.v. and s.c., respectively) with an intervening washout period of 7 days, and an absolute neutrophil count (ANC) was determined. Data analysis was performed using mixed-effects modeling as implemented in the NONMEM software package. The final PK/PD model incorporates a two-compartment PK model with bisegmental absorption from the s.c. site, first-order and saturable elimination pathways, and an indirect PD model. A sigmoidal E_{max} model for the stimulation of ANC input rate (k_{in}) was superior to the conventional E_{max} model (E_{max} = 12.7 ± 1.7; EC_{50} = 4.72 ± 0.72 ng/mL; Hill = 1.34 ± 0.19). In addition, a time-variant scaling factor for ANC observations was introduced to account for the early transient depression of ANC after r-metHuG-CSF administration. The absolute bioavailability after s.c. administration of r-metHuG-CSF was estimated to be 0.619 ± 0.058 and 0.717 ± 0.028 for 375 μg and 750 μg s.c. doses, respectively. The time profiles of concentration and ANC, as well as the concentration approximate ANC relationship of r-metHuG-CSF in healthy volunteers, were well described by the developed population PK/PD model.

On the other hand, Hernandez-Bernal et al. evaluated the equivalence of the pharmacokinetic, pharmacodynamic, and safety properties of two commercially available recombinant G-CSF formulations [Hebervital (Heber Biotec, Havana, formulation A) and Neupogen (Hofman-La Roche S.A, formulation B)] in 24 healthy male volunteers using a standard two-way randomized crossover double-blind study, with a 3-week washout period [118]. A single 300-μg G-CSF dose was administered subcutaneously. Absolute neutrophils (ANC), white blood cells (WBC), and $CD3^{4+}$ cell counts were the pharmacodynamic variables measured up to 120 h. Other clinical and laboratory determinations were used as safety criteria. The pharmacokinetic parameters for formulation A and B were very close to each other (i.e., AUC, 235.9 vs. 270.0 ngh/mL; C_{max}, 29.2 vs. 33.4 ng/mL; T_{max}, 4.2 vs. 4.7 h; half-life, 3.2 vs. 2.8 h; CL, 260.9 vs. 277.2 mL/h; Vd, 1.2 vs. 1.1 L; and MRT, 7.58 vs. 7.38 h). The pharmacodynamics showed high similarity because ANC and WBC had the same profiles for both products and no differences were detected for the estimated parameters. The $CD3^{4+}$ cell count increments were evident for both formulations in a similar way as well. According to the overall results, these formulations could be considered as clinically comparable.

6.3.4.4 G-CSF Formulation

Generally, peptide/protein drugs undergo extensive hydrolysis in the gastrointestinal tract and have short circulating half-lives in the blood. For optimal clinical efficacy, therefore, they must be given by daily injections. Recently, it has been

found that attaching a polyethylene glycol (PEG) moiety (PEGylation) improves the pharmacokinetic and pharmacodynamic profiles of peptide/protein drugs [119]. Conjugating peptide/protein drugs with PEG, a process known as pegylation, is now an established method for increasing the circulating half-life of protein and liposomal pharmaceuticals. PEGs are nontoxic water-soluble polymers that, owing to their large hydrodynamic volume, create a shield around the pegylated drug, thus protecting it from renal clearance, enzymatic degradation, and recognition by cells of the immune system [120].

For the formulation of G-CSF, PEGylated filgrastim (pegfilgrastim) has a longer half-life than unmodified filgrastim and, when administered as a single dose, has been shown to be at least as efficacious as daily filgrastim. As a result of its reduced renal clearance, the elimination of pegfilgrastim is predominantly neutrophil-mediated, so its clearance is self-regulated. In addition, pegfilgrastim can be administered at a fixed dose instead of in weight-based doses. For these reasons, pegfilgrastim can potentially increase patient adherence and acceptance of treatment, thus having a beneficial effect on their quality of life. Furthermore, treatment is likely to cost less because of the reduced need for medical interventions. Similarly, pegylated liposomal doxorubicin has a longer half-life than unmodified doxorubicin and has been shown, because of its reduced reticuloendothelial system clearance, to produce higher concentrations of doxorubicin in tumors and to have greater clinical efficacy than doxorubicin in the treatment of some solid tumors. Pegylated liposomal doxorubicin is also associated with less myelosuppression and febrile neutropenia.

For the pegylated formulation for subcutaneous route, van Der Auwera et al. produced a pegylated G-CSF formulation, Ro25-8315, which is produced by conjugation of rhG-CSF mutant with PEG [121], where the pharmacodynamics and pharmacokinetics of Ro25-8315 was evaluated in comparison with rhG-CSF (filgrastim). Subjects received single subcutaneous doses of Ro25-8315 ranging from 10 to 150 μg under a double-blind, randomized, placebo-controlled design. Filgrastim was administered as a single dose (5 or 10 μg/kg) and, following a 14-day washout period, daily for 7 days. Ro25-8315 increased absolute neutrophil count (ANC) by six- to eight-fold and $CD3^{4+}$ cell count more than 30-fold at the highest doses tested. Single doses (60–150 μg) of Ro25-8315 and multiple doses of filgrastim had similar effects on ANC and $CD34^{+}$. The phamacokinetic profile of Ro25-8315 was dose-dependent, with peak concentrations and the AUC increasing 100-fold over the range of doses studied. Time to reach peak concentration (T_{max}) and half-life of Ro25-8315 averaged 20–30 h at all doses, approximately three times longer than with filgrastim. Adverse events were not serious and occurred with similar frequency with both products. Pegylation of rhG-CSF mutant results in more desirable pharmacokinetic properties and a longer duration of action with effective increases in ANC and measures of peripheral blood progenitor cell mobilization for at least 1 week.

More recently, Maeda et al. developed a new sustained-release formulation of rhG-CSF [122]. The formulation is a double-layer minipellet (DL-MP) that is designed to maintain a sustained release of rhG-CSF without an initial burst. The DL-MP is composed of a core of collagen matrix and a coating layer with collagen. This formulation of rhG-CSF was then prepared, and its characteristics were determined, in normal rats. After subcutaneous administration, it was found that blood rhG-CSF concentration was maintained for about 1 week. Moreover, after admin-

istration of the DL-MP rhG-CSF formulation with additional condroitin sulfate, a persistent increase in white cell count was found. Therefore, the DL-MP formulation system was useful as a long-acting formulation of rhG-CSF characterized by excellent long-acting properties without an initial burst.

In general, an oral route is most popular form of administration; however, peptide/protein drugs without some pharmaceutical modifications should not be applicable because of poor absorption based mainly on extensive hydrolysis in the gastrointestinal tract. Taking this background into consideration, Eiamtrakarn et al. designed a new formulation of G-CSF for oral administration [123], where a new gastrointestinal mucoadhesive patch system (GI-MAPS) has been designed for the oral delivery of G-CSF in beagle dogs. The system consists of four layered films, $3.0 \times 3.0\,mm^2$, contained in an enteric capsule. The 40-μm backing layer is made of a water-insoluble polymer, ethyl cellulose (EC). The surface layer is made of an enteric pH-sensitive polymer such as hydroxypropylmethylcellulose phthalate (HP-55), Eudragit L100 or S100, and was coated with an adhesive layer. The middle layer, a drug-containing layer, made of cellulose membrane is attached to the EC backing layer by a heating press method. Both drug and pharmaceutical additives including an organic acid, citric acid, and a non-ionic surfactant, polyoxyethylated castor oil derivative (HCO-60), were formulated in the middle layer. The surface layer was attached to the middle layer by an adhesive layer made of carboxyvinyl polymer (Hiviswako103). The same three kinds of GI-MAPSs containing 125 μg of rhG-CSF were prepared and orally administered to dogs, and the increase in total white blood cell (WBC) counts were measured as the pharmacological index for G-CSF. Comparison with the total increase of WBCs after i.v. injection of the same amount of G-CSF (125 μg) indicated the pharmacological availabilities (PA) of G-CSF were 23%, 5.5%, and 6.0% for Eudragit L100, HP-55, and Eudragit S100 systems. By decreasing the amount of HCO-60 and citric acid, the PA of G-CSF decreased. These results suggest the usefulness of GI-MAPS for the oral administration of protein.

For pulmonary drug delivery, the opportunity for systemic administration of peptides and proteins that are, at present, usually administered parenterally has been available [124]. As a result of the large surface area, good vascularization, immense capacity for solute exchange, and ultra-thinness of the alveolar epithelium are unique features of the lung, which can facilitate systemic delivery via pulmonary administration of peptide/protein drugs. Physical and biochemical barriers, lack of optimal dosage forms, and delivery devices limit the systemic delivery of biotherapeutic agents by inhalation. Current efforts exist to overcome these difficulties to deliver metabolic hormones. Systemic delivery of rhG-CSF can readily induce an increase in circulating levels of natural GCSF to approximately three to five times greater than baseline. Niven et al. [125] showed that rhG-CSF induced systemic response after delivery by aerosol in hamsters. The absorption from the lung was rapid, with a concomitant increase in white blood cells to four times baseline. The bioavailability was 45.9% of the administered dose and 62.0% of the dose reached the lung lobes. In a study that compared pulmonary administration of rhG-CSF powder with solution [126], a normal systemic response was obtained, indicating that rhG-CSF retains its activity in the solid state after formulation. Dissolution and absorption of rhG-CSF from powders were not rate limiting because the plasma concentration versus time profiles peaked at similar times in both powder and solution administration.

More recently, Miyamoto et al. developed the *in vivo* nasal absorption system of the FITC-dextrans with a mean molecular weight ranging from 4.3 to 167 kDa and rhG-CSF [127], in which the effect of poly-L-arginine (poly-L-Arg) on the *in vivo* nasal absorption in rats were studied. When FITC-dextrans were coadministered intranasally with 1.0 w/v% poly-L-Args of different molecular weight [MW, ca. 45.5 and 92 kDa, poly-L-Arg (50) and poly-L-Arg (100)], the bioavailability increased markedly compared with that after administration of FITC-dextran alone. However, the bioavailability decreased exponentially with the increasing molecular weight of FITC-dextrans. There was no significant difference between the enhanced nasal absorption of FITC-dextrans achieved by the coadministration of poly-L-Arg (50) and poly-L-Arg (100). Moreover, the relationship between the bioavailability and the molecular weight of FITC-dextrans indicated that the molecular weight of protein drugs, which exhibited efficient absorption with poly-L-Arg, was about 20 kDa, whereas the lower limit of bioavailability for developing a potent transnasal delivery system was assumed to be about 10%. Indeed, the nasal absorption of rhG-CSF, which has a molecular weight of 18.8 kDa, was also increased after coadministration of 1.0 w/v% poly-L-Arg (50) and the bioavailability was about 11%. It seems likely that poly-L-Arg can be used to provide adequate nasal absorption of various protein drugs, which have a molecular weight of about 20 kDa, thereby allowing the successful development of a variety of transnasal drug delivery systems.

6.3.5 INTERFERON

6.3.5.1 Background

Interferons (IFNs) are classified into three major groups that reflect antigenic and structural differentiation. IFN-α (leukocytic interferon) is produced by B lymphocytes, null lymphocytes, and macrophages; its production can be induced by foreign, virus-infected, tumor or bacterial cells [128]. Human IFN-α is a family of more than 15 subtypes, with molecular masses of 17.5–23 kDa. These proteins are composed of 165–166 amino acid residues and show approximately 80% sequence homology. The secondary structure of human IFN-α consists of 55–70% α-helix and less than 16% β-sheet. In general, human IFN-α does not contain N-linked glycosylation sites. There are 13 species of subtype IFN-α, and each IFN-α subtype has a different affinity for IFN receptor or a different antiviral activity [129]. These IFNs tend to be acidic, with isoelectric points of 5.7–7.0. In commercial settings, native IFN-α (Ly-IFN-Ly) and recombinant IFNs (IFN-α 2a, IFN-α 2b, and IFN-α con) are available [130]. IFN-β (fibroblast interferon) is a product of fibroblasts, epithelial cells, and macrophages that can be induced by viral and other nucleic acids. Human IFN-β is a single species with the molecular size of the natural glycoprotein 23 kDa with 166 amino acid residues. IFN-β shows 29% structural homology to IFN-α. The secondary structure consists of 36% α-helix and 33%-β sheet. The isoelectric point falls between 6.8 and 7.8. Now, native IFN-β and recombinant IFN-β, IFN-β 1b are available [131]. IFN-γ (immune interferon) is a product of activated T lymphocytes stimulated by foreign antigens and is composed of 143 amino acids. Human IFN-γ is heterogeneous, the molecular size depending on glycosylation and possibly oligomerization. Higher molecular sizes of 50–70 kDa

have been reported, suggesting oligomerization. It shows no statistically significant sequence homology to IFN-α or IFN-β. IFN-γ is acid-labile and highly basic, with an isoelectric point of 8.6–8.7 [132].

A lot of works involving IFNs has been done with natural or cloned human IFN preparations. In the 1970s, human testing of IFNs was restricted by their limited availability, purity, and specific activity; however, recombinant DNA technology has provided high-purity (>99%) and high-specific-activity preparations for large-scale human testing [133]. Human leukocyte interferon was the first preparation available. Early phase I studies, intending to establish the safety, tolerance, pharmacokinetics, and efficacy of interferons, targeted a host of viral and oncologic diseases using animal species [134–136]. In clinical use, the results were often disappointing. However, the importance of the route and rate of administration as treatment variables had been identified. On the other hand, the pharmacokinetics of conventional drugs commonly demonstrates species specificity. In case of IFNs, however, the catabolism and excretion of IFNs are similar across most species. Therefore, animals may serve as suitable models for the pharmacokinetics of IFNs in humans.

6.3.5.2 Pharmacokinetics of Interferon in Animals

Absorption of IFN-α from intramuscular [137, 138], subcutaneous [139, 140], intraperitonea1 [141], intradermal [142], duodenal, and rectal [143] sites has been reported. In general, IFN-α absorption from these sites is prolonged, and maximum serum concentrations occur 1–6 h post injection, followed by measurable concentrations through 8–24 h post injection. The concentration-time profile appears to be independent of the purity or source of IFN-α, namely, partially purified, natural, or recombinant. In addition, the disposition profiles were similar across the tested species, including mice, rabbits, dogs, and monkeys. Several of these studies have determined the absolute bioavailability from the intramuscular site to be 42% in dogs [139] and 93% [144] and 56% [136] in monkeys.

The absorption of IFN-β from intramuscular, subcutaneous, and intraperitneal sites is similar to that observed for IFN-α. The concentration-time curves are also similar to those seen with IFN-α, namely, prolonged absorption with concentrations persisting from 9 to 24 h after the injection. Estimates of absolute bioavailability from the intramuscular site can be obtained from published data: 60% in rats [141], 33% [145] and 60% in rabbits, and 43% in monkeys [145]. Recently, a bioavailability of 2.2% was reported for IFN-β after intranasal administration to rabbits [146]. However, absorption appears to be independent of species and interferon source. Contraly to this appearance, the absorption of IFN-γ has not been studied as extensively as that of IFN-α or -β. According to the results of Weck et al., serum concentrations of IFN-γ were very low or nondetectable after intramuscular injection of nonglycosylated IFN-γ in monkeys [147].

After bolus injection, the initial decline in serum concentrations following intravenous administration is rapid for IFN-α, -β, and -γ for all species tested with the half-lives of initial distribution on the order of minutes. Serum concentrations initially decrease rapidly, then decline more slowly, with terminal elimination half-lives ranging from minutes (30–40 min for IFN-α in mice) [148] to hours (7–12 h

for IFN-β in rabbits) [145] depending on the species selected and the type of interferon.

Both IFN-α and IFN-β have a volume of distribution after intravenous administration that ranges from 20% to 100% of body weight in mice [148], rats [149], rabbits [145], dogs [139], and monkeys [138], suggesting distribution into a volume that approximates total body water. Similar data for IFN-γ are not available. The tissue content of the interferons generally parallels that found in serum or plasma. Measurable concentrations or titers of interferons have been demonstrated in the brain, spleen, lung, liver, and kidney. For IFN-β and -γ, the amount of interferon determined in specific organs or tissues reflected the amount found in the serum or plasma, suggesting no uptake of these interferons into the sample organs or tissues. For IFN-α, the uptake results on tissue distribution studies have been mixed. Heremans et al. [141] reported the uptake of IFN-α by liver, lung, and spleen after intraperitoneal administration of homologous mouse IFN-α to mice. In contrast, Bohoslawec et al. [148] showed no appreciable uptake of murine IFN-α into brain, liver, lung, or spleen after intravenous administration to mice. However, the kidney showed an appreciable uptake of murine IFN-α. Two human IFN-α subtypes, A and D, and one human hybrid, A/D, displayed a tissue distribution profile similar to that of biologically active mouse IFN-α [148].

The catabolism of interferons has been the most widely researched area of preclinical IFN pharmacokinetics. Undoubtedly, the gastrointestinal tract is the most effective and efficient system for catabolizing proteins. The liver has also been shown to play a role in the catabolism of dycosylated proteins, and the kidney is the major catabolic organ for circulating low-molecular-mass (<60 kDa) proteins. In addition, other organs and tissues, such as the lungs and muscles, are thought to play minor roles in protein catabolism. For the catabolism of interferons, IFN-α has been the most extensively studied of the three types of interferons. In general, IFN-α is filtered through the glomeruli of the kidney followed by luminal endocytosis and proximal tubular reabsorption [150]. During reabsorption, IFN-α undergoes proteolytic degradation by lysosomal enzymes; therefore, negligible amounts of intact IFN-α are excreted in the urine. In nephrectomized animals (rats and rabbits), therefore, the clearance was significantly decreased [151, 152]. In addition to the above findings, Bocci et al. demonstrated that the liver has been shown to play a small role in the catabolism of IFN-α [153]. On the other hand, both IFN-β and IFN-γ undergo renal catabolism [153], but to a much smaller extent than IFN-α. Natural IFN-β and -γ are glycoproteins that contain sialic acid groups; they are therefore subject to the liver catabolism characteristic of this class of proteins. For recombinant IFN-α, there is an evidence that it reduces hepatic drug metabolism activity in mice [154]. Moreover, it has been demonstrated that the greater the antiviral activity of a given IFN in murine cells, the greater its ability to depress hepatic microsomal cytochrome P450 content in mice [154].

6.3.5.3 Pharmacokinetics of Interferon in Humans

The pharmacokinetics of interferons has been evaluated using a variety of dosing regimens varying from intermittent to continuous administration. Although definitive pharmacokinetics has not been reported in all cases, enough information is available to define their basic disposition characteristics. Serum interferon concen-

trations after intravenous administration decline rapidly in a biexponential manner for IFN-α and IFN-β [155, 156]. On the other hand, monoexponential decline has been observed for IFN-γ [157]. IFN concentrations fall several orders of magnitude over the measurable serum concentration-time course. Terminal half-lives range from 4 to 16 h for IFN-α, 1 to 2 h for IFN-β, and 25 to 35 min for IFN-γ. At the doses tested, serum concentrations are generally measurable for between 8 and 24 h after dosing of IFN-α and up to 4 h after injection for IFN-β and -γ. The total body clearance of IFN-α has been reported to range from 4.9 to 21 liters/h or 24 liters/h per/m^2. For IFN-β, the total body clearance is much higher, 19–38 liters/h per/m^2, whereas that of IFN-γ falls between the two at 12.66–32.4 liters/h.

Oral absorption of intact proteins has met with limited success because of the natural proteolytic capabilities of the gastrointestinal tract. The systemic absorption of interferons from sites other than the gastrointestinal tract has been remarkably good, considering the size of these molecules. Intramuscularly and subcutaneously administered IFN-α [158, 159] and nonglycosylated IFN-γ [160] are well absorbed, >80% for IFN-α and 30–70% for IFN-γ. These routes exhibit protracted absorption, which results in maximum serum or plasma concentrations occurring after 1 to 8 h. Concentrations are measurable for 4 to 24 h after injection for both IFN-α and IFN-γ. Maximum serum concentrations following these routes of administration are at least an order of magnitude less than the highest concentration observed after intravenous administration of an equal dose. The absorption of IFN-β from muscle or skin has not been sufficient to produce much greater serum concentrations because of the limits of assay detection.

The volume of distribution is similar for both IFN-α and IFN-γ, ranging from 12 to 40 liters [158, 161]. Although this volume is not physiological, it is approximately 20% to 60% of body weight. Information regarding IFN-β has not been established. On the other hand, the penetration of interferons across the human blood-brain barrier has been actively studied. Partially purined [162], natural [163], and recombinant [162] interferons do not readily cross the blood-brain barrier intact after intravenous, intramuscular, or subcutaneous administration. These data suggest that direct effect of parent interferon for the nervous system is not responsible for the occurrence of neurotoxicity, a common side effect of interferon therapy.

6.3.5.4 Interferon Formulation

Other routes of administration have been evaluated, such as inhalation, intralesional, intranasal, intraperitoneal, intraventricular, and intraocular rates, in clinical studies. For the most part, these alternative routes were attempts to improve the delivery of interferon to sites not easily accessible via the systemic circulation. These dosing strategies have provided adequate concentrations of interferon in cerebrospinal fluid, lymph, nasal mucosa, and peritoneal fluid, but have not led to clinical success, undoubtedly reflecting the lack of understanding of the inherent mechanism of interferon action [164].

The recommended twice-weekly administration of IFN-α does not maintain sustained plasma concentrations of the drug, thereby adversely affecting the potential biological response [165]. During the last few years, "pegylation technology" has been used to develop long-acting forms of IFN-α that help to avoid most of these

problems [166]. Polyethylene glycols are nontoxic water-soluble polymers that, owing to their large hydrodynamic volume, create a shield around the pegylated drug, thus protecting it from renal clearance, enzymatic degradation, and recognition by cells of the immune system. Two separate compounds, peginterferon α-2a (PEGASYS) and peginterferon α-2b (PEG-Intron), are now both approved for use alone or in combination with ribavirin for the treatment of chronic hepatitis C [167]. Interferon therapy for chronic hepatitis C is not a cure, but it is able to decrease the viral load and may decrease the risk of complications (e.g., cirrhosis, liver failure, and liver cancer) [168]. Pegylation of the interferon increases the amount of time the interferon remains in the body by increasing the size of the interferon molecule. Increasing molecule size slows the absorption, prolongs the half-life, and decreases the rate of interferon clearance [169]. Thus the duration of biological activity is increased with pegylated INF over nonpegylated INF. The pegINF-α products offer an advantage over nonpegylated INF-α products because of less frequent administration. Tolerability of the pegylated INF is comparable with the nonpegylated formulations. Monotherapy with these agents produces a better response in some patients than monotherapy with the nonpegylated formulation [170]. Combination therapy with ribavirin is more effective than monotherapy. In 1995, Nalin et al. demonstrated that conjugation of IFN-α 2a to a linear polyethylene glycol (PEG) (M, 5000) via a urea linkage increased the half-life, and plasma residence time parameters of IFN-α 2a were one and one-half fold and two fold greater than those corresponding to the native IFN-α 2a in rats [171], with reduced immunogenicity in mice [172]. In humans, a twice-weekly dosing of PEG_{5K}-IFN-α 2a is required to achieve antiviral levels similar to those attained with unconjugated IFN, as shown in a phase II trial involving chronic hepatitis C patients [173]. Ramon et al. reported that the conjugation of INF-α 2b (IFN-α 2b) to a branched-chain (40,000) polyethylene glycol ($PEG_{2,40K}$-IFN-α 2b) markedly improved the resistance to tryptic degradation and the thermal stability of IFN-α 2b. The serum half-life of $PEG_{2,40K}$-IFN-α 2b showed 330-fold longer, whereas plasma residence time was increased 708 times compared with native IFN [174]. Pegylation alters the pharmacokinetic properties of IFN-α and allows for once-weekly administration. Pegylated IFNs contain either linear PEG chains of small molecular weight, as in pegylated IFN-α-2b (12 kD), or larger branched moieties, as in pegylated IFN-α-2a (40 kD). There are pharmacokinetic and pharmacodynamic differences between these two IFNs. The much-increased sustained virological response rates observed with pegylated IFN-α-2a (40 kD) and pegylated IFN-α-2b (12 kD) support the rationale for pegylation of IFN [175]. The absorption half-life of standard IFN-α is 2.3 h, whereas absorption half-lives for pegylated IFN-α-2a and α-2b are 50 h and 4.6 h, respectively. The volume of distribution for pegylated IFN-α-2a is considerably restricted, whereas the volume of distribution for pegylated IFN-α-2b is only approximately 30% lower than that for conventional IFN. As a result of its large size, the 40-kD pegylated IFN-α-2a has a more than 100-fold reduction in renal clearance compared with conventional IFN-α. Clearance of pegylated IFN-α-2b is about one tenth that of unmodified IFN-α. Although data are limited, both drugs appear to show differences in the initial viral decay pattern in patients with chronic hepatitis C. However, it remains unknown whether these differences in the initial viral decline predict differences in the primary clinical endpoint, sustained virological response.

The development of new IFN-α delivery strategies is a key issue to simplify its administration and improve its therapeutic effects while reducing its dose-related

side effects. One of the most attractive approaches toward this purpose is the encapsulation of IFN-α into microspheres by a biodegradable polymer, poly(lactic-glycolic acid) (PLGA). Sanchez et al. developed the method of encapsulation of IFN-α into biodegradable microparticles and nanoparticles using PLGA and poloxamer 188, which is a stabilizing agent, and encapsulated IFN-α within PLGA/poloxamer blend microspheres or nanospheres [176] where their preparation techniques led to the efficient encapsulation of IFN-α and the modulation of their particle size ranging from 280 nm to 40 μm. The antiproliferative activity of the IFN-α varied depending on the formulation. Moreover, PLGA/poloxamer blend microspheres were able to provide significant amounts of active IFN-α for up to 96 days.

In 2004, Peleg-Shulman et al. developed a new type of pegylated INF-α-2 conjugate, peg_{40}-FMS-IFN-α-2, which is capable of regenerating native INF-α-2 at a slow rate under physiological conditions [177]. A 2-sulfo-9-fluorenylmethoxycarbonyl (FMS)-containing bifunctional reagent, MAL-FMS-NHS, has been synthesized, enabling the linkage of a 40-kDa peg-SH to IFN-α-2 through a slowly hydrolyzable bond. The *in vitro* rate of regeneration of native interferon from this preparation was estimated to have a half-life of 65 h. Following subcutaneous administration to rats and monitoring of circulating antiviral activity, active IFN-α-2 levels peaked at 50 h, with substantial levels still being detected 200 h after administration. This value contrasts with a half-life of about 1 h measured for unmodified interferon. The concentration of active IFN-α-2 scaled linearly with the quantity injected. Comparing subcutaneous to intravenous administration of peg40-FMS-IFN-α-2, the long circulatory lifetime of IFN-α-2 was affected both by the slow rate of absorption of the pegylated protein from the subcutaneous volume and by the slow rate of discharge from the peg in circulation.

More recently, Ito et al. demonstrated the usefulness of the oral patch preparations for INF-α [178]. The patch preparations were composed of three layers; a water-insoluble backing layer, a drug-containing layer with an absorption enhancer, and a surface layer containing pH-dependent polymer were prepared. As absorption enhancer, three surfactants, Gelucire44/14 (lauroyl macrogol-32 glycerides), Labrasol (caprylocaproyl macrogol-8 glycerides), and HCO-60 (polyoxyethylated hydrogenerated castor oil) were used in preparing the IFN-α patch preparations, an in vitro release study showed that the time when half of the formulated IFN-α is released from the patches were 3.4 ± 0.1 min for HCO-60, 7.8 ± 0.1 min for Gelucire44/14, and 11.4 ± 0.1 min for Labrasol preparations. An in vivo absorption study showed that Gelucire44/14 preparation showed a higher C_{max}, 7.66 ± 0.82 IU/mL, and AUC, 12.85 ± 1.49 IU h/mL, than Labrasol (6.51 ± 0.89 and 8.30 ± 1.34 IU h/mL) and HCO-60 (6.02 ± 1.14, 7.53 ± 1.84 IU h/mL) preparations, respectively. By comparing the AUC obtained after s.c. injection of the same dose of IFN-α with rats, bioavailability was estimated to be 7.8% in the Gelucire44/14 preparation.

6.3.6 GROWTH HORMONE

6.3.6.1 Background

Growth hormone (GH) is an endocrine hormone produced and stored in the anterior pituitary gland, which is secreted into the blood circulation in a pulsation

pattern. Deficiency of GH results in abnormally poor growth. This disease state, namely hypopituitary dwarfism, has been recognized for several years. By the end of 1950s, it was found that a patient with hypopituitary dwarfism given injections of extracts of human pituitary tissue grew remarkably well. However, the supply of human GH (hGH) was extremely limited, because the only source of hGH was from cadaver pituitaries. Specific criteria were established for identifying patients who were clearly GH-deficient and who stood the best chance of benefiting from therapy. If identified, a child would receive intramuscular injections of these pituitary extracts three times per week. The dosing levels were limited and the continuing therapy was always threatened by shortages of material. In addition to being in thin supply, the problem of purifying the material provided a further challenge. As with any therapeutic drug that is derived from human tissue, contaminants of other protein hormones as well as those of viral origin had to be removed. However, more recently, the availability of synthesized hGH, produced through recombinant DNA technology, greatly reduced these concerns and provided a plentiful supply of hormone. As part of the process for proving the safety and efficacy of the use of hGH in humans, pharmacokinetic studies have been conducted in a number of species including mice, rats, monkeys, and humans.

6.3.6.2 Pharmacokinetics of Growth Hormone in Animals

In 1982, Sigel et al. studied that the disappearance rates of hGH and a 20-kDa variant over 10 min after intravenous injection of iodinated material in male and female mice [179]. The half-lives of hGH and the 20-kDa variant in males were 4.1 and 3.9 min, respectively, whereas the half-lives in females were 4.7 and 4.0 min. There were no significant differences in the protein half-lives between male and female mice. In addition, there was no apparent relationship between the half-lives, the dissimilar binding characteristics for the target sites, and growth-promoting activities. In 1988, the pharmacokinetics of biosynthetic human growth hormone (B-hGH) and pit-hGH were compared in rats [180]. Normal and hypophysectomized male and female rats were injected subcutaneously and intramuscularly with 0.1 mg/kg B-hGH and pit-hGH and intravenously with 0.06 mg/kg B-hGH and pit-hGH. A smaller distribution volume and a slower metabolic clearance rate were found for B-hGH compared with pit-hGH. Moreover, a smaller distribution volume and a slower metabolic clearance rate were found for hypophysectomized rats compared with normal rats for both proteins. The plasma half-lives was estimated to be about 3–7 min in the initial elimination phase and 29 min in the terminal elimination phase. The plasma levels of hGH were higher after subcutaneous compared with intramuscular administration for both proteins. From these results, it was suggested that an extensive local degradation took place at the subcutaneous and intramuscular injection sites. In addition, comparative tissue distribution studies with radioiodinated B-hGH and pit-hGH showed no differences between the growth hormones. The females accumulated relatively more label in the liver than the males, whereas the males accumulated relatively more label in the kidneys.

On the other hand, the total body clearance (CL) of synthetic hGH was studied in eight adult rhesus monkeys [181], where four monkeys were lean (<20% body fat) and the other four were obese (>20% body fat). The monkeys were given a

single i.v. bolus injection of hGH (2.5 mg/kg), followed by a constant infusion of hGH (250 mg/hr) for 2.5 h. Venous blood samples were collected before the infusion and every 10 min during the infusion. In both groups, steady state was reached 70 min after the start of the infusion. The mean CL of synthetic hGH was 12.7 ± 1.7 liters/24 h in the lean group and 19.5 ± 2.9 liters/24 h in the obese group ($p < 0.007$). However, the CL values that standardized by body weight were the same in both groups. These observations suggest that the CL of hGH is directly proportional to body weight, and the lower plasma GH levels in obesity may be caused by an increase in its CL not compensated for by an appropriate increase in the rate of GH secretion.

As for the metabolism, the metabolic fate of GH in peripheral tissues has not been clearly defined as with other protein hormones. The clearance of GH from the systemic circulation is thought to occur by receptor-mediated uptake at the liver and filtration at the kidney [182]. After intravenous injection of [^{125}I]hGH to female rats, hGH was speciacally taken up by the liver with radioactivity ultimately becoming associated with the lysosomal subfraction. The specific uptake of [^{125}I]hGH into rat liver was associated with accumulation in the Golgi apparatus [183, 184]. Interestingly, in each of these studies, radioactivity in the liver was characterized by TCA solubility and membrane binding as an intact hormone. These findings suggest that receptor-mediated uptake of GH in the liver is not directly linked to hydrolytic inactivation of the hormone.

6.3.6.3 Pharmacokinetics of Growth Hormone in Humans

In the early phases of product development, data from laboratory animals can sometimes be used to predict the phamacokinetic profile in humans [183]. Dosing levels for initial clinical trials can thus be selected. In the later stages of development, when human data were available, allometeric analysis is useful for evaluating the clinical relevance of pharmacological data collected in laboratory animals. Actually, the phamacokinetic parameters in humans can often be predicted by using pharmacokinetic data collected in laboratory animals by extrapolation by following equations based on body weight. Application of this method assumes that the pharmacokinetics are dose-proportional over the dosage range under condition. The allometric approach uses the following equation: $Y = aW^b$, where Y represents a pharmacokinetic parameter and W represents body weight in kg; constants, a and b represent the allometric constants and the allometric exponent. Using the allometric equations, that pharmacokinetic parameters (total body clearance, initial volume of distribution, and volume of distribution at steady state for rhGH in mice, rats, monkeys, and humans) show a strong association among these pharmacokinetic parameters as a function of body weight. This good interspecies agreement supports the use of pharmacokinetic data collected in laboratory animals to predict the distribution of rhGH and other proteins in humans [183].

6.3.6.4 Growth Hormone Formulation

GH is a pituitary hormone responsible for postnatal growth. Like all polypeptide hormones, GH was long thought to be circulating exclusively in the free form rather than being bound to plasma proteins, which was in contrast to some other

hormones of hydrophobic nature (e.g., steroids), which required protein binding for solubilization in the aqueous plasma environment. It is a 20–22-kDa polypeptide that exists in several molecular forms. GH acts by binding to GH receptors in multiple tissues; it initiates a cascade of biochemical events, among which the generation of insulin-like growth factor-I (IGF-I) is important for the growth process at the local tissue level. Other important actions of GH are those involved in anabolism, such as intracellular transport of amino acids and other cellular constituents, nitrogen, and protein synthesis. The biochemical events immediately following GH binding to receptors (intracellular signaling) are only incompletely understood. In 1987, the hepatic GH receptor was cloned and structurally characterized; it is a single-chain glycoprotein with a 620-amino acid backbone, of which 246 are extracellular, 24 form a hydrophobic transmembrane domain, and 350 are intracellular [185]. Like all polypeptide hormones, GH was long thought to be circulating exclusively in the free form rather than being bound to plasma proteins. At the end of 1980s, however, it was found that GH also circulates by binding to specific GH-binding proteins in plasma [186]. At least two GH-binding proteins (GH-BP) have been identified in human plasma; one binds GH with high affinity, the other with lower affinity.

hGH is currently administered by injection daily or three times a week. To improve patient compliance, there have been a lot of research efforts for the development of long-acting formulations of protein drugs. The parenteral delivery route often requires frequent dosing because of the short half-lives of these drugs. A few clinical studies have shown that a continuous infusion of hGH via a pump resulted in growth velocity and insulin-like growth factor-I (IGF-I) levels comparable with those of daily injections. The results indicate that pulsatile hGH release may not be required for clinical efficacy, and the sustained-release formulation may improve patient compliance and efficacy with a suitable pharmacokinetics release profile [187]. For a development of sustained-release formulation of protein drugs, one of the key requirements may be the integrity of the protein drugs within microparticles during and after formulation processes contrary to small-molecular-weight drugs; proteins have three-dimensional structures to retain their bioactivity. Some stresses (e.g., temperature, pH, or organic solvents) associated with the preparation of sustained-release formulation can cause deamidation, oxidation, denaturation, or aggregation of the protein, which can turn the protein biologically inactive and even immunogenic.

From the end of the 1990s to the early 2000s, rapid development in molecular biology and recent advancement in recombinant technology increased identification and commercialization of potential protein drugs. It is well known that traditional forms of administration for the peptide and protein drugs often rely on their parenteral injection, as the bioavailability of these therapeutic agents is poor when administered nonparenterally. Tremendous efforts by numerous investigators across the world have occured to improve protein formulations and, as a result, a few successful formulations have been developed including sustained-release hGH. At the end of 1990s, a sustained-release system was developed for rhGH using biodegradable microsphere formulations composed of polymers of lactic and glycolic acid (PLGA). Lee et al. reported that long-acting formulations of rhGH were prepared by stabilizing and encapsulating the protein into three different injectable, biodegradable microsphere formulations composed of PLGA [188]. In this study, the microsphere

formulations were compared in juvenile rhesus monkeys by measuring the serum levels of rhGH and two proteins induced by hGH, insulin-like growth factor-I (IGF-I) and IGF binding protein-3 (IGFBP-3) after single s.c. administration. The results showed that PLGA formulations induced a higher level of IGFBP-3 than was induced by injections of the same amount of rhGH in solution. Moreover, Brodbeck et al. evaluated the effects of altering dynamics of PLGA solution depot on the sustained-release delivery of hGH by subcutaneous injection in rats, and obtained about 28 days of long-term sustained-release profiles from the PLGA solution depot of hGH in normal rats at serum levels of 10–200 ng/mL [189].

In the early 2000s, several other formulations of hGH have been developed. In 2001, Maeda et al. developed a sustained-release collagen film of hGH and evaluated its effect on wound healing in db/db mice [190]. The release profiles of hGH from the collagen films varied with composition and preparation conditions; however, the film prepared by air-drying of the mixture of hGH and collagen solution released hGH continuously over 3 days both in vitro and in vivo. By application of collagen film containing 3 mg of hGH twice at an interval of 6 days to wounds, the area of wounds on day 21 was significantly reduced compared with that of nontreated wounds in mice. In 2002, Kim et al. reported the usefulness of the synthesized HA/Pluronic composite hydrogels [temperature-sensitive hyaluronic acid (HA) hydrogels, which were synthesized by photopolymerization of vinyl group modified HA in combination with acrylate group end-capped poly(ethylene glycol)-poly(propylene glycol)-poly(ethylene glycol) tri-block copolymer (Pluronic F127)] [191]. This HA/Pluronic composite hydrogels gradually collapsed with increasing temperature over the range of 5 to 40°C suggesting that the Pluronic component formed self-associating micelles in the hydrogel structure. The mass erosion occurred much faster at 37°C than at 13°C, indicating that at the higher temperature, the ester linkage between the Pluronic and acrylate group might be more exposed to an aqueous environment and thus be more readily hydrolyzed because of Pluronic micellization. This HA/Pluronic composite hydrogels is applicable for a formulation of rhGH in sustained-release profiles that followed a mass erosion pattern.

More recently, aiming at once-a-week injection, a novel sustained-release formulation of rhGH using sodium hyaluronate (SR-rhGH) was developed for the treatment of children who have growth failure caused by lack of adequate secretion of endogenous GH [192, 193]. SR-rhGH was produced in the form of solid microparticles by spray-drying technology. A single administration of a prototype formulation of SR-rhGH with a ratio of hGH : HA-1 : 1 to cymomolgus monkeys through a fine 26-gauge needle induced continuous elevation of serum IGF-I level for 6 days, demonstrating the bioactivity of hGH released from the prototype formulation. When the ratio of hGH to HA changed from 1 : 1 to 1 : 3, hGH released more slowly in vitro from SR-rhGH with almost complete release of hGH loaded. According to phamacokinetic and pharmacodynamic studies in beagle dogs, sustained release of hGH from the optimized formulation of SR-rhGH continued for a more extended period longer than 72 h with a lower C_{max} than those of prototype formulations. The single administration resulted in an elevation of serum insulin-like growth factor-I (IGF-I) level for 6 days, with a maximum value that was higher than the baseline level by 350 ng/mL, which supported the possibility of SR-rhGH as a once-a-week injection formulation of hGH. The bioavailability of both

formulations was comparable with that of hGH daily injection formulation. Finally, toxicity studies revealed no evidence of adverse effect in both cymomolgus monkeys and beagle dogs [193].

As for a formulation using another administration route, Leitner et al. developed a nasal delivery system of hGH [194] based on the thiomer polycarbophil-cysteine (PCP-Cys) in combination with the permeation mediator glutathione (GSH). Microparticles were prepared by dissolving PCP-Cys/GSH/hGH (7.5:1:1.5), PCP/hGH (8.5:1.5), and mannitol/hGH (8.5:1.5) in demineralized water, followed by lyophilization and micronization. PCP-Cys/GSH/hGH and PCP/hGH microparticles showed a comparable size distribution (80% in the range of 4.8 to 23 μm) and swelled to almost four fold size in phosphate-buffered saline. Both formulations exhibited almost identical sustained drug release profiles. The intranasal administration of the PCP-Cys/GSH/hGH microparticulate formulation resulted in a relative bioavailability of 8.11%, which represents a three fold and a 3.3-fold improvement compared with that of PCP/hGH microparticles and mannitol/hGH powder, respectively. The nasal microparticulate formulation based on PCP-Cys/GSH/hGH might represent a promising novel tool for the systemic delivery of hGH.

6.3.7 LEUPROLIDE

6.3.7.1 Background

Leuprolide acetate is a synthetic and superpotent agonist of luteinizing hormone-releasing hormone (LHRH) with a biphasic effect on the pituitary (Figure 6.3-2).

It is a decapeptide hormone that is effective in the treatment of hormone-dependent diseases such as prostate and mammary tumors and endometriosis [195, 196]. It initially stimulates the secretion of both luteinizing hormone (LH) and follicle stimulating hormone (FSH), and on long-term continuous administration it inhibits secretion of LH and FSH, and the concentration of testosterone in men and estrogen in women drop sharply. It is administered pulsatively for adjuvant hormonal therapy and continuously for hormone-related anti-neoplastic therapy comprising prostatic and breast cancer and endometriosis [197]. As leuprolide is a peptide, it is orally inactive and generally given subcutaneously or intramuscularly. Recently, however, several attempts are considered to improve bioavailability and effectiveness of leuprolide as well as a patient's convenience for taking the medicine.

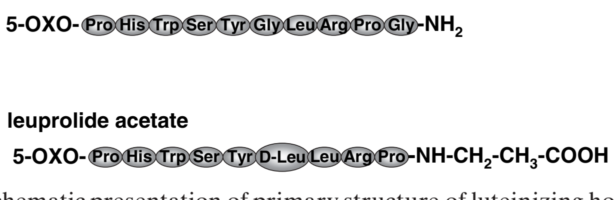

Figure 6.3-2. Schematic presentation of primary structure of luteinizing hormone-releasing hormone (LH-RH) and leuprolide acetate.

6.3.7.2 *In vitro* Permeation Study of Leuprolide

For most polypeptides, oral administration is often limited by enzyme instability in the gastrointestinal tract. Furthermore, because peptides are highly ionized, and thus are mostly hydrophilic, their potential for permeating gastrointestinal absorption barriers is poor. Attempts to understand the degradation and permeation behavior in the intestine are beneficial to improve oral efficacy. Intramuscular and intranasal routes are the common routes of administration. Undoubtedly, the oral route is the most convenient. However, plasma levels of leuprolide after oral administration of an aqueous solution to rats and humans are mostly below the limit of detection (0.2 ng/mL) [198]. Therefore, it is important to understand and elucidate the absorption and degradation mechanisms of leuprolide in the intestinal tract. In 2004, Guo et al. reported the transport mechanism of leuprolide across rat intestine, rabbit intestine, and Caco-2 cell monolayer [199]. Using techniques based on everted gut sac and Caco-2 cell monolayer, it was found that flux of leuprolide increased with increasing concentration of drug, showing a passive diffusion pathway. At a low concentration of leuprolide, trypsin inhibitor had a strong enhancement effect on the permeability of drug by protecting enough drug for permeation. Chitosan had no affect on the activity of α-chymotrypsin. In addition, the authors found that the increase in permeation of leuprolide was caused by opening of the tight junctions and interaction with cells. Therefore, the authors concluded that both inhibition of proteolytic enzymes and opening the tight junctions to allow for paracellular transport of leuprolide improved the intestinal absorption.

6.3.7.3 Clinical Pharmacokinetics of Depot Leuprolide

In 1984, for cancer treatment, a sustained-release intramascular formulation based on biodegradable microspheres had been developed by Saunders et al. and thereafter marketed (Lupron@ Depot, TAP Pharmaceuticals) [200]. This injectable microsphereiscapable of sustaining required drug levels over a period of 1, 3, and 4 months after a single administration. These systems, in addition to improving the patient convenience and compliance, reduce the needed dose to one-quarter to one-eighth of the injected aqueous solution by sustaining therapeutic drug levels at target receptor sites [201]. More recently, sustained-release depot formulations, in which the hydrophilic leuprolide is entrapped in biodegradable highly lipophilic synthetic polymer microspheres based on polylactic/glycolic acid (PLGA) or polylactic acid (PLA), have been developed to avoid daily injections [202], where leuprolide is released from these depot formulations at a functionally constant daily rate for 1, 3, or 4 months, depending on the polymer type (PLGA for a 1-month depot and PLA for depot of >2 months), with doses ranging between 3.75 and 30 mg. The mean peak plasma leuprolide concentrations of 13.1, 20.8–21.8, 47.4, 54.5, and 53 μg/L occur within 1–3 h of depot subcutaneous administration of 3.75, 7.5, 11.25, 15, and 30 mg, respectively, compared with 32–35 μg/L at 36–60 min after a subcutaneous injection of 1 mg of a nondepot formulation. Sustained drug release from the PLGA microspheres maintains plasma concentrations between 0.4 and 1.4 mg/L over 28 days after single 3.75-, 7.5-, or 15-mg depot injections. The

mean areas under the concentration-time curve are similar for subcutaneous or intravenous injection of short-acting leuprolide 1mg; a significant dose-related increase in the AUC from 0 to 35 days is noted after depot injection of leuprolide 3.75, 7.5, and 15mg. The mean volume of distribution of leuprolide is 37L after a single subcutaneous injection of 1mg, and 36, 33, and 27L after depot administration of 3.75, 7.5, and 15mg, respectively. The total body clearance is 9.1L/h and the elimination half-life is 3.6h after a subcutaneous 1-mg injection; corresponding values after intravenous injection are 8.3L/h and 2.9h. A 3-month depot PLA formulation of leuprolide 11.25mg ensures a mean plasma peak concentration of around 20μg/L at 3h after subcutaneous injection, and continuous drug concentrations of 0.43 to 0.19μg/L from day 7 until before the next injection. In addition, an implant administration of these sustained-release systems of leuprolide provided a lasting delivery of leuprolide for 1 year. Serum leuprolide concentrations remained at a steady mean of 0.93mg/L until week 52, suggesting zero-order drug release from the implant.

6.3.7.4 Transdermal Iontophoretic Delivery of Leuprolide

As for another route of administration of leuprolide, Kochhar et al. demonstrated an application of transdermal delivery of leuprolide using heat-separated human epidermal membrane from cadaver skin of multiple donors. The author used an iontophoresis technique to deliver the drug and examined the effect of constant voltage or constant current application [203, 204]. When the heat-separated human epidermal membrane was subjected to constant voltage within the range of 250 to 1000mV during the iontophoretic phase, iontophoretic enhancement of leuprolide permeation at pH 7.2 was greater than at 4.5. A developed model to account for iontophoretic enhancement yielded that, first, the porosity increased with the applied voltage to as much as three times the original at 1000mV. Second, the lipid pathway scontributed approximately 20% to the total permeation during the passive phase. Third, the electro-osmotic flow contributed significantly to the enhancement and its direction was from anode to cathode at pH 7.2 and the opposite at pH 4.5. The magnitude of the electro-osmotic flow was at pH 4.5 somewhat lower than at pH 7.2. Repeated iontophoretic applications of 250mV on the same skin specimen resulted in the same enhancement every time and did not cause any barrier alterations when applied for 1h every 24h, which was not the case if the duration between the two iontophoretic applications was only 3h. In contrast, keeping the current densities at 0.5 to 2.3μA/cm^2, the permeation rate of leuprolide increased linearly with the current density for the universal buffer and at pH 7.2 was almost double that at pH 4.5 despite the greater ionic valence of the drug at pH 4.5 compared with pH 7.2. The drug transference number at both pH values was approximately 0.5%. Replacement of the universal buffer with polymaleic acid yielded higher drug permeation rates and increased its transference number at a comparable pH. Transference number of the drug with polymaleic acid appeared to increase with current density. From these in vitro investigations, the authors concluded that the fluxes obtained for both electrolyte systems with the present experimental arrangement could be extrapolated to deliver therapeutically relevant doses of the drug.

6.3.8 DESMOPRESSIN

6.3.8.1 Background

Desmopressin (the vasopressin analog 1-deamino-8-D-arginine vasopressin, dDAVP), a potent synthetic peptide hormone of the natural pituitary hormone vasopressin, is used chiefly for treatment of enuretic disorders, such as central idiopathic or secondary diabetes insipidus [205, 206] and nocturia and nocturnal enuresis in young children [207]. Desmopressin has also proven to be useful in the treatment of bleeding diseases by activating and mobilizing factor VIII and von Willebrand's factor reserves in hemophilia A and von Willebrand–Jurgens syndrome [208]. The 1100-Da molecule, which is typically taken in doses of 1–20 μg, shows variable and low oral and nasal bioavailability (0.1% and 3.4%, respectively) [1]. Although injectable formulations demonstrate better bioavailability, they are poorly suited for routine use in young children. For the treatment of these disorders, desmopressin (Desmopressin®) in usually administered intranasally by use of sprays or drops. This route of desmopressin administration was shown to be more efficacious than the oral route, because bypassing the gastrointestinal tract increases the absolute bioavailability from less than 1% to approximately 5% [209]. A more acceptable route of administration with potentially good bioavailability could be offered by transdermal delivery. It is well documented that the stratum comeum, the outermost layer of the skin, constitutes an impermeable barrier to hydrophilic or high-molecular-weight drugs. These molecules can only be delivered into or through the skin if the barrier function of the stratum corneum is disrupted by any of a number of available methods. In this field, ultrasound and iontophoresis, which are known to enhance transdermal delivery of small molecules, have also been proposed for use with peptides and macromolecules.

6.3.8.2 Pharmacokinetics of Desmopressin in Humans

As a basic study, Rembratt et al. investigated the pharmacokinetic and pharmacodynamic profiles of desmopressin after oral and intravenous ad-mini-stration in men with a high incidence of nocturia [210]. Based on an open-randomized and four-way crossover design, desmopressin was administered orally (0.2 mg) and intravenously (2 μg) at daytime and nighttime. The concentration-time curve after 2 μg intravenous desmopressin was best fitted by a biexponential equation. The mean (95% CI) AUC at night was 302 (272–335) pg h/mL and in the day was 281 (253–312) pg h/mL. No statistically significant differences were detected between night and day except for terminal half-life, which was 3.1 h at night and 2.8 h in the daytime ($p = 0.02$). Peak plasma concentration (C_{max}) was 6.2 (5.1–7.5) pg/mL at night and 6.6 (5.5–7.9) pg/mL in the daytime, respectively. Median time to reach C_{max} (t_{max}) was 1.5 (range 1.0–4.1) h at night and 1.5 (range 0.5–0.3) h in the day, and the oral bioavailability was 0.08%. The pharmacodynamic effects of oral and intravenous desmopressin given in the daytime were similar during the first 6 h after dosing. The nighttime dosing and daytime intravenous dose resulted in antidiuresis throughout the measuring period, whereas the effect of the daytime peroral dose receded after 6 h. The authors concluded that the terminal half-life was longer at

night than in the daytime, but the difference is considered too small to be of clinical importance. Moreover, they also concluded that, despite low bioavailability, the pharmacodynamic effects of oral desmopressin were similar in magnitude to those after intravenous dose at night and during the first 6h after daytime administration.

More precisely, d'Agay-Abensour et al. investigated the absolute bioavailability of an aqueous solution of desmopressin from different regions of the gastrointestinal tract (stomach, duodenum, jejunum, ileum, colon, rectum) in 6 healthy male volunteers aged 24 to 35 years [211]. For intravenous administration, the subjects received 4μg of desmopressin. For intestinal administration, 400μg of desmopressin was directly applied to six distinct sites in the GI tract via two- or four-channel tubes with or without a distal occlusive balloon. After intravenous administration, the elimination half-life, total body clearance, amount excreted in urine, and renal clearance of desmopressin were 60.0min, 1.7mL/min/kg, 2.0μg, and 0.8mL/min/kg, respectively. The mean bioavailability of desmopressin after gastric, duodenal, jejunal, distal ileal, proximal colonic, and rectal application was 0.19%, 0.24%, 0.19%, 0.03%, 0.04%, and 0.04%, respectively. Thus, absorption was significantly higher in the three upper GI regions in comparison with the three lower regions.

6.3.8.3 Renal and Biliary Excretion and Sex Differences in Desmopressin Pharmacokinetics

Agerso et al. investigated the differences in pharmacokinetic profiles of desmopressin between healthy subjects and renally impaired patients after intravenous administration [212]. Overall, 18 renal impairment and 6 healthy volunteers were enrolled in the study. Each subject received a single intravenous dose of 2-μg desmopressin, and blood and urine samples were collected for 24h, where plasma concentrations and the amounts of desmopressin excreted in the urine were analyzed simultaneously by means of a technique of mixed effects modeling. Their results showed that both renal and nonrenal clearances of desmopressin were found to vary with the creatinine clearance (CrCL). A decrease of 1.67% in the CrCL was found to cause a 1.74% decrease in the renal clearance and a 0.95% decrease in the nonrenal clearance. The fall in renal failure caused the amount of desmopressin excreted in urine to decrease from 47% in healthy subjects to 21% in the patients with severe renal impairment. The mean total body clearance of desmopressin in healthy subjects and patients with severe renal impairment was 10L/h and 2.9L/h, respectively. Correspondingly, the mean terminal half-life was 5.7h in healthy subjects and 10h in patients with severe renal impairment. The authors concluded that great caution should be taken when deciding on an efficient dosage regimen if patients with moderately or severely impaired renal function are to be treated with desmopressin at all, despite the drug appearing to be safe and well tolerated by patients with impaired renal function.

The pharmacokinetic profiles of desmopressin in the liver were also investigated. Lundin et al. demonsted the biliary excretion of drug after intrajugular venous, intraportal venous, and intraduodenal venous administration in conscious pigs [213]. In all cases of administration routes, the biliary excretion was less than 1% of the administered dose with the plasma/bile concentration ratio of less than 1.0. A significant first-pass effect was found when the liver was exposed to a high intra-

portal dose of desmopressin. The uptake study of [^{3}H]desmopressin by incubating with liver tissue slices showed that desmopressin was rapidly removed from the incubation medium, indicating desmopressin was markedly metabolized in the liver.

As another parameter to alter the pharmacodynamic profile of desmopressin, a sex difference is most important. In 2004, Odeberg et al. demonstrated that there was a sex difference in a human pharmacokinetic (PK) and pharmacodynamic (PD) study [214], where desmopressin was administered intravenously as a single dose (for the PK study, a 2-μg dose; for the PD study, a 0.2-μg dose), and parameters for urine flow and urine osmolality were estimated. The pharmacokinetics of desmopressin after a fixed bolus injection were influenced neither by piroxicam nor by sex of subjects. However, the pharmacodynamics of desmopressin showed a sex difference where females exhibited a more pronounced antidiuretic effect than males, which was statistically significant when the effects were submaximal (>4.5 h after dose). The sex differences were diminished after pretreatment with an NSAID, piroxicam, indicating a prostaglandin PGE_2-mediated mechanism.

6.3.8.4 Desmopressin Formulation

Usually, desmopressin is administered intranasally by use of sprays or drops. This administration route of desmopressin was considered to be more efficacious than the oral route, because bypassing the gastrointestinal tract increases the absolute bioavailability from less than 1% to approximately 5%. However, nasal application of desmopressin is accompanied by high intersubject and intrasubject variability in plasma pharmacokinetics [215]. Therefore, there have been several pharmaceutical research efforts to improve nasal delivery of desmopressin.

In 1987, Lethagen et al. demonstrated a comparison study, which was made of intranasal administration of 300-μg desmopressin by spray, with intravenous administration of 0.2-, 0.3-, and 0.4-μg/kg desmopressin in 10 healthy volunteers [216], where the effect of desmopressin was measured on the antihemophilia factor, factor VIII (F VIII), and on plasminogen activator release. Plasma levels of desmopressin showed a clear dose response with the maximum levels at 0.4 μg/kg intravenous dose. The affect of the spray approximated the 0.2-μg/kg response. However, the maximum response in both F VIII complex and plasminogen activator release was obtained after a 0.3-μg/kg i.v. dose. The response at a 0.4-μg/kg i.v. dose was not significantly different from the response at a 0.3-μg/kg dose, indicating that maximum stimulation was reached with 0.3 μg/kg. There was no correlation between plasma levels of F VIII and desmopressin, indicating that the biological response to the drug is subject to saturation kinetics. The reproducibility of the effect of the spray dose on F VIII was 21% (c.v.) and 27% for the intraindividual and interindividual variation, respectively, and compared favorably with intravenous administration. Therefore, they concluded that intranasal desmopressin (300 μg) is as effective as 0.2 μg/kg intravenously and provides an accurate, reproducible, and convenient alternative to parenteral administration. Moreover, in 1988, Harris et al. reported the effects of concentration and dose volume on the nasal bioavailability and biological response to desmopressin in humans [217]. A nasal formulation of 300 μg of desmopressin was administered using a premetered spray device in doses of either 1 × 50-, 2 × 50-, or 1 × 100-μL actuations to both nostrils.

Intravenous administration of 0.2 μg/kg was also given as a reference for bioavailability calculations. The biological response was determined by measuring circulating levels of F VIII. Peak plasma levels of desmopressin were greatest after the 2 × 50-μL dose, followed by the 1 × 50- and 1 × 100-μL doses. The bioavailability of desmopressin from the 2 × 50-μL dose was 20%, which was significantly greater than the 11% after the 1 × 50-μL ($p < 0.01$) and 9% after the 1 × 100-μL ($p < 0.001$) doses. The biological response was clearly enhanced after the 2 × 50-μL dose compared with the 1 × 50- and 1 × 100-μL doses. The interindividual response in F VIII levels to nasal desmopressin ranged from 20% (CV) to 30%, which compared favorably with the 36% variation after intravenous administration. These results show that by optimizing concentration, volume, and splay apparatus, a significant enhancement can be obtained in bioavailability and clinical efficacy of desmopressin.

More recently, as a new apparatus for desmopressin delivery, Cormir et al. reported the usefulness of a coated microneedle array patch system (Macronux technology) to deliver desmopressin through the skin [218]. Although it is available in injectable, intranasal, and oral formulations, intranasal and oral administration result in low and variable bioavailability. However, administering desmopressin transdermally using Macronux technology, which uses a microneedle array to overcome the skin barrier, is markedly useful to improve the bioavailability of desmopressin. In their reports, the tips of microneedles in 2-cm^2 arrays were covered with a solid coating of various amounts of desmopressin and applied to the skin of hairless guinea pigs for 5 or 15 min. Pharmacologically relevant amounts of desmopressin were delivered after 5 min. Bioavailability was as high as 85% and showed acceptable variability (30%). Immunoreactive serum desmopressin reached peak levels after a T_{max} of 60 min. Elimination kinetics for serum desmopressin was similar after other transdermal and intravenous delivery, suggesting the absence of a skin depot. These results suggest that transdermal delivery of desmopressin by Macroflux technology is a safe and efficient alternative to currently available routes of administration.

6.3.9 ANTIBODIES

6.3.9.1 Background

Antibodies serve two important functions: They bind and modulate antigens and they bind complement and immune effector cells, such as natural killer cells and monocytes. Recently, targeted therapies using monoclonal anti-bodies (mAbs) have gained increased therapeutic application. As shown in Table 6.3-1, overall, 19 mAbs are currently approved by FDA to treat various disease states, such as oncology, inflammation, infectious disease, and cardiovascular disease [219]. All approved mAbs are of the IgG class. Each IgG molecule contains two identical heavy chains and two identical light chains, 13 of which are intact mAbs, three are conjugated, and one is an mAb fragment (Fab). A feature of mAb therapeutics is the high specificity conferred by the antibody interaction with a specific region on the targeted antigen. The antigen-binding site is formed by the intertwining of the light-chain variable domain (V_L) and the heavy-chain variable domain (V_H). Each V domain contains three short stretches of peptide known as the complementarily

TABLE 6.3-1. Therapeutic Antibodies Approved by FDA

Approved	Generic name	Trade mame	Disease indication
1986	muromanab–CD3	0KT3	Allograft regction
1994	abciximab	ReoPro	Adjunct to PTCA
1995	edrecolomab	Panorex	Colorectal cancer
1997	rituximab	Rituxan	Non-Hodgkins lymphoma
1997	daclizumab	Zenapax	Prevention of kidney Transplantr rejection
1998	trastuzumab	Herceptin	Metastatic breast cancer
1998	palivizumab	Synagis	RSV propylaxis
1998	basiliximab	Simulect	Prevention of kidney Transplantr rejection
1998	infliximab	Remicade	Rheumatoid arthrists, Crohn's disease
2000	gemtuzumab ozogamicin	Mylotarg	CD33-acute myeloid leukemia
2001	alemtuzumab	Campath	B-cell chronic lymphocyte leukemia
2002	ibritumomab tiuxetan	Zevalin	Non-Hodgkings lymphoma
2002	adalimumab	Humira	Rheumatoid arthrists, Crohn's disease
2003	omalizumab	Xolair	Asthma
2003	efalizumab	Raptiva	Prorisis
2003	tosirtumomab	Bexxar	Non-Hodgkings lymphoma
2004	cetuximab	Erbitux	Colorctal cancer
2004	bevacizumab	Avastin	NSCL cancer

determining regions (CDRs); the CDRs are the prominent determinants of antigen-binding affinity and specificity. The light chain contains one constant domain, C_L. The heavy chain contains three constant domains, C_H1, C_H2, and C_H3. The C_H2 and C_H3 domains allow interactions of the IgG molecule with various components of the immune system by either binding C1q, which activates the complement cascade and elicits complement-dependent cytotoxicity, or by binding to Fcγ receptors on immune effector cells, which elicits antibody-dependent cellular cytotoxicity (Figure 6.3-3).

These same variable and constant domains of the molecule also affect IgG catabolism and elimination [220]. In addition to their contributions to mAb pharmacological activities, the FcyRs could also regulate elimination and pharmacokinetics of mAbs. Other factors, such as mAb structure and engineering, host factors, concurrent medications, and immunogenicity, can alter the pharmacokinetic and pharmacodynamic profiles. Hence, understanding the factors that affect the pharmacokinetics of mAb is of high importance for effective therapeutic application.

6.3.9.2 Pharmacodynamics and Pharmacokinetics of mAbs

mAbs can exert their pharmacological effects via several different mechanisms, such as neutralizing antigen function, activating receptors by mimicking

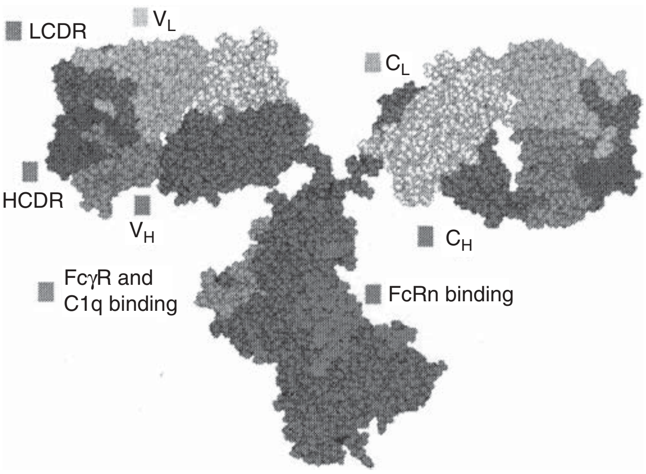

Figure 6.3-3. Representation of the space-filling model of an IgG molecule.

endogenous receptor ligands, delivering toxins to specific cells (targeted delivery), and eliciting effector functions in conjunction with antigen modulation [221]. Under some circumstances, where antigen expression is high in crucial organs (e.g., heart, lung, and vasculature), the effector function might not be desirable and could be deleterious; however, in other instances, such as applications in hematological malignancies, effector functions might be a significant part of the mechanism of action and maximizing the antibody effector functions might be highly desirable. Clearance of antibodies through the cells of the reticuloendothelial system (RES) can be regulated through the interaction with various Fc receptors. FcRns are expressed on phagocytic cells of the RES and protect IgG from rapid clearance. Similarly, cells of the RES express various types of Fcγ receptors. Interactions of IgG antibodies with this subset of receptors could potentially impact antibody clearance. As discussed, polymorphism in Fcγ receptors impacted the therapeutic response to rituximab [222]. Although the favorable clinical outcome was attributed to a more efficient Fcγ RIIIa-dependent cytotoxicity, it is not clear if polymorphism in Fcγ receptors could have any potential impact on antibody clearance. Polymorphism in Fcγ RIIIa was shown to impact in vivo clearance of red blood cells (RBC) coated with an anti-D IgG3 antibody in humans [223]. The faster clearance was attributed to a more efficient elimination of opsonized RBC by phagocytic cells in the spleen of the subjects homozygous for Fcγ RIIIa-F/F158 [223]. These results are consistent with previous data demonstrating the impaired clearance of IgG-sensitized RBC in the presence of an anti-Fcγ RIIIa antibody [224]. In addition, downregulation of Feγ receptor on cells of monocyte lineage by immunomodulatory drugs, such as methotrexate (MTX), might potentially impact the clearance of mAbs such as adalimumab.

As the site on IgG that is responsible for binding to FcRn has been mapped and well characterized, the trend in the field of antibody engineering is to mutate the FcRn-binding site. Therefore, an increased FcRn binding provides altering the pharmacokinetics of mAbs. In 2002, Dall'Acqua et al. found that major improvement in FcRn binding occurred when mutations were introduced at positions 252,

254, 256, 433, 434, and 436, which are at the interface of the Fc-FcRn-binding region [225]. More recently, Hinton et al. discovered two mutations, T250Q and M428L, that caused, respectively, a three fold and seven fold increase in FcRn binding and, when combined together, caused a 28-fold increase in FcRn binding [226]. After intravenous administration of the M428L or T250Q/M428L mutant, about a two fold increase in plasma half-life was observed in rhesus monkeys compared with the parental molecule. As these positions are conserved among different human IgG isotypes, the authors proposed that the beneficial effect of these mutations should hold good for other isotypes as well.

As another way to alter the pharmacokinetics of mAbs, there is a PEGylation technology (the process of conjugating polyethylene glycol chains to the antibody fragments) of mAbs. PEGylation of proteins and liposomes has been a time-tested and successful technique that offered the advantage of reducing immunogenicity, increasing the plasma half-life, increasing solubility, and reducing protease sensitivity [227]. Therefore, the science of antibody PEGylation has two primary aims, which are (1) to preserve the antigen-binding activity completely and (2) to link the PEG molecule to the antibody in a stable manner. These aims are achieved by performing site-specific PEGylation using maleimide chemistry. Site-specific PEGylation was done by introducing a free cysteine to the end of the hinge region in a Fab [228] or by incorporating the hinge region on the C-terminus of a Fab and scFv [229]. The increase in half-life observed with PEGylated antibody fragments is usually caused by a prolongation of the distribution phase that represents the redistribution of a molecule in the extravascular environment. It, therefore, appears that PEGylation slows the redistribution of the mAbs from the systemic circulation to the interstitial compartment. In the following section, representative mAbs will be described.

6.3.9.3 Muromonab CD-3 Pharmacokinetics

In 1986, Muromonab CD-3 (OKT-3), which is a monoclonal antibody was first introduced to clinical practice, and the agent has been effective in reversing corticosteroid-resistant acute rejection in renal, liver, and cardiac transplant recipients. OKT-3 is administered only by intravenous injection and has a harmonic half-life of approximately 18 h. It binds specifically to the CD-3 complex, which is involved in antigen recognition and cell stimulation, on the surface of T lymphocytes. Immediately after administration, CD-3-positive T lymphocytes are abruptly removed from the circulation. OKT-3 may be removed by opsonization by the reticuloendothelial system when bound to T lymphocytes, or by human antimurine antibody production [230].

6.3.9.4 Basiliximab Pharmacokinetics

Basiliximab (Simulect) is a chimeric monoclonal antibody for immunoprophylaxis against acute rejection in renal transplantation. Basiliximab is a glycoprotein produced by recombinant technology. It is used to prevent white blood cells from acute renal transplantation rejection. It specifically binds to and blocks the alpha chain of interleukin-2 receptors (IL-2R alpha), also known ascD25 antigen, on the surface of activated T lymphocytes. In 1997, to identify a single-dose regimen providing IL-2R-saturating serum concentrations in the critical first posttransplant month,

Kovarki et al. examined the pharmacokinetic aspects of basiliximab in a multicenter open-label, prospective dose-escalation study [231]. Thirty-two recipients (20 men and 12 women, 47 ± 11 years old, 65 ± 12 kg body weight) of primary mismatched cadaver kidneys were enrolled. The immunosuppression regimen consisted of steroids and azathioprine from day 0 and cyclosporine from day 10. Basiliximab was infused over 30 min as a single dose (40 mg or 60 mg). Peak concentration and area under the concentration versus time curves increased proportionally with dose. Postinfusion concentrations declined in a biphasic manner with a terminal half-life of 6.5 ± 2.1 days. Widely dispersed correlations were noted between body weight and distribution volume (r = 0.29) or between it and total body clearance (r = 0.45), suggesting no clinical relevance for weight-adjusted dosing. Moreover, there were no apparent gender-related differences in basiliximab disposition. As serum concentrations in excess of 0.2 μg/mL are sufficient to saturate IL-2R epitopes on circulating T lymphocytes, the authors concluded that 40 mg and 60 mg of infusion dose was sufficient to keep this threshold level for 26 ± 8 days and for 32 ± 11 days, respectively.

Moreover, Kovarki et al. reported the results of a randomized, open-label prospective study with recipients of primary cadaveric liver allografts to characterize the disposition and immunodynamics of basiliximab for immunoprophylaxis of acute rejection [232]. Patients received a total intravenous dose of 4-mg basiliximab in addition to baseline dual immunosuppression consisting of cyclosporine and steroids. The central volume of distribution was 5.6 ± 1.7 L, with a steady-state volume of 7.5 ± 2.5 L. The total body clearance and elimination half-life were 75 ± 24 mL/h and 4.1 ± 2.1 days, respectively. Basiliximab was measurable in drained ascites fluid, and clearance by this route was an average of 20% of total clearance. Total body clearance correlated positively with the volume of postoperative blood loss (r = 0.5253, p = 0.0101), suggesting that bleeding may represent an additional route of drug removal. More recently, they conducted a population pharmacokinetic screen to identify demographic-clinical covariates of basiliximab in kidney and liver transplantation [233, 234]. In kidney transplantation (169 basiliximab-treated patients), basiliximab clearance was 36.7 ± 15.2 mL/h, distribution volume 8.0 ± 2.4 L, and half life 7.4 ± 3.0 days. Body weight (range, 44–131 kg) and age (range, 20–69 years) each contributed to the variability in clearance and volume. However, gender, ethnic group, and the presence of proteinuria had no clinically relevant influences on basiliximab disposition. Receptor-saturating basiliximab concentrations were maintained for 36 ± 14 days (range, 12–91) when patients received 4-mg basiliximab [233]. On the other hand, in liver transplantation (184 basiliximab-treated patients), basiliximab clearance was 55 ± 26 mL/h, the distribution volume was 9.7 ± 4.2 L, and the half-life was 8.7 ± 6.7 days. Patient weight, age, sex, ethnicity, history of alcoholism, hepatitis C seropositivity, and notable post-operative bleeding had no clinically relevant influences on basiliximab disposition; however, the cumulative volume of drained ascites fluid in the first week was positively correlated with the clearance. Receptor-saturating basiliximab concentrations (≧0.1 μg/mL) were maintained for 38 ± 16 days, which was negatively correlated with the cumulative volume of drained ascites fluid in a week [234]. However, there was no apparent relationship between the incidence or day of onset of acute rejection episodes during CD25 saturation and basiliximab concentration in kidney and liver transplants.

6.3.9.5 Trastuzumab Pharmacokinetics

Trastuzumab (Herceptin) is a monoclonal antibody for human epidermal growth factor receptor 2 (HER2)-positive metastatic breast cancer (MBC). A phase II study by Baselga et al. demonstrated the safety, efficacy, and pharmacokinetics of trastuzumab monotherapy given as first-line treatment once every 3 weeks in women with HER2-positive MBC [235]. Patients received a loading dose of trastuzumab, 8 mg/kg intravenously and then 6 mg/kg at 3-week intervals until disease progression or patient withdrawal. In total, 105 patients received a median of five cycles of therapy. The overall response rate was 19% and the clinical benefit rate was 33%. Median time to progression was 3.4 months. The most common treatment-related adverse events were rigors, pyrexia, headache, nausea, and fatigue. Median baseline left ventricular ejection fraction was 63%. The mean trough levels of trastuzumab in plasma were lower and the peak levels were higher with 3-weekly trastuzumab compared with weekly treatments. The author concluded that administering higher doses on a three-times-per-week schedule did not compromise the efficacy and safety of trastuzumab in women with HER2-positive MBC, and average exposure was similar to that observed with weekly therapy. In addition, a population pharmacokinetic analysis was performed by Bruno et al. to investigate precise aspects of trastuzumab pharmacokinetics [236]. A nonlinear mixed-effect model was applied for the pharmacokinetic data from phase I, II, and III studies of 476 patients. The phase I study enrolled patients with advanced solid tumors. The phase II and III studies enrolled patients with HER2-positive MBC. Patients in the pivotal phase II and III studies were treated with a 4-mg/kg loading dose of trastuzumab followed by 2 mg/kg weekly for up to 840 days. A two-compartment linear pharmacokinetic model best described the data and accounted for the long-term accumulation observed after weekly administration of trastuzumab. Population estimates for total body clearance, volume of distribution of the central compartment, and terminal half-life of trastuzumab were 0.225 L/day, 2.95 L, and 28.5 days, respectively. Interpatient variabilities in the total body clearance and volume of distribution were 43% and 29%, respectively. The number of metastatic sites, plasma level of extracellular domain of the HER2 receptor, and patient weight were significant baseline covariates for total body clearance, volume of distribution, or both. However, these covariate effects on trastuzumab exposure were modest and not clinically important in comparison with the large interpatient variability of CL. Concomitant chemotherapy (anthracycline plus cyclophosphamide, or paclitaxel) did not appear to influence clearance.

6.3.9.6 Infliximab Pharmacokinetics

Infliximab (Remicade) is a chimeric monoclonal antibody against tumor necrosis factor (TNF)-alpha that has shown efficacy in Crohn's disease and rheumatoid arthritis with a disease-modifying activity and rapid onset of action [237]. It is administered intravenously, generally in a schedule with initial infusions at 0, 2, and 6 weeks, followed by administration once every 8 weeks. Infliximab is effective in the treatment of patients with moderately to severely active Crohn's disease with an inadequate response to other treatment options or those with fistulizing disease. In combination with methotrexate, infliximab reduced signs and symptoms and

delayed disease progression in patients with active, methotrexate-refractory rheumatoid arthritis and in those with early disease. However, direct pharmacokinetic trials of infliximab in healthy volunteers or patients are not yet available. Infliximab is predominantly distributed to the vascular compartment and eliminated with a t1/2beta between 10 and 14 days. No accumulation was observed when it was administered at intervals of 4 or 8 weeks Methotrexate may reduce the clearance of infliximab from serum [238].

6.3.9.7 Rituximab Pharmacokinetics

Rituximab (Rituxan) is a B-cell-depleting anti-CD20 chimeric IgG κ monoclonal antibody being investigated for the treatment of rheumatoid arthritis and is approved for the treatment of B-cell lymphoma [239]. Kim et al. investigated pharmacokinetic profiles of rituximab in rabbits following intravitreal administration [240]. After intravitreal injections of 1-mg rituximab, the elimination half-life of rituximab, estimated based on the two compartments, was 4.7 days. Fitting the data to a two-compartment model yielded a clearance from the aqueous humor of 1.2 μL/min. The clearance was less than the reported rate of aqueous humor outflow, indicating that elimination by this route could have been sufficient to account for the disappearance of the drug from the eye. The duration of time over which sustained levels of rituximab were achieved suggests that intravitreal administration warrants further investigation as an approach to treating vitreous and anterior chamber infiltrates in patients with primary intraocular lymphoma. In addition, a population pharmacokinetic analysis of rituximab using a total of 102 patients by Ng et al. [239] demonstrated that body surface area and gender were the most significant covariates for both a total body clearance and a volume of distribution in central compartment. Body surface area alone only explained about 19.7% of the total interindividual variability of the total body clearance. In a simulation study, body surface area-based dosing normalized drug exposure over a wide range of body surface area but did not seem to improve the predictability of rituximab AUC in rheumatoid arthritis patients. Therefore, no rationale for body surface area-based dosing for rituximab in rheumatoid arthritis patients was found.

6.3.9.8 Palivizumab Pharmacokinetics

Respiratory syncytial virus (RSV) infection represents a major cause of pediatric respiratory hospitalizations. RSV is the most common cause of lower respiratory tract infection in infants. Palivizumab (Synagis) is a humanized monoclonal antibody to the fusion protein of RSV, and is active in animal models for prevention of pulmonary RSV replication [241]. Based on a phase I/II multicenter, randomized, double-blind, placebo-controlled, dose escalation trial by Subramanian et al. in premature infants or infants with bronchopulmonary dysplasia, it was found that the mean half-life of 20 days was comparable with that of other immunoglobulin G preparations. Mean trough serum concentrations 30 days after infusion were 6.8, 36.1, and 60.6 μg/mL for the 3-, 10-, and 15-mg/kg dose groups, respectively. Mean serum concentrations of palivizumab that have been shown to produce a 2-log reduction in pulmonary RSV titer in cotton rats were maintained when 10- or 15-mg/kg palivizumab was given every 30 days to pediatric patients at high risk

for serious RSV disease. In addition, based on another phase I/II multicenter, randomized, double-blind, placebo-controlled, dose escalation trial in 99 healthy children hospitalized with acute RSV infection by Saez-Llornes et al., it was found that mean serum concentrations of palivizumab in the 5- and 15-mg/kg groups, respectively, were 61.2 and 303.4 µg/mL at 60 min and 11.2 and 38.4 µg/mL after 30 days. There were no significant differences in clinical outcomes between placebo and palivizumab groups for either dose. A single 15-mg/kg dose achieved serum palivizumab concentrations above the 25–30-µg/mL concentration associated with 2-log reduction of pulmonary RSV titer in the cotton rat model [242].

6.3.10 RECOMMENDATIONS FOR FUTURE STUDY

Recombinant DNA technology has produced many proteins and peptides drugs in large scale, and they are becoming increasingly important as therapeutic agents. The successful development of recombinant proteins depends on the proper characterization of their pharmacokinetics and an understanding of the relationship between drug exposure or dose and the pharmacological response. Although pharmacokinetic characterization of proteins is often complicated because of the absence of a specific assay, difficulties exist in identifying metabolites, endogenous circulating concentrations, and the presence of binding proteins. However, nanobiotechnologically derived formulations for peptide/protein drugs also show some new challenges. Numerous methods have been explored for increasing the residence time of proteins in the systemic circulation or oral bioavailability and enhancing the pharmacological effect. Some of the techniques have been employed to include site-specific mutagenesis, polymer modifications, and fusion with immunoglobulins, targeted through the use of liposomes or conjugation to toxins, radionuclides, and other proteins. In the future, these methods should provide adequate formulations of peptide drugs to increase the successful therapeutic efficacy when formulations are administered through the alternative administration routes.

6.4.1 INTRODUCTION

Since the introduction of recombinant DNA techniques, it is possible to produce proteins on a large scale. These include proteins that are identical or nearly identical to endogenous human proteins, but also foreign proteins like streptokinase and asparaginase. Not only foreign proteins, but also recombinant human protein therapeutics are potentially immunogenic, and indeed most of these products induce antibodies in some patients after a certain period of treatment (see Table 6.4-1 for examples). Patients will first develop binding antibodies (BAbs), and this can be followed by the formation of neutralizing antibodies (NAbs). BAbs usually do not cause major complications, but NAbs bind to the active site of the protein and may interfere with the therapeutic effect. NAbs sometimes also cross-react with the endogenous protein, which can lead to serious complications [3, 4].

This chapter gives an overview of the current knowledge about the immunogenicity of therapeutic proteins. First the mechanisms by which antibodies are formed will be discussed, followed by the factors that can influence the immune response. An assay strategy for the detection of antibodies in human sera is discussed. The

biological and clinical consequences are summarized, and the U.S. Food and Drug Administration (FDA) procedure to handle immunogenicity concerns of novel products is explained. Next, we give some examples of therapeutic proteins with immunogenicity problems, followed by the final conclusions.

6.4.2 IMMUNE MECHANISMS

Depending on the type of therapeutic protein, antibodies can be formed via two pathways (Table 6.4-2): a classic immune response to foreign proteins and breaking of immune tolerance to self-proteins [1].

6.4.2.1 Classic Immune Response

A classic immune response occurs after administration of foreign proteins. Antigen-presenting cells (APCs) will take up the protein, digest it, and present peptides on major histocompatibility complex (MHC)-molecules on their surface. T cells will recognize these peptides in combination with the MHC-molecules and will activate B cells to produce antibodies against the foreign protein. This type of reaction is observed when proteins of animal, microbial, or plant origin are administered to patients. The antibody formation is usually fast, within days to weeks, and often occurs after a single injection. The antibodies are mostly NAbs and persist for a long time.

A classic immune response can also occur on administration of recombinant human proteins to patients with an innate deficiency, e.g., children lacking growth hormone. These children lack the immune tolerance that normally exists for self-proteins.

TABLE 6.4-2. Types of Immune Reaction Against Therapeutic Proteins[1]

	Classic Immune Response	Breaking of Immune Tolerance
Properties of Product	Microbial or Plant Origin	Human Homologue
Characteristics of antibody formation	Fast Often after a single injection High incidence Neutralizing antibodies Long duration	Slow After prolonged treatment Low incidence Mainly binding antibodies Disappear after stopping of treatment and sometimes during treatment
Cause of immunogenicity	Presence of non-self-antigens	Impurities and presence of aggregates Mechanism of antibody formation is unknown
Consequences	Loss of efficacy in most cases	In most patients, no consequences

[1] Taken from Ref. 5.

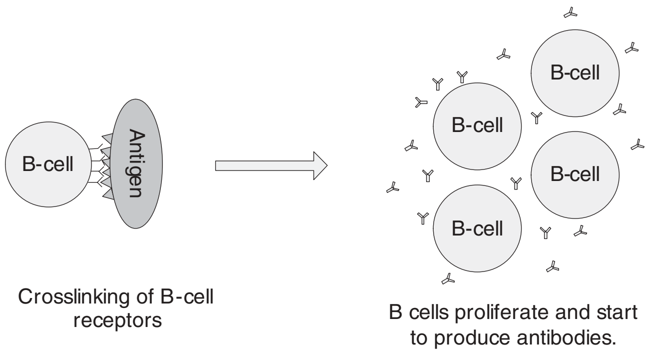

Figure 6.4-1. Schematic representation of a possible mechanism of breaking B-cell tolerance. The antigen contains multiple epitopes that cross-link B-cell receptors. The cross-linking of the receptors is observed as a danger signal because of which the B cells start to proliferate to plasma cells and produce antibodies.

6.4.2.2 Breaking of Immune Tolerance

Most recombinant human proteins are homologous to their endogenous counterparts. The immune system of the patients will therefore recognize the protein as a self-protein, for which the patient is tolerant. Antibody formation against self-proteins can occur through breaking of this immune tolerance. The antibody formation via this process is slow and often becomes apparent only after months of chronic administration of the protein to the patient. Usually the antibodies disappear when treatment is stopped. The exact mechanism of breaking of immune tolerance is not known. Multimeric antigen presentation with a narrow (~5–10 nm) spacing, however, is known to break immune tolerance, possibly by cross-linking of B-cell receptors (Figure 6.4-1). The only natural proteins showing this closely spaced multimeric antigen presentation are microbial antigens, and apparently during evolution, there was a strong selective pressure to react vigorously to this type of antigen presentation [6–8].

6.4.3 FACTORS INFLUENCING IMMUNOGENICITY

Many factors influence the immune response induced by therapeutic proteins. These can be divided into product, patient, and treatment characteristics, and several factors are still unknown.

6.4.3.1 Product Characteristics

Proteins are complex structures consisting of primary, secondary, tertiary, and sometimes quaternary structures. Changes in one of these structural levels might influence the immune response. How a protein is formulated influences the chemical and physical stability of the protein. Therefore the formulation can also influence the immunogenicity. Moreover, contaminants and impurities play an important role.

Primary Sequence. Based on amino acid sequence, no definite predictions about the immunogenicity of a product can be made. A single amino acid change in insulin was enough to elicit a strong immune response [9]. Consensus interferon alpha (co-IFNα), on the other hand, has several amino acid changes as compared with the naturally occurring human IFNαs (10–23 amino acid differences and on average 89% homology with naturally occurring IFNαs), but it has no increased immunogenicity [10]. Foreign proteins, such as streptokinase, staphylokinase, bovine adenosine deaminase, and salmon calcitonin will elicit a classic immune response in patients.

Chemical changes of the primary structure, such as oxidation or deamidation of amino acids, can lead to novel epitopes, which can induce a classic immune response [11]. Moreover, the chemical change can induce aggregation leading to multimeric antigen presentation and, thus, breaking of immune tolerance.

Glycosylation. Glycosylation is a common posttranslational modification and is cell and species specific. The glycans can differ in chain length, sequence, and linkage position to the peptide backbone [12]. Endogenous proteins often consist of several glycosylated isoforms [13]. The carbohydrates can play a role in molecular stability, *in vivo* activity, serum half-life, and immunogenicity. Carbohydrates can decrease the immunogenicity of therapeutic proteins, by shielding immunogenic epitopes [12, 14] or by increasing the solubility of the protein and thereby preventing aggregation [15].

Production of therapeutic proteins in plants is being developed, but concerns are raised about the immunogenicity of plant glycans. Glycosylation of proteins in plants and humans differ in fine detail [16]. Especially the plant-specific α(1,3)-fucose and β(1,2)-xylose groups are considered immunogenic in humans [12]. Metabolic engineering of the plant N-glycan biosynthesis pathway is being pursued to prevent the insertion of these sugars in the glycan chains [16].

PEGylation. The most successful approach to increase the mean plasma half-life of proteins is by chemically coupling poly(ethylene glycol) (PEG) moieties to the protein. The attachment of PEG (PEGylation) decreases the overall rate of clearance of the protein, shields the protein from proteolytic enzymes, and masks immunogenic sites [17, 18]. The PEG molecules can differ in conjugation type, molecular weight, and conformation (i.e., linear, branched, or multiple-branched) [19]. PEGylation can decrease the immunogenicity of a therapeutic protein by blocking antibody binding sites, promoting solubility, and permitting less frequent dosing [20]. Branched PEG is more effective than linear PEG in improving the immunological properties of the protein [21]. Although in most cases PEGylation decreases the immunogenicity of a therapeutic protein, two examples of therapeutic proteins are known in which the PEGylated protein was more immunogenic than the non-PEGylated variant: PEGylated recombinant human megakaryocyte growth and development factor (PEG-rhMGDF) [4] and recombinant methionyl human tumor necrosis factor binding protein PEGylated dimer [22]. The reason for this increased immunogenicity is not known, but it might be related to the increased plasma half-lives, which leads to prolonged exposure to the immune system.

Impurities and Contaminants. Recombinant proteins can be produced in different expression systems, each having advantages and disadvantages [16]. Impurities from the expression systems can be of influence on the immunogenicity of the final product. They can act as adjuvants or be immunogenic themselves [11]. Patients receiving *Escherichia coli*-derived granulocyte-macrophage colony-stimulating factor (GM–CSF) were shown to develop antibodies to GM–CSF as well as *E. coli* proteins [23].

Secondary Structure. Many studies have shown the importance of aggregation in inducing and/or increasing an immune response [24–27]. Aggregation usually occurs after partial unfolding of the protein due to, e.g., shear/shaking or high temperature [28]. Aggregation may expose new epitopes on the surface of the protein for which the immune system is not tolerant. This will lead to a classic immune response. Aggregation can also lead to multimeric antigen presentation, which is known to break B-cell tolerance. Therefore, assessing the presence of aggregates in protein formulations is considered to be very important, although not all aggregates will induce an immune response as was shown in our laboratory [29]. The analytical tools for characterizing the aggregates in a formulation are described elsewhere in this book.

6.4.3.2 Patient Characteristics

Patient characteristics, such as genetic background and the disease status, are known to influence rate and type of immune reactions [11]. Hemophilia patients with severe genetic defects are more prone to antibody formation than patients with minor genetic defects [30, 31]. Eprex (Ortho Biotech, Tilburg, The Netherlands) associated pure red cell aplasia (PRCA) was only observed in patients with renal failure and not in cancer patients [32].

6.4.3.3 Treatment Characteristics

Also the treatment characteristics can have an influence on the immunogenicity of therapeutic proteins. Usually antibodies are only induced after prolonged treatment of the protein. The intramuscular (i.m.) route of administration is less immunogenic than subcutaneous (s.c.) administration. Intravenous (i.v.) administration usually is the least immunogenic route of administration.

6.4.3.4 Other Factors

When evaluating the immunogenicity of therapeutic proteins, one also has to consider the immunomodulatory effects of the protein. For instance, IFNα may increase the antibody production because of its innate immunomodulatory effects [33]. The timing of blood sampling may influence the amount of antibody present in the sera. If a blood sample is taken too early after the administration of the protein, antibodies can still be complexed to the antigen and the sample may prove to be false-negative. If the sample is taken too long after the last injection, antibodies may already have disappeared [34].

6.4.4 DETECTION

Detection of antibodies can be done by several methods (Table 6.4-3). As there are no standardized assays for antibodies to most products and laboratories mostly use their own in-house methods, comparison of results from different studies is in principle impossible. Ideally, a combination of standardized assays should be performed to ensure that all possible types (low affinity and high affinity, classes and isotypes, binding and neutralizing) of antibodies are detected.

6.4.4.1 Assays

Antibody assays can be divided into two main categories: binding assays and bioassays. The binding assays detect in principle any antibodies with sufficient affinity

TABLE 6.4-3. Advantages and Disadvantages of the Most Commonly Used Assays to Detect Binding Anti-Drug Antibodies in Patient Sera[1]

Type of Assay/ Method	Advantages	Disadvantages
ELISA (bridging format; coating with drug and detecting with labeled drug)	• Detection of all isotype responses • Species independent • High throughput • Easy to use • Good sensitivity	• Low-affinity antibodies may be missed • Epitopes may be masked by immobilization • Protein conformation may becompromised by immobilization • Antibody classes/isotypes are not discriminated
ELISA (direct format; coating with drug and detecting with labeled anti-Ig	• High throughput • Easy to use • Good sensitivity • Isotype detection possible (by using isotype specific conjugates)	• Immobilization • Protein conformation may be compromised by immobilization • Low-affinity antibodies may be missed
ELISA (indirect format; coating with a specific Mab or biotin and then drug)	• Coating plate with specific MAb keeps drug in oriented position • Consistent coating and epitope exposure	• MAb should not alter epitopes' accessibility • MAb epitope should be clinically irrelevant • Isotype detection determined by conjugate • Species specificity determined by conjugate • Low-affinity antibodies may be missed
Radioimmuno (precipitation) assay (RIP/RIA)	• Solution phase, which retains the conformation of the antigen • Moderate-to-high throughput • Generally good sensitivity	• Uses radioactivity • Conjugation chemistry might degrade or alter molecule • May trap labeled drug nonspecifically in precipitate

TABLE 6.4-3. *Continued*

Type of Assay/ Method	Advantages	Disadvantages
Immunoblotting	• Dissects the specificity of the antibodies • Profile of reactivity against subcomponents of the product • Sensitivity is good	• Nonquantitative • Low throughput • Conformational epitopes are missed
Surface plasmon resonance	• Solution phase, which mostly retains the conformation of the antigen • Automated • No detection conjugate required • Not species-specific • Detection of all isotypes • Determination of association and dissociation constants • Enables detection of low-affinity antibodies	• Linking chemistry may affect molecule or mask epitopes • Regeneration step may degrade molecule • Low throughput • Requires dedicated equipment • Sensitivity usually lower than ELISA or RIA (except for low-affinity antibodies)

[1] Adapted from Refs. 35 and 36.

for the therapeutic protein. A bioassay tests whether the antibodies detected by the binding assay can neutralize the biological effects of the therapeutic protein. In most cases, BAbs have no clinical effect, but the binding assay is used as a screening tool to identify samples with possible neutralizing activity.

Binding Assays. Several binding assays are available that can detect antibodies against therapeutic proteins, with solid phase binding assays being the most commonly used for antibody detection. Table 6.4-3 summarizes the advantages and disadvantages of the most commonly used techniques. The advantage of surface plasmon resonance over the other methods is the possibility to measure the binding of the antibodies in real time, which gives information about the affinity of the antibodies. Figure 6.4-2 shows a sensorgram of sera containing antibodies with different association and dissociation profiles. A Western blot gives information about the specificity of the antibodies in the serum and may show antibodies to impurities as was shown in patients receiving GM–CSF [23]. For a more detailed description of these methods, we refer to specialized literature [35–37].

Neutralizing Assays. The detection of neutralizing antibodies is performed in assays that can show inhibition of the biological activity of the therapeutic protein. In general this will be a bioassay. The therapeutic protein is incubated with the serum to be tested, and the mixture is tested in the bioassay. If the antibodies in the serum have neutralizing capacities, the biological activity of the mixture is reduced, as compared with the pure therapeutic protein.

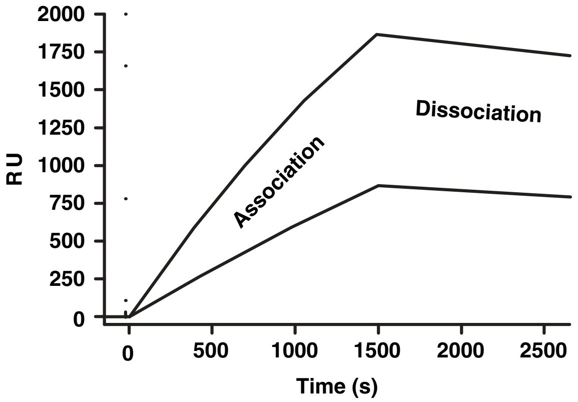

Figure 6.4-2. Sensorgram obtained with a BIAcore 3000 using anti-rhIFNα2b sera with different association and dissociation profiles.

6.4.4.2 The Design of an Assay Strategy

Long-term studies are needed to fully assess the immunogenicity of a product. Also, the timing of sampling is important. A pretreatment blood sample should be taken, and several time points should be considered because antibodies may be induced only after prolonged treatment. If a sample is taken too early after administration of the therapeutic protein, the circulating protein may interfere with the antibody assay [9]. Conversely, if the sampling is too long after the last administration of the protein, antibody levels might already have dropped below the detection limit of the assays. Both situations will lead to an underestimation of the incidence of antibody positive patients.

To fully assess the immunogenicity of a therapeutic protein, a combination of assays is necessary. In general, sera are screened first by an enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay (RIA) type of binding assay, which have a high through-put and are easy to perform. A screening assay is optimized for sensitivity and therefore suffers from a relative high number of false-positive results. So, all initial positive sera should be confirmed, e.g., by showing a reduced binding after adding the product to the serum. The confirmed positive sera are then tested for neutralizing activity. Further characterization of the antibody response may follow to determine isotype, affinity, and so on. Whatever approach is used, it is important to validate the assays to show reproducibility, precision, robustness, and so on [35, 38]. International reference preparations are only available for a limited number of assays, but they are crucial for making comparison between different laboratories possible [39].

6.4.4.3 Predictive Models

Most of the data about immunogenicity of therapeutic proteins come from clinical trials or postmarketing surveillance. It would of course be better if the immunogenicity of a product could be predicted before the clinical phase of development.

Conventional Animals. Conventional animal models may be useful to predict the immunogenicity of microbial products as staphylokinase and streptokinase, which are foreign proteins for humans as well as animals [40]. Conventional animals can also be used if the therapeutic protein shows a high degree of intraspecies sequence homology. An example is human thrombopoietin, which induced neutralizing antibodies in animal models as well as in patients [41]. However, most recombinant human therapeutic proteins are foreign proteins for animals that will elicit an immune response in all cases. So their predictive value for the immunogenicity of human proteins in humans is low. Nonhuman primates that share a higher level of sequence homology with humans have been shown to be excellent models for some products such as human growth hormone and lys-pro insulin [42], but for other proteins, their predictive value has shown to be limited.

Immune Tolerant Animals. In most cases, the induction of antibodies to human therapeutic proteins in patients is based on breaking B-cell tolerance. This process makes animals tolerant for the protein the best model for predicting immunogenicity in humans. Mice are the species of choice to induce tolerance, which can be achieved by chronic administration of the protein in large quantities [43] or by making the animals transgenic for the gene expressing the protein [44]. Obvious drawbacks of the first method are the large quantities of protein required and the need for testing the tolerance of each animal. Mouse lines expressing the transgene only need to be evaluated for immune tolerance once and only need testing by polymerase chain reaction (PCR) to identify transgene positivity after breeding. Transgenic animals, immune tolerant for insulin [45], tissue plasminogen activator (tPA) [46], IFNα2 [26], and IFNβ [47] are available. The insulin and tPA models were used to evaluate whether amino acid substitutions in the protein introduced new epitopes [43, 44]. The interferon models were used to study the effect of aggregates and other degradation products on immunogenicity [26, 29, 47].

Some therapeutic proteins might have immune modulatory effects that influence the induction of antibodies. If the human protein lacks this effect in mice, their predictive value may suffer. This deficiency can be prevented by challenging both the human as well as the murine homologue. Braun et al. showed that mixtures of murine and human IFNα2a caused an increase in immune response in wild-type mice to the human protein [26]. Another point of consideration when using transgenic mice as predictors for immunogenicity is the difference between mouse and human MHC and their presentation of T-cell epitopes [39, 41]. Also, important individual patient characteristics, such as disease burden and concomitant therapy influencing the antibody response, are difficult to reproduce in the transgenic immune-tolerant animal model. Although these models will never become predictors of the individual patient's antibody response, they will be very useful in the development phase of a new protein therapy or after a formulation or production change. The transgenic immune-tolerant mice can also be used to study the mechanism of antibody induction, because they share tolerance for the protein with patients.

6.4.4.4 Prediction on Basis of Structure and Sequence

Other strategies, based on structural analysis, have been described to predict the immunogenicity of therapeutic proteins. Immunogenic epitopes can be predicted

based on amino acid sequence analysis and MHC-binding. Modifications in an immuno-dominant T-cell epitope by a single amino acid was reported to reduce the immunogenicity of rhIFNβ-1b in BALB/cByJ mice [48]. Analysis of B-cell epitopes is more difficult, but it is also ongoing [49]. These types of analyses may help to reduce the immunogenicity, in case the product is a foreign protein inducing a classic immune response. As discussed, in most of cases, the induction of antibodies in patients is based on breaking B-cell tolerance. Although the exact mechanism is still unknown, we know that the product quality, independent of the amino acid sequence, plays an important role.

6.4.5 BIOLOGICAL AND CLINICAL CONSEQUENCES

The clinical effects of antibody formation vary from no effect to severe life-threatening situations [50]. Binding antibodies can alter the pharmacokinetic properties of the therapeutic protein [51, 52]. Neutralizing antibodies cannot only affect the pharmacokinetics but also block the pharmacological effect of the therapeutic protein [51–53]. Severe side effects occur if NAbs cross-react with an endogenous protein, as was observed for PEG–rhMGDF and recombinant human erythropoietin (epoetin). Patients receiving PEG–rhMGDF developed NAbs cross-reacting with endogenous thrombopoietin, which resulted in a severe thrombocytopenia [4]. Patients receiving Eprex (an epoetin formulation marketed in Europe, Canada, and Australia) developed NAbs that cross-reacted with endogenous erythropoietin, resulting in PRCA [3]. The number of patients with antibody-mediated PRCA rapidly increased after a formulation change of Eprex, as will be discussed below. Besides the formation of antibodies, allergic reactions can occur.

6.4.6 A RISK-BASED APPROACH OF IMMUNOGENICITY

The FDA evaluates immunogenicity concerns of novel products in development and for major changes in manufacturing or clinical uses via a risk-based approach. A schematic representation of this approach is given in Figure 6.4-3. Three elements are considered important for the risk assessment strategy: the severity of consequences of the immune response to a therapeutic protein, host-specific factors that impact the immunogenicity positively or negatively, and product-specific factors that impact the immunogenicity positively or negatively. Based on their expertise and literature data from marketed products, the FDA decides whether immunogenicity testing should be performed before or during clinical trials.

6.4.7 EXAMPLES

6.4.7.1 Epoetin: How a Formulation Change Increased the Immunogenicity

Erythropoietin is a protein produced by the kidneys that stimulates the production of erythrocytes. Epoetin is mainly used in patients suffering from anemia associated with chronic renal failure or cancer. Three forms of epoetin are commercially

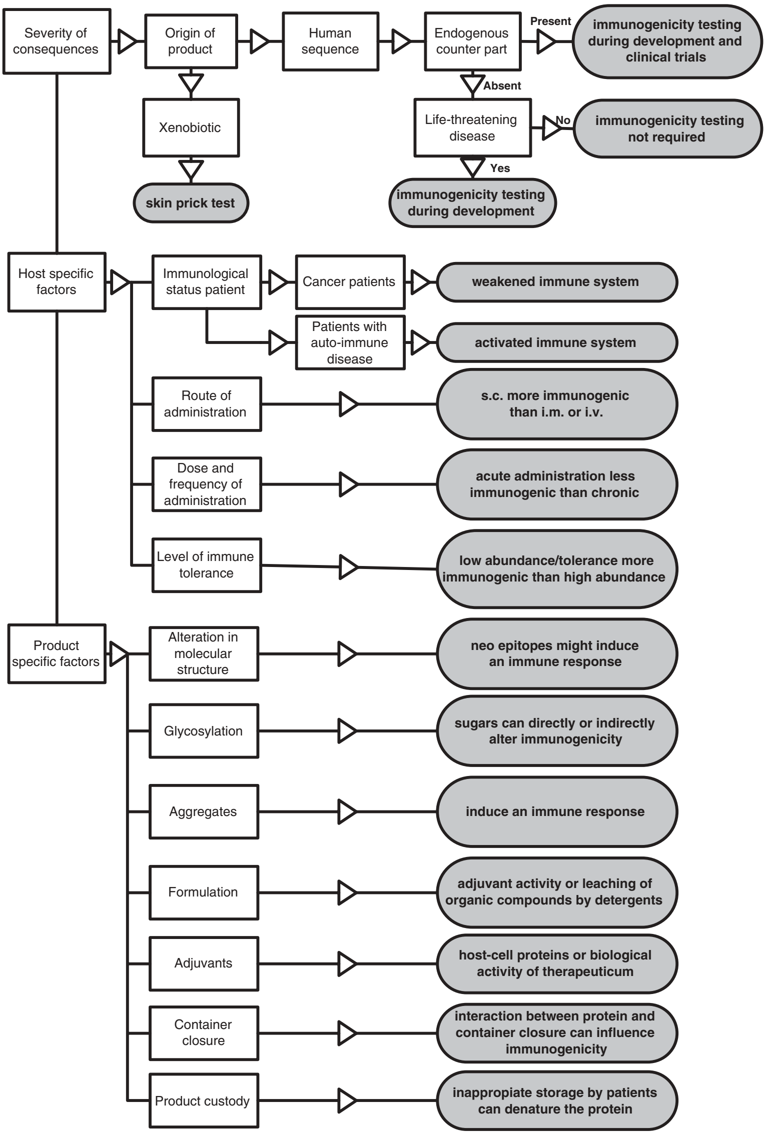

Figure 6.4-3. Schematic representation of the risk-based approach that the FDA uses for novel products in development and for major changes in manufacture and clinical use of licensed products. Adapted from Refs. 54 and 55.

available, epoetin alfa, epoetin beta, and darbepoetin alfa, which is a hyperglycosylated analog [32]. In 1997 the first patient with antibody-mediated PRCA was reported [56]. Antibody-mediated PRCA is caused by antibodies induced by exogenous epoetin that cross-react with endogenous erythropoietin. In 2002, 13 patients were reported that had developed antibody-mediated PRCA, after administration of Eprex [3]. These cases occurred after 1998. Since then, more patients with antibody-mediated PRCA were identified. In 1998 the formulation of Eprex was changed: Human serum albumin (HSA) was replaced by glycine and polysor-

bate 80. Several hypotheses have been postulated to explain the increase in PRCA cases. Hermeling et al. hypothesized that some epoetin molecules were solubilized in micelles, which might have led to multimeric antigen presentation [57]. Others claim that the polysorbate 80 extracted leachates out of the uncoated rubber stoppers, which had an adjuvant effect, leading to an increase in antibodies [58]. An adjuvant, however, can only increase an existing immune response and cannot break B-cell tolerance by itself. It will be very diffcult to pinpoint the exact cause of the increased number of PRCA cases. In 2002, actions were taken to decrease the number of PRCA cases: emphasizing strict adherence to storage and handling conditions, the introduction of a contraindication for s.c. administration of Eprex in chronic renal failure in many countries and the introduction of coated rubber stoppers. These actions decreased the number of patients with antibody-mediated PRCA, but the question remains of what exactly caused the increased immunogenicity.

6.4.7.2 RhIFNβ: Immunogenicity of Glycosylated and Nonglycosylated Variants

Interferon beta is a cytokine with anti-inflammatory, antitumor, antiviral, and cell-growth-regulatory effects. It is mainly produced by macrophages and epithelial and fibroblast cells [59, 60]. Administration of rhIFNβ has been established as a treatment for relapsing-remitting multiple sclerosis [60]. Natural hIFNβ is glycosylated, contains 166 amino acids, and has a molecular weight of approximately 25 kDa [38]. Three forms of rhIFNβ are available on the market (Table 6.4-4). RhIFNβ-1a (Rebif and Avonex) has an amino acid sequence similar to that of endogenous hIFNβ, is produced in Chinese hamster cells, and is glycosylated. RhIFNβ-1b (Betaseron) is produced in *E. coli* and thus not glycosylated. Moreover, Cys-17 has been mutated to Ser-17 and the N-terminal methionine is lacking.

All three formulations induce neutralizing antibodies of the IgG-type, reducing the efficacy of the therapy [24, 61–63]. The antibodies are usually detectable after the first 6 to 12 months of the treatment [61, 63], but the clinical effects do not appear until after 18–24 months after the start of the treatment [64]. RhIFNβ-1b induces antibodies in more patients than does rhIFNβ-1a [59, 65]. This increased incidence of immunogenicity of rhIFNβ-1b as compared with rhIFNβ-1a is probably due to the lack of glycosylation, which makes the protein more prone to aggregation. Size-exclusion chromatography showed that 60% of rhIFNβ-1b in Betaseron is heavily aggregated [15]. It was shown that Betaseron can break the tolerance of transgenic immune tolerant mice [47], which suggests that these animals may be predictive for the immunogenicity observed in patients.

TABLE 6.4-4. Currently Marketed rhIFNβ Formulations

rhIFNβ-1a	rhIFNβ-1b[1]
Avonex (Biogen-Idec, Cambridge, MA)	Betaseron (Berlex Laboratories, Montville, NJ)
Rebif (Serono, Rockland, MA)	Betaferon (Schering, Berlin, Germany)

[1] Betaseron and Betaferon are the same formulations, marketed by two companies.

6.4.7.3 RhIFNα2: Reduction of the Immunogenicity by Optimizing Production and Formulation

RhIFNα2 is used for the treatment of a variety of malignancies and viral diseases [66]. It inhibits viral replication, increases class I MHC expression, stimulates Th1 cells, and inhibits proliferation of many cell types [2]. Two regular and two PEGylated forms of rhIFNα2 are on the market (Table 6.4-5). The PEGylated forms are less immunogenic than the non-PEGylated forms. RhIFNα2a and rhIFNα2b only differ in 1 amino acid. RhIFNα2b is produced in *E. coli* cells, which implies that the protein is nonglycosylated. Natural hIFNα2 is O-glycosylated [67]. Patients receiving rhIFNα2a initially produced higher levels of antibodies and at higher incidences than rhIFNα2b. This difference was shown not to be related to the difference in amino acid sequence. The antibodies induced by rhIFNα2a fully cross-react with rhIFNα2b and vice versa [68]. Co-IFNα is a non-naturally occurring synthetic recombinant type I interferon. Its amino acid sequence (166 amino acids) is created by taking for each position the amino acid most commonly observed in 13 IFNα subtypes. Despite the nonsimilarity of co-IFNα with human IFNα species (10–23 amino acid differences and on average 89% homology with naturally occurring IFNαs) [69], the number of patients producing antibodies against co-IFNα is similar to the number of patients producing antibodies after rhIFNα2b treatment [70].

Table 6.4-6 shows that optimization of the production and formulation process decreases the immunogenicity [34]. Storing the formulation at room temperature

TABLE 6.4-5. Currently Marketed rhIFNα2 Formulations

[3] Formulations A–C were made before the production process was fully optimized and therefore also contained oxidized rhIFNα2a [72]. Formulations D and E contained ultra-pure material.

leads to oxidation and increases the immunogenicity of a rhIFNα2a formulation (formulation A vs. formulation B). Better purification methods further reduce the immunogenicity (formulation C vs. formulations D and E). Formulations A–C were shown to contain aggregates responsible for the increased immune response [26].

Recently it has been shown that not all aggregates, but only aggregates of rhIFNα2b with a native-like structure, can elicit an immune response in transgenic mice immune tolerant for hIFNα2 [71]. It was also shown that not the oxidation, but the aggregation, accompanying the oxidation was the reason for the immunogenicity.

6.4.8 CONCLUSIONS

Many factors influence the immune response against therapeutic proteins. Unfortunately, it is still impossible to fully predict the immunogenicity of a therapeutic protein before going into clinical trials. The presence of (native-like) aggregates in a formulation is one main factor known to increase the immune response. Formulation changes might have an effect on the immunogenicity as was observed for epoetin and rhIFNα2a. The effect of a formulation change is also difficult to predict, but it can be evaluated in immune-tolerant transgenic mice. Although these tests will not fully predict the immunogenicity of a product, it can give information about the immunogenicity of a new formulation/product as compared with previous formulations/products. As most therapeutic proteins only induce antibodies in a small number of patients, postmarketing surveillance is important. Also basic studies to link physical–chemical properties with immunogenicity are important, and these studies may avoid animal testing in the future.

6.5.1 INTRODUCTION

This laboratory is investigating a drug targeting strategy that employs anti-drug antibodies to increase drug binding in blood, minimize systemic unbound drug exposure, and reduce the systemic drug toxicity after intraperitoneal (i.p.) chemotherapy [1, 2]. The approach uses i.p. administration of an anticancer drug with

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.
Copyright © 2007 John Wiley & Sons, Inc.

simultaneous intravenous (i.v.) administration of anti-drug antibodies, where the antibodies are employed to impart regio-specific alterations in drug disposition.

To test the feasibility of this approach, earlier studies in this laboratory used methotrexate (MTX) as a model drug [2, 3]. Pharmacokinetic investigations demonstrated that systemic administration of polyclonal anti-MTX Fab with i.p. administration of MTX led to a decrease in the systemic exposure of unbound MTX, while not altering peritoneal exposure [2]. To facilitate further evaluation of anti-MTX antibodies on MTX induced toxicity, monoclonal anti-MTX IgG and Fab were produced and purified [4]. Subsequent studies demonstrated that after this combination therapy, anti-MTX Fab could allow a fivefold increase of the maximum tolerated dose of i.p. MTX and enhance the median survival time of mice bearing peritoneal tumors [5].

Based on these promising results, we have proposed to apply this targeting strategy to enhance the selectivity of i.p. topotecan (TPT) chemotherapy, as TPT has been shown to be the most active second-line therapy for refractory, metastatic ovarian cancer [6–9]. To facilitate testing hypotheses related to i.p. TPT chemotherapy, it was necessary to develop anti-TPT antibodies. Relative to polyclonal antibodies, monoclonal antibodies would demonstrate more reproducible properties (i.e., affinity and specificity) and may be more feasibly produced in large quantities. In this chapter, we describe the development of hybridomas secreting monoclonal antibodies against TPT, and the production, purification, characterization, and pharmacokinetics of an anti-TPT monoclonal antibody and of monoclonal anti-TPT Fab fragments.

6.5.2 MATERIALS AND METHODS

6.5.2.1 Development of Hybridomas Secreting Anti-TPT Antibodies

Preparation and Characterization of KLH-TPT Immunogen. Topotecan was provided by Drug Synthesis & Chemistry Branch, Developmental Therapeutics Program, Division of Cancer Treatment and Diagnosis, National Cancer Institute, National Institutes of Health (Bethesda, MD). TPT was conjugated to keyhole limpet hemocyanin (KLH) via the Mannich reaction using Pierce PharmLink Immunogen Kit (Pierce, Rockford, IL). Briefly, 0.9-mg TPT was linked with 2-mg KLH by condensation with formaldehyde. The reaction was incubated at 50°C overnight, followed by dialysis against PBS (pH 7.4) for 2 h, and then at 4°C overnight. The synthesized immunogen was further diluted by PBS to a final concentration of 1 mg/mL. The degree of conjugation was estimated by ultraviolet (UV) spectroscopy at 411 nm for topotecan and at 280 nm for KLH.

Development of Hybridomas that Secrete Anti-TPT Antibodies. Approximately 100-μg KLH–TPT was dissolved in PBS and emulsified with an equal volume of Freund's incomplete adjuvant (Sigma, St. Louis, MO). Female Balb/c mice (Harlan, Indianapolis, IN) were immunized with 200-μL emulsion by i.p. injection every 3 weeks. Animals were bled via the saphenous vein 7 days after each dose of KLH–TPT. Whole blood was collected and centrifuged. The resulting plasma was used to assess anti-TPT activity via a previously validated HPLC assay [10]. Briefly, plasma was diluted with PBS and incubated with 250-ng/mL TPT for 2 h. Free TPT

was then separated from bound TPT through ultra-filtration using Centrifree tubes (10-KD molecular-weight cutoff; Bellerica, MA). The high-performance liquid chromatography (HPLC) assay employed an isocratic mobile phase of a mixture of 10-mM KH_2PO_4 water–methanol–triethylamine (72:26:2, v/v/v, pH 3.5), with fluorescence detection at an excitation wavelength of 361 nm and an emission wavelength of 527 nm. Blank mouse plasma was used as the control. The mouse with the highest activity (i.e., the lowest ratio of free TPT to that of control) was sacrificed, and the spleen was aseptically removed.

Spleen cells were obtained by teasing the spleen apart with forceps and by passing tissue fragments through a stainless steel screen. The spleen cells were washed in RPMI media (Invitrogen, Grand Island, NY) twice by centrifugation at 500*g* in tabletop centrifuge (International Equipment Co., Needham, MS). Myeloma cells, SP2/0-Ag 14 (ATCC, Manassas, VA), were washed once in RPMI. Spleen cells were mixed with myeloma cells and centrifuged. The cell pellets were carefully suspended in 1-mL 50% poly(ethylene glycol) (PEG, Sigma) for 1 min by gently swirling in 37°C water. Cells were diluted and washed again in RPMI media by centrifugation and then resuspended in RPMI HAT (hypoxanthine, aminopterin, and thymidine) medium (Invitrogen) with 10% fetal bovine serum (Invitrogen). Cells suspended in HAT medium were dispensed into the wells of several 96-well plates, which were then incubated at 37°C. Clones, which became visible in 2–3 weeks, were then transferred into the wells of 24-well plates.

Screening of Anti-Topotecan Activity by HPLC Assay. Anti-TPT activities within cell culture supernatants were assessed via HPLC, using similar methods as described above. Initial screening was conducted by pooling six hybridoma supernatants together, and the pooled culture supernatants (195 µL) were incubated with 5 µL of TPT solution (in saline) to a final concentration of 25 ng/mL for 2 h. Unbound TPT was separated from bound TPT through ultra-filtration and then quantified by HPLC. The lower limit of quantitation (LOQ) for TPT was 0.02 ng on column (corresponding to 1 ng/mL in 20-µL samples). Blank RPMI HAT media spiked with TPT was used as a control. After demonstration of binding from pooled supernatants, the individual wells from that pool were further tested as described above.

6.5.2.2 Characterization of Anti-Topotecan IgG (ATI)

Isotype and Binding Affinity/Capacity of ATI. The isotypes of secreted antibodies were determined through the use of a mouse monoclonal antibody isotyping kit (Cell Sciences, Norwood, MA). An anti-TPT IgG1 antibody (ATI), secreted by hybridoma 8C2, was selected for further characterization. The 8C2 supernatant (with a constant ATI con-centration) was incubated with increasing concentrations of TPT (100, 125, 150, 175, 200, 225, and 250 ng/mL) for 2 h to allow binding between TPT and ATI. Free TPT was then separated from antibody-bound TPT by ultra-filtration and assayed via HPLC.

The concentration of bound TPT was calculated by subtracting the measured unbound TPT concentration from the known total TPT concentration. TPT–ATI binding was characterized through the construction of Woolf and Rosenthal binding plots, according to the relationships:

$$\frac{F}{B} = \frac{1}{K_A \times nPt} + \frac{F}{nPt} \text{ and } \frac{B}{F} = nPt \times K_A - K_B \times B$$

respectively. In each equation, B represents the molar concentration of TPT bound to ATI, F is the molar concentration of unbound TPT, K_A is the equilibrium association constant (i.e., a measure of binding affinity), and nPt is the total antibody binding capacity. Initial estimates for K_A were determined as the inverse of the intercept times the slope of the Woolf plot or as the negative slope of the Rosenthal plot. The TPT binding capacity (nPt) was calculated as the inverse of the slope of the Woolf plot or as the negative ratio of intercept over slope of the Rosenthal plot. Final parameter estimates were determined by fitting the parameters of the equation:

$$B = \frac{nPt \times F}{1/K_A + F}$$

to the unbound and bound TPT concentration data using WinNonLin v.2.1 software (Pharsight, CA).

6.5.2.3 Production and Purification of ATI and ATF

Production of ATI. The hybridoma cells secreting ATI were grown in serum-free medium supplemented with 0.5% gentamicin (Hybridoma SFM, Invitrogen). Large quantities of ATI were produced using a Unisyn Cell Pharm hollow fiber bioreactor (10 ft^2, 10-KDa molecular-weight cutoff, BioVest International, Minneapolis, MN). Briefly, seed hybridoma cells were first grown in culture within 1-L spinner flasks kept in a CO_2 incubator (Model 2100, VWR, West Chester, PA). Approximately 1 $\times 10^9$ hybridoma cells in 60 mL of serum-free medium were loaded aseptically into the extracapillary space of the bioreactor cartridge. The temperature was maintained at 37°C, and RPMI 1640 medium (Fisher, Pittsburgh, PA), supplemented with 5-g/L glucose and 5-mg/L gentamicin, was fed into the intracapillary space. Medium containing the anti-TPT monoclonal antibody was harvested from the extracapillary space at a rate of 30–75 mL/day and was replaced with fresh serum-free medium. The collected media were centrifuged for 10 min at 7000 rpm and filtered with a sterile 0.22-µm cellulose acetate bottle-top filter (Corning) before purification.

Purification of ATI. ATI was purified from culture medium via protein-G affinity chromatography (HiTrap Protein-G, Pharmacia, Piscataway, NJ) using an automated BioLogic medium-pressure chromatography system (Bio-Rad, Hercules, CA). Briefly, culture medium was loaded onto the column, which was then washed with 20-mM Na_2HPO_4 (pH 7.0), and antibody was eluted using 100-mM glycine buffer (pH 2.8). The ATI concentrations were assessed by UV absorbance at 280 nm, with the assumption that 1-mg/mL ATI corresponds to 1.35 AU [11].

Production and Purification of Anti-TPT Fab (ATF). ATF was prepared by papain digestion of ATI. Briefly, ATI at a concentration of 5 mg/mL in sodium acetate buffer (pH 5.5) was incubated in 37°C water in the presence of papain, cysteine, and ethylene diamine tetraacetic acid (EDTA) for 6 h. The reaction was stopped by the addition of incubation of 305-mg iodoacetamide, and subsequent

incubation with the reaction mixture for 30 min. The digested mixture was dialyzed against 5-mM KH_2PO_4 (pH 6.0) overnight. ATF fragments were then purified from the dialysate by hydroxyapatite chromatography (BioRad) with 5-mM KH_2PO_4 (pH 6.0) as loading buffer and 400-mM K_2HPO_4 (pH 6.0) as elution buffer. The concentration of ATF was also assessed by UV absorbance as described above.

Assessment of Antibody Purity by SDS-PAGE. The purity of ATI and ATF was assessed through sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS–PAGE) using a 10% polyacrylamide gel with a 4% stacking gel. Purified ATI (2 µg), purified ATF (2 µg), and the ATI digest mixture were prepared in a nonreducing sample buffer and boiled for 5 min. Samples were then loaded on the gel, and electrophoresed at 140 V for 15 min and 200 V for 35 min. The gel was stained with Coomasie blue R-250 (Bio-Rad) and destained with 40% methanol/10% acetic acid overnight, and the migration distances of ATI and ATF were compared with the migration distances of molecular-weight standards (MW-SDS-200, Sigma).

6.5.2.4 Development of ELISA for Quantification of ATI and ATF in Rat Plasma

Using a similar approach as described by Hansen and Balthasar [12], a species-specific ELISA was developed to quantify ATI and ATF in rat plasma. Briefly, goat anti-mouse IgG (250 µL, 1 : 500 dilution with 20-mM Na_2HPO_4 buffer, no pH adjustment, Sigma) was immobilized on Nunc Maxisorp 96 well microplates (Roskilde, Denmark) overnight at 4°C. On the next day, wells were washed with phosphate buffer containing 0.05% Tween (Sigma) to remove unbound protein, 250 µL of standards or quality control (QC) samples were then added, and the plates were incubated for 2 h. The wells were washed again and incubated with 250 µL of 1 : 500 diluted Fab-specific goat anti-mouse antibody-alkaline phosphatase conjugate (in 20-mM Na_2HPO_4 buffer, no pH adjustment) for 1 h. After washing, 200 µL of p-nitro phenyl phosphate (Pierce), 4 mg/mL in diethanolamine buffer (pH 9.8), was added and the change of absorbance at 405 nm was monitored with a micro-plate reader (Spectra Max 250; Molecular Devices, Sunnyvale, CA).

Standard curves were constructed by plotting the change in absorbance with time (dA/dt) versus concentration of ATI or ATF. Standards for the assay were prepared by dilution of stock solutions of ATI or ATF to the appropriate concentrations (0, 25, 50, 100, 175, and 250 ng/mL for ATI; 0, 5, 10, 20, 50, and 100 ng/mL for ATF) with PBS (pH 7.4), with the addition of 1% (v/v) blank rat plasma. Assays were validated with respect to precision and accuracy, by analysis of QC samples at 25, 100, 250 ng/ml for ATI and 5, 20, 100 ng/ml for ATF, respectively. Intra-assay and inter-assay variability were determined through the analysis of QC samples.

6.5.2.5 Pharmacokinetic Studies of ATI and ATF in Rats

Female Sprague–Dawley rats (Harlan, Indianapolis, IN), 180–200 g, were instrumented with jugular vein cannulas under ketamine/xylazine (90/10 mg/kg) anesthesia. Phar-macokinetic studies for ATI were conducted 2–3 days after surgery by i.v. administration of 1-, 15-, or 100-mg/kg ATI (n = 4/group) via jugular vein cannula. Blood samples (200 µL) were collected through cannula at 1, 3, 6, 12, 24, 48, 96, and 168 h. For ATF studies, the antibody fragments were administered i.v.

at doses of 1, 15, and 60 mg/kg (n = 4/group) via the jugular vein cannula, and blood samples were collected at 0.25, 0.5, 1, 3, 6, 12, and 24 h. After the collection of blood, plasma was immediately isolated by centrifugation at 10,000 *g* for 2 min. Plasma samples were stored at −20°C before to analysis by ELISA.

Pharmacokinetic Analysis. Standard noncompartmental analyses were conducted to assess ATI and ATF pharmacokinetics using WinNonlin software (v. 2.1) (Pharsight, Mountain View, CA). The areas under the plasma concentration versus time curve from time zero to infinity (AUC_{inf}) were determined via the log-linear trapezoidal method. The terminal half-life was determined from the relationship of $t_{1/2} = \ln 2/\lambda$, where λ is the negative slope of the terminal phase of the lnC versus time plot. Systemic clearance (CL) was estimated by dividing the administered dose by AUC_{inf}. The volume of distribution at steady state (V_{ss}) was determined by the product of clearance and the mean residence time.

Statistics. One-way analysis of variance and Bonferroni's post hoc tests were used to compare values of half-life and systemic clearance for ATI and ATF. Differences were considered to be significance when $p < 0.05$.

6.5.3 RESULTS

6.5.3.1 Development of Hybridomas Secreting Anti-TPT Antibodies

TPT is a small hapten with an MW of 421 D, and to stimulate an immune response, TPT was coupled to keyhole limpet hemocyanin via the Mannich reaction. The resultant immunoconjugate preparation was found to contain 90 ± 42 molecules of TPT per molecule of KLH.

After the immunization of mice with KLH–TPT, each mouse was found to show high TPT binding activity in plasma. Fusion of spleen cells with myeloma cells led to the generation of >500 hybridoma cells. Hybridoma 8C2 was identified as showing significant anti-TPT activity via HPLC. As shown in Figure 6.5-1, the ultra-filtrate of control media (blank RPMI HAT media) that was spiked with TPT demonstrated a TPT peak area of 2.5×10^6 units. The response from culture supernatant pool #17, which consisted of media pooled from six individual hybridomas, showed a >50% decrease in the TPT peak area. Further analysis of each hybridoma contributing to this pooled mixture revealed that the media in the well of 8C2 contained antibody against TPT, as the unbound TPT peak area decreased to 5.2% of control (Figure 6.5-1C).

6.5.3.2 Characterization of ATI

The antibody secreted by 8C2 was identified as an IgG1 (data not shown). Good linearity was obtained in the Woolf plot (R^2 = 0.9999, Figure 6.5-2) and in the Rosenthal plot (R^2 = 0.9997, Figure 6.5-3). Additionally, both plots provided very close estimates of the apparent binding affinity ($K_A = 4.28 \times 10^8 M^{-1}$ from Woolf plot and $5.01 \times 10^8 M^{-1}$ from Rosenthal plot) and identical values for binding capacity ($nPt = 3.2 \times 10^{-7} M$ from both plots). The curves were consistent with the existence of a single "type" of binding site, as expected for a monoclonal antibody. Final

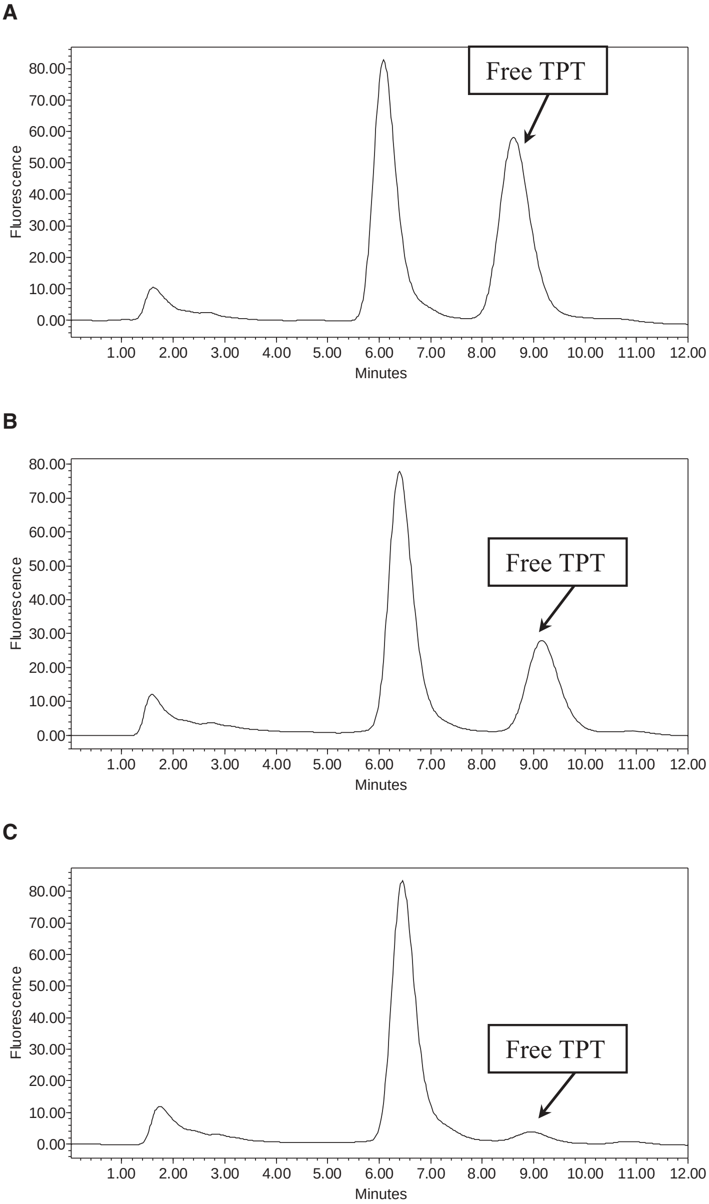

Figure 6.5-1. HPLC screening of positive hybridomas secreting ATAb (see detailed descriptions in text). (A) Negative control: blank HAT media spiked with TPT. (B) Response from the plate # 17 column 1 (well A1, B1, C1, D1, E1, and F1). (C) Response from 17A1 (8C2).

estimates of binding parameters obtained via nonlinear least-squares fitting were $K_A = 4.8 \times 10^8 M^{-1}$ (CV = 5.2%) and nPt = 3.2×10^{-7} M (CV = 0.46%, Figure 6.5-4). We could not detect unbound TPT concentrations below the dissociation constant K_D value ($K_D = 1/K_A = 1.01$ ng/L) due to limitations in the sensitivity of the HPLC assay; nonetheless, the accuracy of the estimated value of K_A is supported by the

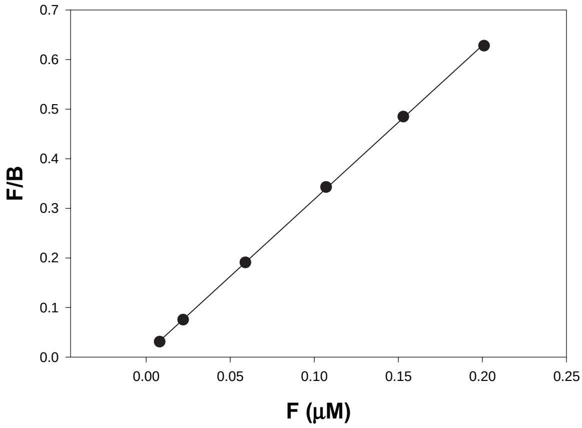

Figure 6.5-2. The Woolf plot was constructed according to the relationship: $\frac{F}{B} = \frac{1}{K_A \times Pt} + \frac{F}{nPt}$, where B is the molar concentration of TPT bound to ATI and F is the molar concentration of free TPT. K_A is the binding affinity of the anti-TPT antibody, and nPt is the total antibody capacity within the media. The slope is 3.13 μM^{-1}, and the intercept is 0.0073.

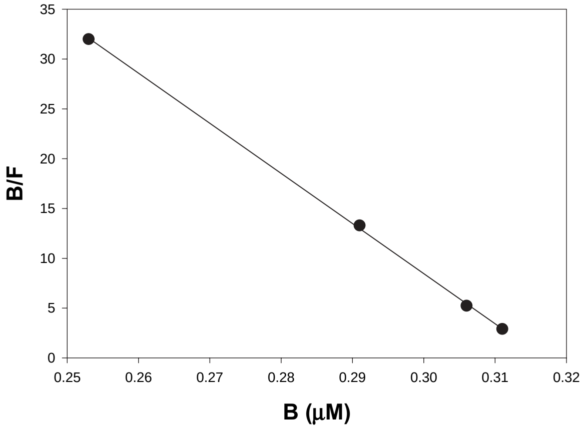

Figure 6.5-3. The Rosenthal plot was constructed according to the relationship: $\frac{B}{F} = nPt \times K_A - K_A \times B$, where B is the molar concentration of TPT bound to ATI and F is the molar concentration of free TPT. K_A is the binding affinity, of the anti-TPT antibody and nPt is the total antibody, capacity within the media. The slope is –501.42 μM^{-1}, and the intercept is 158.85.

excellent linearity obtained in both Woolf and Rosenthal plots and the low coefficient of variance associated with the fitted value.

6.5.3.3 Production and Purification of ATI and ATF

Antibody production from 8C2 cells growing within the hollow fiber bioreactor reached 240 mg/wk by the third week. ATI was purified from the media through protein G affinity chromatography (Figure 6.5-5). Final ATI concentrations in the

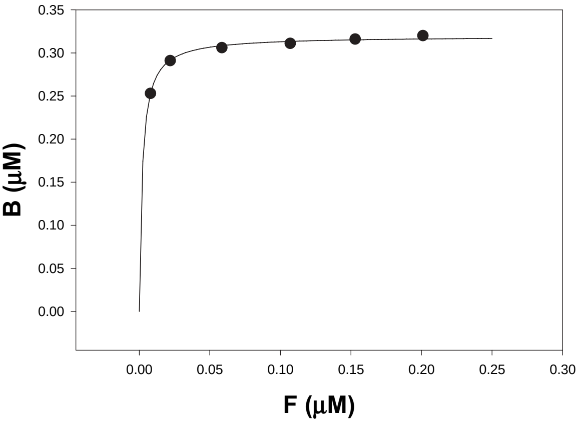

Figure 6.5-4. Bound vs. free TPT plot for 8C2 by fitting the free and bound TPT concentration data to the following equation: $B = \frac{nPt \times F}{1/K_A + F}$, where B is the molar concentration of TPT bound to ATI, F is the molar concentration of free TPT, K_A is the binding affinity of the anti-TPT antibody, and nPt is the total antibody capacity within the media.

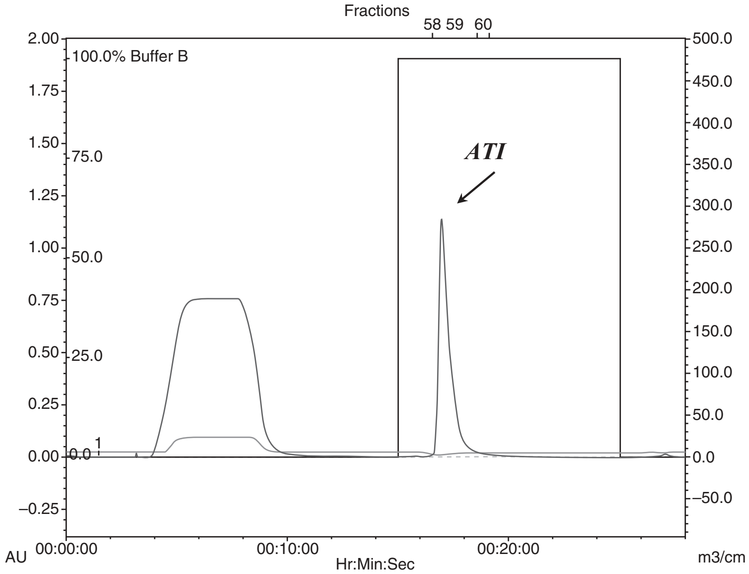

Figure 6.5-5. Purification of anti-topotecan IgG by a protein G column chromatograph. ATI containing media was loaded onto the column using 20-mM Na_2HPO_4 (pH 7.0) and eluted using 100-mM glycine buffer (pH 2.8) at a flow rate of 4 mg/mL (the line represents the percentage of elute buffer onto the column, indicated by buffer B on the y-axis).

elution buffer were typically 0.5–1.2 mg/mL. ATF was produced from the digestion of ATI with papain, and ATF was then purified from undigested ATI, Fc fragments, and secondary digestion products via hydroxyapatite chromatography (Figure 6.5-6). The purity of purified ATI and ATF were assessed by SDS–PAGE, and both ATI and ATF migrated as clear, single bands, apparently free from high- and low-molecular-weight contaminants (Figure 6.5-7). Estimated molecular weights were consistent with expectations for IgG (~150 KD) and Fab (~50 KD).

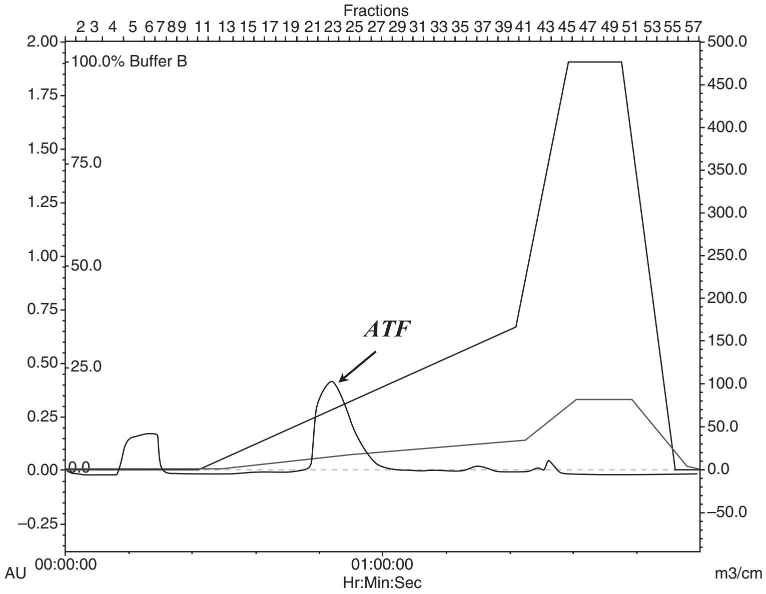

Figure 6.5-6. Purification of anti-topotecan Fab (ATF) by a hydroxyapatite chromatograph. ATF fragments were then purified from the dialysate by hydroxyapatite chromatograph with 5-mM KH_2PO_4 (pH 6.0) as loading buffer and 400-mM K_2HPO_4 (pH 6.0) as elution buffer (the line represents the percentage of elute buffer onto the column, indicated by buffer B on the y-axis).

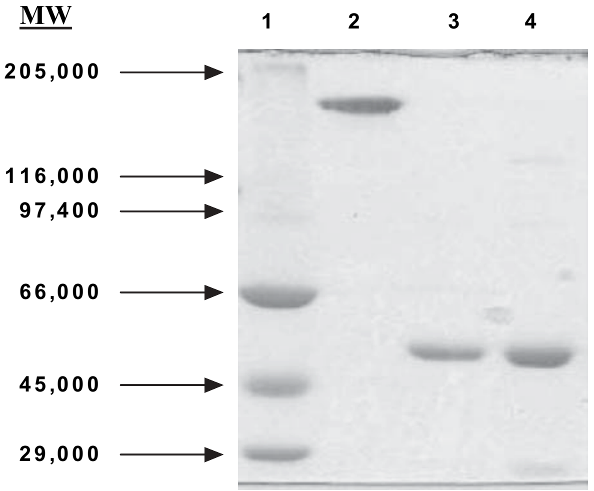

Figure 6.5-7. SDS–PAGE analysis of the purity of ATI and ATF. Lane 1 shows the molecular weight standards; lane 2 was the purified ATI (2 μg) collected from a protein G chromatograph of 8C2 serum-free media; lane 3 was the purified ATF (2 μg) collected from a hydroxyapatite chromatograph from a digested ATI mixed solution; lane 4 was an ATI digested mixed solution.

6.5.3.4 ELISA Validation

Representative standard curves are shown in Figure 6.5-8 (ATI) and Figure 6.5-9 (ATF). The curves were linear over the range of 0–250 ng/mL for ATI and 0–100 ng/mL for ATF. Intra-assay recovery for ATI ranged from 88.3% to 103%, with CVs less than 12%. The interassay recovery for ATI ranged from 94.4% to 102%, with CVs less than 8% (Table 6.5-1A). Similarly, the assay for ATF demonstrated an intra-assay recovery of 94.2% to 108%, with CVs less than 11%, and interassay recoveries ranged from 95.1% to 95.8%, with CVs less than 13% (Table 6.5-1B).

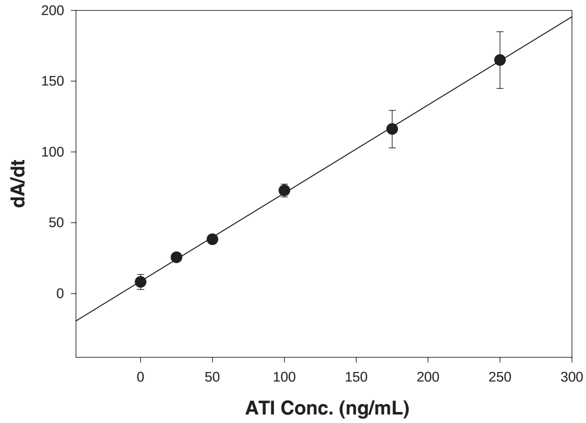

Figure 6.5-8. Representative ELISA standard curve for ATI over the range of 0–250 ng/mL ($r^2 = 0.999$). Error bars represent the standard deviation of the mean of the three replicates.

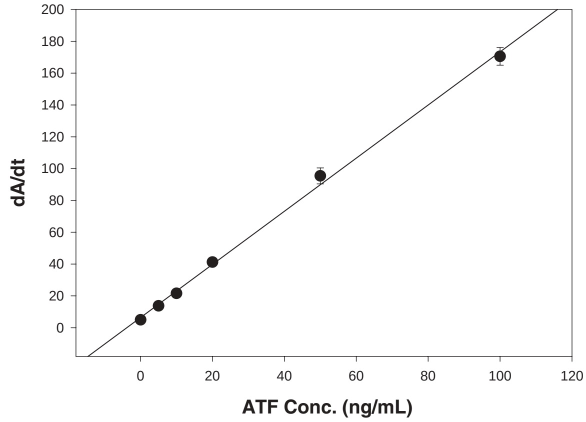

Figure 6.5-9. Representative ELISA standard curve for ATF over the range of 0–100 ng/mL. Analysis of linear regression shows an $r^2 = 0.998$. Error bars represent the standard deviation of the mean of the three replicates.

TABLE 6.5-1. The Accuracy and Precision (CV%) Of ELISA Associated with Assayed Concentrations of Quality Control Samples for (A) ATI and (B) ATF in Rat Plasma Samples (n = 3)

(A) ATI

	QC Conc. (ng/mL)	Assayed Conc. (ng/mL)	CV (%)	Recovery (%)
Intra-assay	25	22.1	11.9	88.3
	100	103	3.0	103
	250	252	5.0	101
Interassay	25	23.9	7.1	95.7
	100	102	4.0	102
	250	236	8.0	94.4

(B) ATF

	QC Conc. (ng/mL)	Assayed Conc. (ng/mL)	CV (%)	Recovery (%)
Intra-assay	5	5.4	9.7	108
	20	18.9	10.6	94.4
	100	94.2	4.5	94.2
Interassay	5	4.8	12.5	95.8
	20	19.0	9.9	95.1
	100	95.1	3.2	95.1

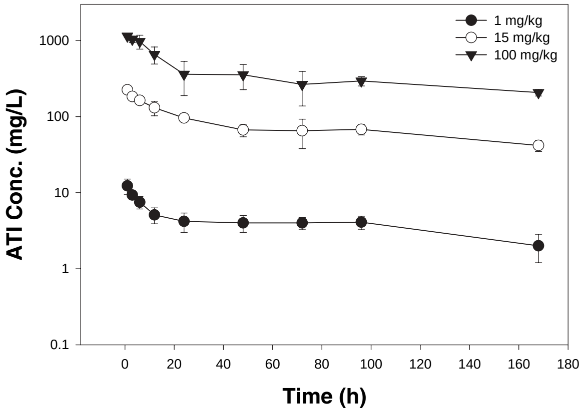

Figure 6.5-10. Plasma concentration-time profile after i.v. bolus of ATI at 1, 15, and 100 mg/kg to rats (n = 4/group). Blood samples were collected at 1, 3, 6, 12, 24, 48, 96, and 168 h. Plasma concentrations of ATI were determined by ELISA.

6.5.3.5 Pharmacokinetics of ATI and ATF

ATI plasma concentration versus time profiles after i.v. administration of 1, 15, and 100 mg/kg are shown in Figure 6.5-10, whereas Figure 6.5-11 shows ATF plasma concentration versus time profiles after i.v. bolus administration of 1, 15, and 60 mg/kg to rats. Noncompartmental analyses of the parameters for ATI and ATF are summarized in Table 6.5-2A and in Table 6.5-2B, respectively. ATI systemic clearance and terminal half-life seem to be dose independent, as no statistical differences were found over the dose range of 1 to 100 mg/kg ($p > 0.05$). No differences

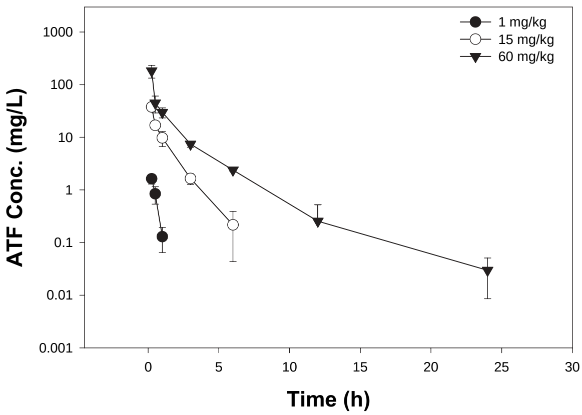

Figure 6.5-11. Plasma concentration-time profile after i.v. administration of ATF at 1, 15, and 60 mg/kg in rats (n = 4/group). Blood samples were collected at 0.25, 0.5, 1, 3, 6, 12, and 24 h. Plasma concentrations for ATF were determined by ELISA.

TABLE 6.5-2. Pharmacokinetic Parameters Estimated by Noncompartmental Analysis for (A) ATI and (B) ATF

(A) ATI

Parameter	Unit	1 mg/kg	15 mg/kg	100 mg/kg
AUC_{inf}	mg/L*h	689 ± 82.8	$(1.46 \pm 0.227) \times 10^4$	$(1.04 \pm 0.292) \times 10^5$
$t_{1/2}$	h^{-1}	105 ± 92.9	118 ± 18.1	154 ± 53.5
V_{ss}	L/kg	0.120 ± 0.030	0.110 ± 0.020	0.200 ± 0.030*
CL	mL/h/kg	1.08 ± 0.330	0.750 ± 0.100	1.00 ± 0.250

(B) ATF

Parameter	Unit	1 mg/kg	15 mg/kg	60mg/kg
AUC_{inf}	mg/L*h	1.17 ± 0.280	38.8 ± 6.80	189 ± 39.7
$t_{1/2}$	h^{-1}	0.360 ± 0.320	0.850 ± 0.24	1.97 ± 1.32
V_{ss}	L/kg	0.330 ± 0.060	0.340 ± 0.030	0.310 ± 0.160
CL	L/h/kg	0.890 ± 0.220*	0.400 ± 0.070	0.330 ± 0.060

*$p < 0.01$

were found for the estimated steady-state volume of distribution of ATI after dosing with 1 and 15 mg/kg, but the value of V_{ss} estimated for the 100-mg/kg group was significantly higher ($p < 0.01$). ATF terminal half-life and steady-state volume of distribution were not dependent on dose ($p > 0.05$ in the dose range from 1 to 60 mg/kg). No differences were found for the systemic clearance of ATF between 15 and 60 mg/kg, but ATF clearance estimated from 1 mg/kg was found to be significantly higher than that observed for the other doses ($p < 0.01$).

6.5.4 DISCUSSION

This laboratory is investigating the use of anti-drug antibodies within an inverse targeting strategy that attempts to increase the pharmacokinetic and therapeutic selectivity of intraperitoneal chemotherapy. The approach combines i.p. chemo-

therapy with systemic administration of anti-drug antibodies or antibody fragments (collectively named ADAb) [1, 2]. It is anticipated that ADAb in the blood may rapidly bind drug that diffuses out of the peritoneum, effectively reducing peak plasma-free (i.e., unbound) drug concentrations, the cumulative systemic exposure to unbound drug, and the extravascular distribution of the anticancer drug. In addition, it is anticipated that ADAb will likely show very slow entry into the peritoneal cavity, leading to little change in the cumulative peritoneal exposure to unbound drug. As such, the proposed targeting strategy may produce desirable regio-specific alterations in drug disposition, which may enhance to therapeutic selectivity of i.p. chemotherapy.

These hypotheses have been supported by a series of preclinical studies that employed MTX and anti-MTX Fab as model drugs [2, 4, 5]. However, MTX is not an ideal drug for future clinical applications of the inverse targeting strategy, due to its limited ability to penetrate solid tumors [13] and due to its relatively low potency. TPT may be an ideal drug for use in the proposed approach; this agent is a preferred therapy for metastatic, refractory ovarian cancer, and TPT is very potent, with a maximum tolerated dose of ~5 mg in humans (via i.p. instillation) [14].

To allow evaluation of TPT within the inverse targeting strategy, we have developed anti-TPT monoclonal antibodies. We applied traditional fusion techniques [11], which led to the generatation of >500 clones per fusion (in our hands). In our initial attempts to screen for hybridomas secreting anti-TPT antibodies, we first developed an antibody capture ELISA [11]. However, the antibody capture assay produced high background responses to a variety of proteins (e.g., bovine serum albumin and ovalbumin), even under stringent blocking and washing conditions (e.g., with various blocking agents such as 3% albumin and 20% milk). Displacement ELISAs also showed high background values when incubated with saline relative to TPT (data not shown). Due to the lack of selectivity associated with these immunoassays, we elected to screen for anti-TPT activity via HPLC.

For screening purposes, HPLC is not an ideal method due to its relatively low sensitivity and due to the low throughput of HPLC (i.e., relative to ELISA). In most cases, the identification of antibody binding via HPLC would require that the assay limit of quantification (LOQ) be substantially lower than the concentration of antibody in the supernatant (nPt), and in most cases, identification of antibody by HPLC would require that the product of LOQ and K_A be approximately equal to or greater than 1. Given that the LOQ of our HPLC assay for TPT was $\sim 2 \times 10^{-9}$ M, we anticipated that we would only identify those hybridomas with high antibody production and those that secrete high-affinity anti-TPT antibodies ($K_A \sim 5 \times 10^8\,M^{-1}$). From our studies with ~1000 hybridomas generated, two hybridomas were found to secrete antibodies in sufficient concentration and with sufficient affinity to allow detection by HPLC. One hybridoma was found to secrete an IgA anti-TPT antibody, and the other hybridoma, 8C2, was found to secrete an IgG1 anti-TPT antibody. Hybridoma 8C2 was selected for further use as, relative to IgA, it is generally easier to produce, purify, and digest IgG into Fab fragments. Consistent with our expectations, nonlinear least-squares regression revealed that 8C2 secreted an anti-TPT IgG with a high binding affinity ($K_A = 4.8 \times 10^8\,M^{-1}$).

To facilitate pharmacokinetic studies for ATI and ATF, a species-specific ELISA was developed and validated to quantify murine ATI and ATF in rat plasma, based

on the method of Hansen and Balthasar [12]. The current assay demonstrated similar CV% values for inter- and intra-assay variability for IgG (Hansen and Balthasar reported less than 8.5% of CV% value for intra-assay variability and less than 25.1% for inter assay variability) [12].

Noncompartmental analysis of ATI plasma data indicated that ATI distributed into a steady-state volume of distribution of 110–200 mL/kg, and that ATI was cleared at a rate of 0.75–1.08 mL/h/kg, with a terminal half-life of 105–154 h. These values are similar to those reported by Bazin-Redureau et al. after single-dose (0.7 mg/kg) i.v. administration of a monoclonal murine IgG1 to rats [15]. In their study, they reported $V_{ss} = 125 \pm 4.0$ mL/kg, systemic clearance = 0.48 ± 0.05 mL/h/kg, and a terminal half-life = 194 ± 19 h.

After i.v. administration, ATF distributed into a steady-state volume of distribution of 0.31–0.33 L/kg, similar to the value (0.38 ± 0.03 L/kg) reported by Bazin-Redureau et al. [15] and similar to the value that reported by Pentel (0.43 ± 0.06 L/kg) in a study of high-dose (7.5 g/kg) human Fab administered to rats [16]. The terminal half-life of ATF was determined to be 0.36–1.97 h, which is comparable with a reported value of 1.71 ± 0.25 h, after administration of radio-iodinated Fab to rats [17], and to the half-life of an anti-MTX Fab (1.36 h) [18], but considerably shorter than the values reported by Bazin-Redureau et al. (9.84 ± 0.74 h) [15] and by Pentel et al. (16.3 ± 2.4 h) [16]. The systemic clearance of ATF was 0.33–0.89 L/h/kg, which is higher than the value reported by McClurkan et al. [19] (0.16 ± 0.05 L/h/kg, after i.v. administration of 120-mg/kg Fab in rat) and markedly higher than the value found by Pentel et al. (for high dose of Fab to rats, 0.03 ± 0.004 L/h/kg) [16] and the value reported by Bazin-Redureau et al. (0.03 ± 0.0004 L/h/kg) [15]. Some differences in IgG or Fab pharmacokinetic parameters may be due to the differences in the species of origin of IgG or Fab (human [16] or rat [17] versus mouse in our study), differences in the types of antibodies preparation (polyclonal versus monoclonal), differences in the dose level studied (possible dose-dependent kinetics), or differences in the sensitivity of the analytical techniques used for quantifying Fab concentrations (radiolabeled antibodies quantification versus ELISA). Additional experiments are underway to investigate the pharmacokinetics of anti-TPT Fab more completely (i.e., over a wider dose range, and using more extensive sampling) in animals bearing peritoneal tumors.

In summary, we describe the production, purification, characterization, and pharmacokinetics of a monoclonal anti-TPT IgG and Fab fragments. The anti-TPT antibodies have demonstrated high affinity and sufficient purity for use in evaluating their use in "inverse targeting" strategies to optimize TPT i.p. chemotherapy.

6.6.1 INTRODUCTION

Antibody technology has existed since the establishment of the hybridoma monoclonal system [1]. In recent years, there has been increasing interest in developing recombinant antibodies (rAb) for immunodiagnostics and immunotherapeutical

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

applications, with the expectation that recombinant antibody fragments will capture a significant share of the US$6 billion per year diagnostic market [2]. Recombinant antibodies have reduced conventional monoclonal antibodies into smaller capture molecules, while holding the promise of improving the sensitivity and specificity of many diagnostic assays. This chapter summarizes some new developments in rAb with a particular emphasis in pathogen detection and immunotherapy.

6.6.2 GENERAL PROPERTIES OF ANTIBODIES

Within the mammalian immune system, there are five general classes of immunoglobulin molecules, IgA, IgD, IgE, IgG, and IgM, differentiated by the structure of their constant regions and their immune function [3]. Immunoglobulins are antigen binding glycoproteins present on the B-lymphocyte (or B-cell) membrane and secreted by plasma cells. IgG is the most abundant class of immunoglobulins in sera. As most antigens offer multiple epitopes, a variety of B-cell clones are induced, each derived from a B-cell that recognizes a particular epitope. The resulting polyclonal antibody serum comprises a heterogeneous mixture of antibodies, each specific to one epitope. The antibodies produced from a single B-cell clone are monoclonal in that they are all specific to a single epitope [3].

The general immunoglobulin structure is a 4-chain "Y"-shaped molecule of two heavy-chain and two light-chain polypeptides joined together by disulfide bridges [3]. The greatest variability of immunoglobulins occurs at the N-terminal, or the tips, of the "Y" molecule. This is where the antibody interacts with the antigen. This variable region includes the ends of both the heavy (V_H) and the light (V_L) chains. Within the variable regions are three discontinuous regions of the greatest variability, known as the hypervariable (HV) or complementarity-determining region (CDR), which directly contacts a portion of the antigen's surface [2]. Separating the HV regions are four highly conserved framework regions that serves as a scaffold to hold the HV regions together and that forms a unique β-barrel antigen-recognition site. In general, more amino acid residues of the heavy-chain CDRs interact with the antigen than in the light-chain CDRs. In many cases, binding of the antigen induces a conformational change in the antibody, antigen, or both [4].

Antibodies have been used as research tools for cell, antigen, or pathogen identification; pathogenesis studies; ligands for column chromatography and molecule purification; diagnostic reagents; therapeutic antibody preparations; and the identification of protective antigens/epitopes in vaccine development.

It is important that antibodies being used for immunodetection of pathogens or for the immunotherapeutic purposes be able to bind strongly and specifically to the pathogen of interest. The most desired antibodies should possess high affinity and specificity for a given pathogen, with little-to-no cross-reactivity to other antigenic targets.

6.6.2.1 Binding Properties

The binding properties observed during antibody interactions with their target antigens are generally described in terms of affinity, avidity, and specificity.

Affinity. Affinity is the strength of interaction between an antibody and an antigen at a single antigenic site. Within each antigenic site, the variable region interacts through weak noncovalent bonds with antigen at numerous sites; the more interactions, the stronger the affinity. Antibodies with more available antigen-binding domains will possess a higher intrinsic antigen affinity.

Avidity. Avidity is a measure of the overall stability or strength of the antibody–antigen complex. It is controlled by three major factors: antibody-epitope affinity; the valence of both the antigen and the antibody; and the structural arrangement of the interacting ligands.

Specificity. Specificity is based on the combination of both affinity and avidity to determine the likelihood that the particular antibody is binding to a precise antigen epitope. The matrix on which the antigen is tested may influence specificity and sensitivity by interfering with the antigen–antibody complex. The more specific an antibody, the less chance there is for cross-reactivity with a nontarget antigen and subsequent false-positive results in immunodiagnostic assays. In immunotherapeutic applications, the desired antibody should only target the harmful pathogen and not any indigenous microorganisms.

Cross-Reactivity. Cross-reactivity refers to an antibody or population of antibodies binding to epitopes on other antigens. This can be caused either by low avidity or specificity of the antibody or by multiple distinct antigens having identical or very similar epitopes.

6.6.2.2 Monoclonal Antibodies Produced from Hybridoma Cell Lines

The fusion of an antibody-producing B-cell with a myeloma cell results in a hybrid cell, called a hybridoma. These cells possess the immortal growth properties of the myeloma cell and secrete the antibody produced by the B-cell. All antibodies produced by the individual hybridoma cell lines have the same antigenic specificity. Monoclonal antibodies (mAbs) require a great investment of resources, as their production is labor intensive and costs much more to develop, produce, validate, and stockpile than polyclonal antibodies [5]. However, once a hybridoma cell line is developed, mAbs can be easily made in large quantities without the lot-to-lot variation observed in polyclonal antibody preparations [6]. Lack of reliable myeloma partners has prevented the hybridoma fusion technique from widespread use in non-rodent species [6]. Monoclonal antibodies are generally of the IgG class. Because of their bivalency, their functional affinity and avidity are greatly increased as compared with monovalent recombinant antibodies [2]. Monoclonal antibodies have been traditionally used in immunoassays for the detection of pathogenic microorganisms.

6.6.2.3 Recombinant Antibody (rAb) Technology

With the advent of recombinant DNA technology, antibody genes can be amplified and selected through phage display, cell-surface display, or cell-free display systems (i.e., ribosome display). A major advantage shared by these systems is the direct

link between the genotype and the phenotype of displayed antibodies during selection. This allows for simultaneous coselection of the desired antibodies and their encoding genes as a result of the binding characteristics of the displayed antibodies. The gene encoding the desired antibody can be further manipulated for improvements in affinity and/or specificity, increased expression, posttranslation modification, or fusion of a secondary protein [7].

Recombinant DNA technology and antibody engineering have increased the available avenues of antibody use, particularly in the application of immunotherapies. Recombinant monoclonal antibodies from various animals can now be produced without a myeloma cell line as a fusion partner. Animals can be immunized by exposure to a desired antigen, and the antibody genes from these animals are amplified by polymerase chain reaction (PCR) and expressed in different expression systems in various formats, such as the Fab, single-chain variable fragment (scFv), and single-domain antibodies (V_H, V_{HH}, and V_{NAR}). Figure 6.6-1 illustrates some different recombinant antibody fragments and the parent antibodies from which they were derived. Recombinant Fab [8], scFv [9], V_H [10], V_{HH} [11], and

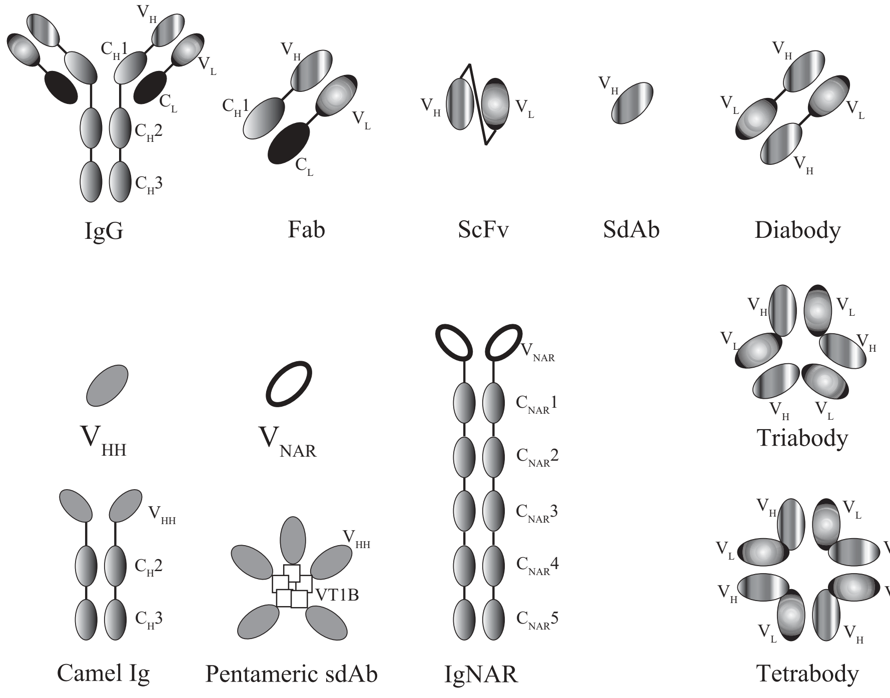

Figure 6.6-1. Schematic representations of common antibody formats and recombinant antibodies. The structure of the immunoglobulin IgG molecule is shown as the "gold-standard" for antibody structure. Homodimeric Camelid Ig and shark IgNAR are indicated along with their representative single-domain antibodies, V_{HH} and V_{NAR}. A variety of common antibody fragments are depicted, as well as some of their multimeric formats. V_H, variable domain of heavy chain; C_H, constant domain of heavy chain; V_L, variable domain of light chain; C_L, constant domain of light chain; V_{HH}; variable domain of Camelid immunoglobulin; V_{NAR}, variable domain of IgNAR; C_{NAR}, constant domain of IgNAR; VT1B, B subunit of Verotoxin 1.

V_{NAR} [12] have been synthesized and found to possess binding characteristics comparable with their respective parental monoclonal antibodies.

The major advantage of these recombinant antibody fragments is that they have increased the available avenues of antibody use, particularly in immunotherapies. They are smaller in size and therefore easier to manipulate genetically and can be expressed in bacterial systems in large quantities with little lot-to-lot variation. The rAbs can be expressed in various surface-display systems (i.e., phage display or cell-surface display) while retaining their functionality during the panning process. As the development of rAbs does not depend on species-specific cell fusion partners, rAbs can be developed from any animal for which one can design an appropriate set of primers for immunoglobulin amplification. Expression and purification of rAbs by bacterial fermentation is less expensive, easier to perform, and less time consuming than production of either polyclonal or monoclonal antibodies [13].

Recombinant antibodies have three key disadvantages when compared with conventional monoclonal antibodies: (1) they are less stable *in vivo* than natural antibodies; (2) they cannot cross-link antigens; and (3) they may lack critical domains necessary for certain biological functions [14].

Numerous differing types of rAbs exist that vary depending on their size, conformation, and source. The following describes the general features of some rAb types.

Fab. Fab fragments, as the classic monovalent antibody fragment, can be produced from an IgG by treatment with papain. The Fab fragment is composed of the entire light antibody chain and part of the heavy chain (Figure 6.6-1). This configuration retains the antigen-binding domain. The interchain disulfide bond remains intact to provide proper tertiary protein conformation. Fab fragments have been shown to have an *in vivo* half-life on the order of hours [15], making them attractive for use in immunotherapeutic applications, as compared with some other rAbs.

Scfv. This antibody fragment is composed of the variable segments of both the heavy and the light antibody chains. The two fragments are typically joined by a flexible peptide linker, most commonly the 15 amino acids of $(Gly_4Ser)_3$, to improve scFv folding and stability. However, the linker between V_H and V_L can interfere with folding in some cases, and this renders the scFv susceptible to proteolysis [16]. Due to rapid *in vivo* blood clearance of scFv, the half-life is in the range of minutes to tens of minutes [17]. The smaller size of scFv antibodies allows them to more easily penetrate tissues.

V_H. These single-domain antibodies are composed entirely of a single-variable antibody domain. Despite early excitement surrounding the functional activity of these, in those that have been studied, they rarely retained the affinity of the parent antibody and were poorly soluble and often prone to aggregation. Exposure of the hydrophobic surface of the V_H to the solvent, which normally interacts with the V_L, causes a sticky behavior of the isolated V_Hs [18]. Because of their small size, it is possible for V_H antibodies to potentially target some epitopes that are inaccessible to larger antibody fragments [10].

V_{HH}. Members of the *Camelidae* family have evolved high-affinity single V-like domains that are mounted on an Fc-equivalent constant domain framework. Their

binding domains consist only of the heavy-chain variable domains, referred to as V_{HH}, to distinguish it from the conventional V_H antibody fragment. The variable domain V_{HH} is immediately followed by the hinge region consisting of the C_H2 and C_H3 domains. Affinities of V_{HH}s are in the nanomolar range and are comparable with those of Fab and scFv fragments, and they can be stable under high temperatures, with specific binding being retained at temperatures up to 90°C [11, 18].

V_{NAR}. The immunoglobulin isotype novel antigen receptor (IgNAR) is a homodimeric heavy-chain complex found in the serum of the nurse shark (*Ginglymostoma cirratum*). IgNAR do not contain light chains [19]. Each molecule consists of a single-variable domain (V_{NAR}) and five constant domains (C_{NAR}). Similarities between the V_{NAR} and the V_{HH} include the presence of disulfide bonds and binding affinities in the nanomolar range [20].

Antibody Variants. Fab and scFv fragments have been engineered into dimeric, trimeric, or tetrameric conjugates using either chemical or genetic cross-links. By reducing the scFv linker length to between zero and five residues, self-assembly is directed into multimers [2]. Bivalent diabodies are the results of joining the V_H of one scFv to the V_L of a second scFv molecule, and vice versa, with stabilization introduced by disulfide bridges [21]. Single-domain antibodies can be fused to the B-subunit of *Escherichia coli* verotoxin, or shiga-like toxin, which self-assembles to form a homopentamer, resulting in simultaneous antibody pentamerization and introduction of increased avidity [22]. Fusion antibodies have also been produced in which secondary proteins, such as green fluorescent protein, are expressed along with the rAb. This is done as a means to facilitate monitoring of the antibodies, making antibody-based pathogen detection easier [23].

6.6.2.4 Antibody Libraries

Three general types of libraries are constructed for selection of rAbs: (1) immune, (2) nonimmune or naïve, and (3) or synthetic/semisynthetic. Immune libraries are generated by cloning antibody genes from B-cells of immunized animals. This approach takes advantage of the fact that antibodies directed against the antigen are enriched in such donors, and that they have been subjected to an *in vivo* affinity maturation by the host immune system. These libraries have the added advantage that many isolated antibodies are already antigen specific [24]. Hybridoma cell lines can also be used for the formation of immune libraries. As each hybridoma cell line theoretically produces only a single type of functional antibody, only one set of immunoglobulin genes is available. However, depending on the myeloma cell line used in the fusion process, rearranged but nonfunctional heavy- and light-chain genes in the hybridoma may be present and preferentially amplified and cloned [25]. To select for functional immunoglobulin genes from hybridoma cell lines, intensive screening of cloned genes through panning of phage-display antibodies is necessary [25].

Nonimmune or naïve libraries are constructed in the same manner as an immune library, but B-cells from nonimmunized donors are used as sources for antibody genes. The diversity of isolated antibodies increases with the library size, and

increasing the library size improves the chance of obtaining high-affinity antibodies [24]. Theoretically, a single universal naïve library can be constructed and used to provide rAbs with any desired specificity. In practice, however, such antibodies have affinities that may be suboptimal [26].

Synthetic/semisynthetic libraries are artificially constructed by using PCR to randomly assemble the genes encoding the HV regions from a naïve B-cell. By employing this process, a unique set of V_H and V_L genes are recombined. These are sometimes referred to as single-pot libraries, because each such library can be source of antibodies directed against multiple antigens. This technology can also be used to display the immunoglobulin genes of conventional hybridomas for the purpose of rescuing unstable clones or improving their binding specificities and/or affinities through genetic manipulations such as *in vitro* mutagenesis or heavy/light-chain shuffling [26].

The use of antibody libraries has numerous advantages over hybridoma antibody technology: (1) They allow for affinity-selection of binding clones and not just to screen for binding activity; (2) recombinant antibody libraries can be rescreened against many different antigens; (3) negative subtraction screening can be done against irrevelent nontarget background proteins, thus reducing the number of nonspecific binders; (4) rAbs can be developed from any species for which primers exist; (5) rAb libraries can be applied to high-throughput screening technologies; and (6) they are well suited to many downstream molecular technologies.

Panning Antibody Libraries. Panning is the methodology by which desirable rAbs are selected from an antibody library. During panning, recombinant antibody libraries are incubated with the target antigen to bind clones bearing specificities of interest. Unbound or weak clones are washed away, and the rAbs that remain bound to the antigen are eluted and amplified for further propagation. After two to four rounds of panning, all binders should be specific to the antigen of interest. Antibody-displaying complexes bearing expressed rAb can be used directly in diagnostic assays or can be genetically modified to express soluble antibody molecules [7, 27].

Because the screening for positive clones takes places in one step, millions of clones are evaluated during each round of selection. Thus, this process requires only a few hours instead of days to months required for screening conventional hybridoma cells for monoclonal antibodies. The clones are indefinitely stable and capable of self-replication when supplies are low. They can be stored as bacterial stocks, phage stocks, or plasmid DNA.

Phage Display. Phage display is often used to screen for recombinant antibodies. It is based on the functional expression of peptides and proteins on the surfaces of bacteriophages. The filamentous bacteriophages are a group of viruses that contain a circular single-stranded DNA genome encased in a long cylinder protein capsule. The infection process is facilitated by attachment to the bacterial pilus. The Ff class of filamentous phages has been most extensively studied. They use the F pilus specific to *E. coli* cells containing the F plasmid [27]. These bacteriophages do not kill their host during reproduction. Rather, the bacterial host is used by the phage for DNA replication as well as for synthesizing phage proteins. There are 11 genes associated with the f1 bacteriophage genome [27]. DNA replication is performed

by the cooperation between three phage genes and the host system. Three phage gene products are used in the assembly of phage particles. There is a single phage gene encoding a major capsid protein and four genes encoding minor capsid proteins. Expression of phage proteins is performed by the bacterial host system. The assembly of the filamentous phage is a membrane-associated event requiring the five capsid proteins, the three assembly proteins, adenosine triphosphate (ATP), a proton motive force, and at least one bacterial protein, thioredoxin [28].

Specific peptides and proteins can be displayed on the phage particles as a result of the fusion of specific proteins to the periplasmic portion of the capsid proteins before bacteriophage assembly. Most phage display libraries of peptides and antibodies have been made using the pIII minor capsid protein as the fusion vector, resulting in a chimeric pIII fusion protein. It has the disadvantage that a maximum of five expressed antibody molecules can be displayed per phage host [29]. The main advantage is that pIII fusion proteins containing large inserts can be packaged into the phage. The gene encoding the displayed peptide is inserted between the signal sequence and the beginning of the first domain of the pIII capsid protein. The insertion of the molecule here places the displayed protein at a single polar end of the phage particle. The pVIII major coat protein can also be used for peptide expression, but it is limited in that only peptides of six or eight amino acids in length can be displayed. The advantage is that many copies of the peptide (up to 2500 copies) are displayed along the entire surface of the bacteriophage [30].

Peptides can also be displayed on smaller filamentous particles referred to as phagemids. The phagemid genome contains the phage origin of replication and an independent gene encoding antibiotic resistance. Chimeric genes encoding peptide-phage protein fusions can be placed under the control of a specific promoter in these phagemid genomes. Superinfection of the bacterial host with a filamentous helper phage activates the phage origin of replication. Subsequent transcription and translation provide all phage-derived proteins and enzymes required for phagemid replication. Using a helper phage containing a defective packaging signal allows most phage particles produced to contain the phagemid ss-DNA. When compared with phage vectors, higher yields of phagemid vectors are obtained by plasmid preparation, and larger inserts are more readily maintained [27]. Bacterial transformation efficiency is higher with phagemid than phage vector, and this may result in greater library diversity [31, 32]. Generally, one to three copies of the pIII fusion protein will be expressed by each phage, whereas up to 200 copies of the pVIII fusion peptides can be expressed on the phage capsid [29]. The main disadvantage of using a phagemid vector is the high background during selection due to the presence of wild-type phages, which have been shown to exhibit nonspecific binding during affinity selection. As a result, the conventional M13K07 helper phage has been modified. The modified helper phage either requires that the host bacterial strain provides the pIII proteins [33] or possesses a trypsin cleavage site within the pIII gene that is absent in the fusion protein [34]. Trypsin treatment of phage after selection can eliminate most phages that do not carry the recombinant coat protein displaying the peptide of interest. Because of the need for a helper phage to rescue phagemid vectors, they are less efficient than phage vectors, which allow higher display levels and make panning more efficient, with more binders being isolated in fewer rounds [35]. The lower valency of phagemid vectors allows the selection of binders with higher affinity. Recombinant antibodies from phagemid vectors

generally have affinities that are 5–10 times higher than those from phage vectors, on average [35]. The higher avidity associated with phage display may result in the selection of lower affinity clones.

Bacterial Display. The display of recombinant peptides on the surface of bacteria such as *E. coli* was first described more than a decade ago. Several peptides have been successfully displayed on bacterial surfaces [36], including antigenic determinants, heterologous enzymes, antibody fragments, and peptide libraries. Numerous reviews detail the various classes of proteins that have been displayed on both Gram-positive and Gram-negative bacteria [24, 29, 37].

The major obstacle for export of foreign peptides to the surface of a Gram-negative bacterial cell is the presence of an extensive network of macromolecules found within the bilayered cell envelope. It is necessary to select a leader sequence that translocates the peptide through the membrane, as well as an anchor protein that displays the rAb without disrupting the membrane integrity. Initially, short gene fragments were inserted into genes for the *E. coli* outer membrane proteins: the maltoporin LamB [38]; outer membrane protein OmpA [39]; and the phosphate-inducible porin PhoE [40], with the gene products being displayed on the surface of the recombinant bacteria. Lipoproteins [41, 42], fimbriae [43] and flagellar proteins [44], as well as dedicated systems with coupled translocation and surface anchoring have also been used for surface display of peptides [45]. Most current studies of bacterial display of antibodies involve the lipoprotein–porin (Lpp–OmpA') fusion system, with expression of recombinant proteins fused to the sorting signal that directs their incorporation on the cell surface [46]. The expressed antibodies retain their binding ability and approximately 60,000 scFv molecules can be displayed per cell [47]. Selection of good binders can be done by fluorescence-assisted cell sorting (FACS) flow cytometry, using fluorescently labeled antigens, thus avoiding the immobilization of the antigen, elution of bound phages, and reinfection of bacteria with eluted phages.

Expression of scFv on the surfaces of Gram-positive bacteria has been investigated. ScFv antibodies have been displayed on the surfaces of *Staphylococcus xylosus* and *Staphylococcus carnosus* through the fusion to the C-terminus of protein A [48]. Recently, spores of *Bacillus subtilis*, a dormant form of living cells known for their resistance to harsh environments, have been used for display of recombinant antibodies. ScFv antibodies have been fused to CotB, a surface-exposed coat component of the *B. subtilis* spore coat [49]. Spores represent a unique opportunity for surface display because of the potential of providing a durable supporting matrix similar to that of chemical polymer beads. There are three advantages of using Gram-positive over Gram-negative bacteria for surface display. First, larger molecules may be displayed on Gram-positive than Gram-negative bacteria. Second, the single-layered cell wall of Gram-positive bacteria may have better efficiency of fusion protein secretion and folding than the double-layered Gram-negative bacterial cell surface. Third, the rigid Gram-positive cell wall may allow the cells to withstand harsh conditions during affinity selection [7].

Yeast Display. The eukaryotic system of yeast offers an advantage of posttranslational modification and processing of mammalian proteins and is,

therefore, better suited for expression and secretion of human-derived antibody fragments than a host such as *E. coli*. Yeasts displaying antibodies share many of the same advantages as bacterial display. Yeast have a rigid, thick cell wall that enables the stable maintenance of surface-displayed proteins [50]. As in bacterial display, the large size of yeast cells allows for efficient selection using FACS flow cytometry [51]. Several systems can be used for expression of rAb on yeast cell surfaces. Yeast display primarily uses the α-agglutinin yeast adhesion receptor to display recombinant proteins on the surface of *S. cerevisiae* [52]. The α-agglutinin receptor acts as an adhesion molecule to stabilize cell–cell interactions and facilitate fusion between yeast cells of opposite mating types. The receptor consists of two proteins, Aga1 and Aga2. The Aga1 protein is secreted from the cell and becomes covalently attached to the extracellular matrix of the yeast cell wall. The rAb–Aga2 fusion proteins bind to Aga1 after secretion and remain attached to the cell via Aga1, displaying the recombinant antibody on the yeast cell surface [53, 54]. The Aga2–fusion rAb can be displayed on the cell surface at 10,000 to 100,000 copies/cell [53].

Glycosylated-inositol (GPI)-anchored proteins have also been used to anchor foreign peptides for cell-surface display in *S. cerevisiae* [55] and *Hansenula polymorpha* [56]. Four different *gpi* genes and their encoded proteins were characterized for the purpose of displaying fusion protein on the cell surface. The *FLO1* gene encodes the Flo1p protein, a lectin-like cell-wall protein thought to form stem-like structures that cover the distance of the cell wall. This protein has also been used to express peptides on the yeast surface [57].

In bacterial or yeast surface display, the phenotype and genotype are linked through the display of the protein on the surface of a cell, in which the DNA can also be propagated and expressed. No subcloning step is required after each selection. Yeast display is particularly beneficial as yeast cells are generally more robust and can express large quantities of heterologous proteins with appropriate post-translational modifications [52]. However, the display of multiple antibody fragments on bacterial or yeast surfaces contributes to an avidity effect, potentially contributing to the selection of rAbs with lower binding affinities [58].

Ribosome Display. This cell-free display system uses the same principle as the phage-display systems in bacteria. The phenotype and genotype of a peptide are linked together and, therefore, can be simultaneously selected based on the function of the peptide. However, the linkage is a physical one in that the genetic material is covalently linked to its encoded product in the formation of an antibody–ribosome–mRNA (ARM) complex through *in vitro* transcription/translation [59].

Ribosome display is an *in vitro* method, with all steps being nucleic acid-based. This allows the assembly of a large-size library with up to 10^{15} members. Mutations can be incorporated in each cycle of selection using PCR-based mutagenesis, thereby allowing for the introduction of diversification during selection. Antibodies with equilibrium dissociation constants improved from the nanomolar to picomolar range using ribosome display have been reported [60, 61].

The key advantage of ribosome display over phage display systems is the freedom from any bacterial transformation step, which typically limits the size of antibody libraries. The library size in phage, bacterial, or yeast display is determined by the

transformation efficiency. Generally, 10^{10} to 10^{11} members represent the upper possible limit of the size of an *E. coli* library. Due to the generally lower transformation efficiency in yeasts, large yeast-display libraries are composed of up to 10^9 clones [53]. Another advantage of ribosome display systems is that the expression of the target peptides is not limited by the host. With *in vivo* display systems, proteins that are toxic or detrimental to cell growth will inhibit or kill the host cell, and this can potentially limit the library size for screening. Furthermore, bacteria are prone to introduce natural mutations into foreign DNA to evade selection pressure. Mutations and/or recombinations within the plasmid are frequently found that may provide benefits to the cells. Undesirable selection pressure on individuals can easily be avoided in a cell-free system. Ribosome display is especially useful for construction of a naïve library, which provides a better library complexity and diversity than its phage display counterpart [7]. The use of a ribosome display cannot only select and enrich high-affinity binders from a library, but also it provides *in vitro* hypermutation for the maturation of selected clones to improve binding characteristics [61, 62].

6.6.2.5 Soluble Antibody Production

Numerous systems are available for the expression of soluble recombinant antibodies. Bacteria, yeasts, plants [63], insects and mammalian cell lines [64], and cloned transgenic animals have all been used for rAb expression [65]. Bacteria, in particular *E. coli*, are favored for expression of small, nonglycosylated Fab, scFv, and V_H fragments and diabodies. ScFv fragments are generally expressed to a higher level over Fab in bacteria, although yields may vary for each rAb fragment [2]. Bacterial expression of rAbs is typically achieved by fusion to N-terminal signal peptides, which targets the protein to the periplasmic space of *E. coli*. This periplasmic expression may render a large fraction of the produced rAb insoluble. Soluble bacterial antibody production can also be directed into the culture medium. The risk is that the production of inclusion bodies often results in insoluble protein aggregates. This necessitates laborious renaturation steps and subsequent *in vitro* folding, resulting in a low final yield [18]. Secretion of rAbs can be associated with cell lysis and subsequent product loss. Also, if the rAb being produced is toxic to the bacteria, production levels will be drastically deceased. Because bacteria cannot carry out eukaryotic posttranslational modification, their use is not suitable when glycosylation of the rAb is required.

Purification of Recombinant Antibodies. Purification of bacterial expressed rAb is assisted by the presence of fusion polypeptides such as c-Myc, poly-His, and the FLAG epitope, which have been added to allow for affinity purification. Subsequent cleavage of the fusion protein yields the rAb of interest.

6.6.3 IMMUNODETECTION OF PATHOGENS

Diagnostic tests for viruses, bacteria, fungi, and their spores are often based on culture-dependent methods. While these methods are very sensitive and generally simple to perform, they can be time consuming, requiring several days, and possibly

weeks, to complete. If microorganisms are nonculturable, microscopy can be used for identification, as is the case for numerous protozoan parasites. Microscopy requires specific training and may be subject to user bias and error. Also, it may be hard to differentiate between microorganisms at a species level. Epifluorescent microscopy, with fluorochrome-conjugated antibodies specific to the target organism, can make this method much easier to perform. Molecular-based methods such as PCR can be used for quick identification of specific target pathogens, but can be expensive and, like microscopy, requires specific training for the operator. However, PCR cannot distinguish between those detected organisms that are viable and infective from those that are dead. Isolation of DNA from some matrices can be problematic because of the presence of inhibitors that can adversely affect PCR [66].

An antibody to be used in immunodiagnostics should ideally have high binding specificity and affinity to the target antigen of interest. As such, many commercially available immunodiagnostic antibodies are produced as monoclonal antibodies. As the production of rAbs becomes more routine, their availability is sure to increase. Table 6.6-1 lists some developed rAbs that could be used in immunodiagnostics. One major advantage of recombinant antibodies is that they are more easily selected for when the target pathogen may be harmful to an animal being immunized for the production of monoclonal antibodies.

6.6.3.1 Formats of Detection

Successful immunodiagnostic applications are based on the availability of antibodies with high affinity and specificity. Initially, polyclonal antibodies from hyperimmunized animals or monoclonal antibodies from hybridoma cell lines were used. More recently, rAbs are being constructed that possess affinities rivaling those of monoclonal antibodies. Therefore, it is anticipated that rAbs will begin to be deployed in greater frequency in immunodiagnostics in the short to medium term.

The efficiency of immunoassays relies on four components: (1) the target antigen to be detected; (2) the antibody used for detection; (3) the method to separate bound antigen and antibody complexes form unbound reactants (if a heterogenous mixture is used); and (4) the detection method. At the most fundamental level, the efficacy of any given immunoassay is dependent on two major factors: the efficiency of antigen–antibody complex formation and the ability to detect these complexes. It is desirable that the antibodies used have high affinity for the target antigen with low cross-reactivity to minimize false positives. Greater sensitivity of immunoassays is generally associated with higher affinity antibodies.

The use of polyclonal antibodies in sera has inherent disadvantages. Laboratory animals are required, and results can vary drastically in their ability to respond to different antigens, resulting in significant variation among different lots of antibodies. The antibody response to a given antigen tends to be broad. This covers both specific and cross-specific epitopes, causing problems such as high-background or unwanted reactivity for contaminants in the antigen preparation. Polyclonal immunoassays can be highly sensitive but may not be very specific [6, 100].

There is an inherent disadvantage when using highly specific antibodies. Antigenic drift or shift can make using monoclonal antibodies difficult. The evolution

TABLE 6.6-1. A List of Some Pathogens Detected by Recombinant Antibodies

Pathogen	rAb Type	Source Library	Reference
Bacterial			
Bacillus subtilis	scFv	Human Naïve	[67]
Burkholderia pseudomallei exotoxin	scFv	Mouse Immune	[68, 69]
Chlamydia psittaci	scFv	Human Naïve	[70]
Chlamydia trachomatis	scFv	Human Naïve	[70]
Cyanobacterial Hepatoxin Microcystins	scFv	Human Semi-Synthetic	[71]
Clostridium difficile Toxin B	scFv	Mouse Immune	[72]
Escherichia coli O157:H7	scFv	Human Naïve	[73]
Moraxella catarrhalis	scFv	Human Semi-Synthetic	[74]
Streptococcus mutans	scFv	V_H of Mouse Immune, V_L of Human Naïve	[75]
Streptococcus suis	scFv	Human Semi-Synthetic	[76]
Fungal			
Candida albicans	scFv	Human Naïve	[77]
Fusarium Mycotoxin Deoxynivalenol	scFv	Mouse Immune	[78]
Phytophthora infestans	scFv	Naïve	[79]
Protozoan			
Cryptosporidium parvum	Fab	Mouse Immune	[80]
Entamoeba histolytica	Fab	Human Immune	[81]
Plasmodium chabaudi	scFv	Mouse Immune	[82]
Plasmodium falciparum	scFv	Mouse Immune	[81]
Viral			
Beet Necrotic Yellow Vein Virus	scFv	Unknown	[83]
Bluetongue Virus	scFv	Mouse Immune	[84]
Cucumber Mosaic Virus	scFv	Mouse Immune	[85]
Ebola Virus	Fab	Human Immune	[86]
Foot and Mouth	scFv	Mouse Immune	[87]
Grapevine Virus B	scFv	Human Semi-synthetic	[88]
Herpes Simplex Virus 1	Fab	Human Immune	[89]
Herpes Simplex Virus 2	Fab	Human Immune	[90]
Human cytomegalovirus	Fab	Human Immune	[91]
Infectious Bursal Disease Virus	scFv	Chicken Immune	[92]
Influenza A	Fab	Human Naïve	[93]
Severe Acute Respiratory Syndrome Coronavirus (SARS-CoA)	scFv	Mouse Semi-synthetic	[94]
Vaccinia Virus	Fab	Human Immune	[95]
Venezuelan Equine Encephalomyelitis Virus	scFv	Mouse Immune	[96, 97]
Other			
Prion – PrP^{Sc}	scFv	Mouse Immune	[98]
Androctonus australis hector (Scorpion) Venom Toxin Aah1	scFv	Mouse Immune	[99]

Abbreviation: PrP^{Sc} = The modified form of PrP^{c} (a normal cellular protein thought to be involved in synaptic function), which may cause disease; i.e., the prion is known as PrP^{Sc} (for scrapie).

of an antigen by either genetic modification or active selection can produce targets capable of evading detection systems. Also monoclonal antibodies rarely possess affinities that match the avidities of good polyclonal preparations [100].

Immunoassays. A variety of methods are available to detect antibody–antigen interactions. Some are well established, whereas others have only been developed recently.

A common way to detect antibody–antigen binding in an immunoassay is the enzyme-linked immunosorbant assay (ELISA). ELISA is based on the target antigen being captured onto a plastic multiwell or tube by a capture antibody previously bound to the solid matrix. Bound antigen is then detected using a secondary antibody. The detector antibody can be directly labeled with a signal-generating molecule, or it can be detected with another antibody that is labeled with an enzyme. These enzymes catalyze the chemical reaction with a substrate that results in a colorimetric change. The color intensity can be measured by a spectrophotometer. The ELISA immunoassay is commonly used by clinical laboratories, can be adapted for high-throughput screening, and is relatively inexpensive. Electrochemiluminescence (ECL) is similar to ELISA except that the detector antibody is directly labeled with a chemiluminescence label. Time-resolved fluorescence (TRF) immunoassay is a sandwich-type assay similar to those used for ELISA except that the detector antibodies are directly labeled with lanthanide chelates. TRF exploits the differential fluorescence life span of lanthanide chelate labels compared with background fluorescence [100, 101].

Lateral flow immunoassays are commonly recognized as dipstick or handheld immunochromatographic assays. Detection of target antigens depends on formation of an antigen–antibody complex that migrates along the matrix by capillary action. Assessment of result is qualitative and subject to operator bias. The sensitivity is generally 1-log worse than that of ELISA [101]. Novel rapid immunoassays have been recently developed for the detection of HIV-1 antibodies in clinical samples [102].

Flow cytometry is based on the use of a fluorescent probe being bound by the target antigen, which is streamed past a laser beam where the probe is excited. A detector analyzes the fluorescent properties of the antigen–antibody complex as it passes through the laser beam. This immunoassay can be used in multiplex formats with little or no loss of sensitivity. However, flow cytometry lacks the sensitivity of ELISA and associated immunoassays, and the system requires training and expertise to operate [100]. *Cyrptosporidium parvum* oocysts have been detected in various matrices by flow cytometry and, recently, in soil samples by using antibodies conjugated to fluorescein isothiocyanate [103].

One of the more popular immunassays for pathogen detection involved the use of antibodies in combination with epifluorescent microscopy, usually referred to as an immunofluorescence assay (IFA). Monoclonal and polyclonal antibodies are conjugated to fluorochromes, so that the pathogen can be more easily detected. However, a lack of specificity sometimes results in these IFA assays, indicating the presence of more than one type of pathogenic organism, especially in species that are closely related [104]. Antibodies developed against *Eimeria acervulina* have been found to cross-react with several different *Eimeria* spp., *Neospora caninum*, *Toxoplasma gindii*, and *C. parvum* [104].

6.6.4 IMMUNOTHERAPY

Immunotherapy is a form of medical treatment intended to stimulate or restore the ability of the immune system to fight infection and disease. It can be either nonspecific or specific. Cytokines, growth factors, and leukocytes can enhance host defencse against a variety of pathogens and are examples of nonspecific immunotherapies. In contrast, the administration of antibodies is a form of specific immunotherapy that, similar to antimicrobial therapy, is directed specifically at the pathogen or toxin [105]. Immunotherapy can also be either replacement or reconstitution therapy, which is intended to correct the underlying immunological defects that predispose people to infection, or augmentative therapy, which is intended to enhance the body's immune function against the pathogen [105].

The first use of antibodies for treatment of ailments was performed in 1890 by Behring and Kitasato. They demonstrated that immunity could be transferred to naïve animals by serum of animals that had been challenged with nonlethal doses of a crude toxin preparation. As all original antibody preparations were derived from the serum of immunized animals or immune human donors, the treatment was called serum therapy. Even though the therapy was effective, the administration of large amounts of foreign animal proteins was often associated with side effects that ranged from immediate hypersensitivity reactions to serum sickness [106]. The use of serum therapy was abandoned due to several drawbacks, such as the occurrence of serum sickness, the risk of disease transmission, and lot-to-lot variations of different serum preparations. In the mid-1930s, the introduction of antibiotics replaced the use of antibodies for therapy against most infectious pathogens. Antibodies retained a niche as a treatment for venoms, toxins, and certain viral infections [106]. With the establishment of hybridoma monoclonal antibody production, there was hope for the rapid development of many therapeutic applications, especially in field of oncology [106].

A renewed interest in the production of antibodies for therapeutic use has occurred as a result of numerous driving forces: (1) the increased incidence of pathogen resistance to antibiotics; (2) the lack of effective chemotherapeutic agents; (3) the toxicity of available drugs; (4) the emergence of new microorganisms and viral diseases; (5) the epidemiological evidence of an important role for the humoral immune system in host control of infection; (6) the increased incidence of chronic disease in individuals with various antibody deficiencies; and (7) the use of antibodies is currently the only means to provide immediate immunological protection against biological agents [105, 107–110].

The action of antibodies in immunotherapy is directed against pathogen stages that are susceptible to antibodies. By blocking the pathogen's interaction with the host cell, antibodies can prevent pathogen attachment and/or invasion [109]. Direct lysis of pathogens can occur, by interfering with microbial gene expression and growth, and by enhancing and activating immune cells or a combination thereof [111]. In bacterial disease, antibodies neutralize toxins, facilitate opsonization, and with complement, promote bacterial lysis [112]. In viral disease, antibodies are the best option for therapy and prophylaxis [113]. Antibodies block viral entry into uninfected cells, promote antibody-directed cell-mediated cytotoxicity by natural killer cells, and neutralize virus alone or with the participant of complement [112]. That a microbe inside a host cell is separated from serum antibody has led to the

belief that serum antibody cannot be effective against intracellular pathogens. However, at some point in the infectious cycle, most intracellular pathogens reside in the extracellular space, where they are susceptible to antibody action [114]. A hallmark of protozoan parasites is their ability to evade the host's immune system. In many cases, this is accomplished by stage-specific expression of unique antigens, causing immune responses to stages that are subsequently lost during development [115, 116].

From the point of view of antibody production for immunotherapy, careful target selection is of the utmost importance. Although it is important that the antibodies are pathogen specific, monospecific antibodies, such as monoclonal antibodies, may not be a good choice because they are too specific. Narrow specificity is advantageous because it prevents development of resistance among nontargeted microorganisms and avoids disturbance of the normal microflora. However, narrow specificity becomes a disadvantage in cases of mixed infections that cannot be treated with a single antibody preparation. It also decreases the potential market for the drug [113]. Moreover, the high specificity is at a disadvantage with the emergence of pathogen variants that lack the determinant that the antibody recognizes, such as viral escape mutants [106]. The use of cocktails of antibodies that are specific for several antigens could obviate this concern. However, this approach would also have the drawback of increasing the cost of production and the complexity of regulatory issues involving efficacy and safety [106]. Therapeutically relevant targets can also be difficult to identifiy.

Most antibodies currently being used for immunotherapy are monoclonal immunoglobulins (i.e., IgG and IgM). Their multivalency and high specificity and affinity make them attractive for therapies. Brekke and Løset [117] and Casadevall [118] have reviewed the various monoclonal antibodies currently available for immunotherapies as well as those undergoing clinical trials. Most antibodies slated for therapeutic and clinical applications are being developed for use in cancer treatment [118]. However, it has been demonstrated that in cancer immunotherapy, the fraction of injected monoclonal antibody that effectively reaches the tumor is usually less than 1% of the injected dose, which is caused by poor tumor penetration and limited target specificity. By reducing the antibody size and increasing its affinity for the target, it should be easier to obtain better targeting molecules [119]. Recombinant antibodies are smaller and can be matured for increased affinity. Therefore, it is not surprising that their use for therapy against viruses and intracellular pathogens is becoming more attractive. Currently, relatively few rAbs are being used for immunotherapy, as compared with hybridoma monoclonals. Table 6.6-2 lists some rAbs currently being studied for immunotherapeutic activities. Because of the need for therapeutic antibodies to be specific, it is feasible that any antibody used for therapy could also be used for immunodiagnostic purposes.

6.6.4.1 Passive Immunotherapy

Passive immunotherapy involves administering preformed antibodies from external sources to the recipient patient, as opposed to therapies like vaccines, which encourage the body to make its own antibodies. Numerous rAbs are specific to various pathogens (see Table 6.6-2). Pathogens that affect humans, plants, and commercial/domestic animals are all being looked at for their susceptibility to antibodies. For

TABLE 6.6-2. A List of Some Recombinant Antibodies that May Be Theoretically Effective in Immunotherapy

Antibody Target	rAb Type	Therapeutic Status	Reference
Bacterial			
Bacillus anthracis Toxin	Fab	Rat; *In Vivo*	[120]
Neisseria meningitidis	scFv	Mouse; *In Vivo*	[121]
Staphlococcus aureus – Methicillin Resistant	Aurograb	Human; Clincal Trial	NeuTec Pharma plc
Fungal			
Candida albicans	scFv	Rat; *In Vivo*	[122, 123]
Candida spp.	Mycograb	Human; Clincal Trial	NeuTec Pharma plc; [124]
Cryptococcus neoformas	scFv	Mouse; *In Vivo*	[108]
Fusarium oxysporum	scFv	In Planta	[125]
Protozoan			
Plasmdodium falciparum	Recombinant Peptide	Cell Culture; *In Vitro*	[126]
Plasmodium yoelii	scFv	Mouse; *In Vivo*	[127]
Plasmodium berghei	scFv	Mosquito; *In Vivo*	[128]
Viral			
Cucumber Mosaic Virus	scFv	In Planta	[129]
Foot and Mouth Disease	Fab	PRNT; *In Vitro*	[130]
Herpes Simplex Virus 1,2	Fab	Cell Culture; *In Vivo*	[131]
HIV-1 Reverse Transcriptase	scFv	Cell Culture; *In Vitro*	[132]
HIV-1 Vif Protein	scFv	Cell Culture; *In Vitro*	[133]
Japanese Encephalitis Virus	Fab	PRNT; *In Vitro*	[134]
Measles Virus	Fab	PRNT; *In Vitro*	[135]
Rabies Virus	scFv-Fc	Mouse; *In Vivo*	[136]
Rotavirus	Fab	Cell Culture; *In Vitro*	[137]
Varicella-zoster Virus	scFv	Cell Culture; *In Vitro*	[138]
Other			
Prion PcP^{Sc}	scFv	Cell Culture; *In Vitro*	[139]
Prion PcP^{Sc}	Fab	Cell Culture; *In Vitro*	[140]

Abbreviation: PRNT = Plaque Reduction Neutralization Test. PcP^{Sc} = The modified form of PrP^{c} (a normal cellular protein thought to be involved in synaptic function), which may cause disease; i.e., the prion is known as PrP^{Sc} (for scrapie). Aurograb = Commercially available recombinant antibody from NeuTec Pharma plc. Mycograb = Commercially available recombinant antibody from NeuTec Pharma plc.

passive immunotherapy to be effective, antibodies must be present at the site of infection long enough to interact with the appropriate infective stage of the organism's life cycle, bind to the appropriate antigen(s), and activate the appropriate effector mechanisms (if any) [109]. For intestinal pathogens, considerations for the effective therapy include dosage schedule, gastrointestinal transit time and residence of the antibody in the small intestine (the primary site of infection), gastrointestinal degradation of the antibody and ways of protecting the antibody activity (formulation), as well as the antigenic specificity and antigenic relatedness of strains or isolates of the pathogen [109]. Passive antibody therapy for infectious diseases is aided by the large antigenic differences between the microorganism and the host and can be optimized by identifying and targeting molecules essential for infectivity and by understanding mechanisms of antibody-mediated neutralization [106, 141]. In some gastrointestinal diseases caused by microorganisms, prophylactic uses of specific antibodies have proven to be much more effective than conventional supportive treatment, such as in human studies of enterotoxigenic *E. coli*-induced "travelers diarrhea" [142] and *Shigella* infections [143]. Unfortunately, rAbs have been found to possess a weaker neutralization effect on pathogens when compared with the corresponding monoclonal antibody [8].

Numerous variables can lead to a negative result from passive immunotherapy. Too little antibody can result in a lack of protective efficiency. Too much antibody can produce a prozone-like effect, whereby more antibody provides less protection than less antibody. The antibodies used in therapy can also be affected by affinity/avidity, specificity, isotype, idiotype, preparation, and route of administration. The genetic background and immune competency of the host can also affect treatment as can route of pathogen infection, genetic background, and inoculum size of the pathogen [114]. A dramatic example of the limitations of passive antibody transfer experiments is provided by the observation that transfer of either too little or too much antibody can result in no protection [114].

Passive antibody therapy and prophylaxis have a natural place in animal health because mammalian species such as pigs, horses, sheep, and cows do not transmit maternal immunity prenatally (antibodies do not cross the barrier of the placenta, as is the case in humans) but postnatally through colostral antibodies [113].

Humanized Antibodies. For human immunotherapeutic applications, the optimal antibody should be of human origin. Immune libraries are perhaps the best way to produce neutralizing antibody responses to protective epitopes on infectious pathogens [26]. For therapeutic purposes, the efficacy of nonhuman-derived monoclonal antibodies is limited by the induction of anti-mouse immune response. Using hybridoma methods to immortalize human B-cells for the construction of human monoclonal antibodies would avoid these issues. However, the absence of a suitable fusion partner and other technical issues has made methods that rely on human B-cell immortalization problematic, forcing reliance on nonhuman organisms [6].

The development of human(ized) antibody molecules is mostly aimed at reduction of unwanted immunological properties in medical applications. Useful antibodies have been isolated from mice and murine-based antibody libraries. However, these antibodies are immunogenic in humans. To use these molecules as successful therapeutic agents, they must be redesigned to reduce their immunogenicity, thereby

reducing the human–anti-mouse (HAMA) immune response [144]. The antigenicity of therapeutic antibodies can be reduced by chimerization, in which nonhuman domains are replaced by human domains, though fusion of unmodified variable domains to the constant regions of the light and heavy chains of a human antibody [144]. Humanization involves not only fusion of the (usually murine) variable domains to human constant regions, but also the alteration of selected murine variable domain framework residues to more closely match the most related available human variable template sequence [18]. CDR grafting involves the substitution of nonhuman CDR from an antibody into the most closely related human antibody sequence available, so that only the CDR domains are nonhuman in origin [144]. Veneering involves changing only exposed residues so that they reflect the human consensus sequences, whereas those residues that are buried are left unmodified [144]. These strategies may often preserve the binding affinity of the murine antibody while significantly reducing immunogenicity [145].

Antibody-based therapies that use human or humanized antibodies have low toxicities and high specificities. The high specificity of antibodies is both an advantage and a disadvantage. The advantage of high specificity is that antibody-based therapies target only the pathogenic organism that causes disease and, therefore, should not alter the host flora or select for resistance among nontargeted microorganisms. However, high specificity also means more than one antibody preparation might be required to target microorganisms with high antigenic variation [106].

Human naïve or semisynthetic libraries, such as the Tomlinson or Griffin libraries, can be screened for pathogen specific rAbs [146]. This eliminates the need for antibody humanization, making them readily available for immunotherapeutic applications in humans.

Delivery of Antibodies. Antibodies can be administered as human or animal plasma or serum, as pooled human immunoglobulin for intravenous (IVIG) or intramuscular (IG) use, as high-titer human IVIG or IG from immunized or convalescing donors, and as monoclonal antibodies [112]. Oral administration of large doses of antibodies resulting in high local concentrations can be given without the serious safety concerns related to systemic administration of foreign proteins (as would be the case for xenogeneic systemic administration). However, oral administration of antibodies is only feasible for treatment of certain types of mucosal infectious diseases, such as *C. parvum*-associated infections. There is a restriction to oral antibody delivery, specifically the possibility of gastrointestinal destruction of the antibody given the low gastric pH and the presence of gastric and intestinal proteases. As a result, duration of the antibody availability due to peristalsis is limited to the order of 1–2 hours [109]. These problems could be remedied by coadministration of antacids, enteric coatings (pH dependant release), bioerodable coating (delayed release, pH independent), or liposomal formulation (enzyme induced release). In addition to protective coatings, formulations must be able to disperse rapidly when the coating is shed [109]. Otherwise, antibodies intended for therapeutic applications need to be administered systemically [113] to provide a much longer duration of activity, on the order of days rather than hours [109]. An important potential advantage of antibody therapies is that they can be synergistic or additive when combined with conventional antimicrobial chemotherapy against bacterial and viral diseases [106].

As antibodies are natural products, they must be produced in cell lines or other live expression systems. This raises the theoretical concern that there could be contamination of antibody preparations by infectious agents such as prions or viruses. Although tight regulation and regulatory vigilance and surveillance can reduce this concern, the need for ongoing monitoring and testing for contamination contributes to the high cost of developing and administering antibody therapies [106].

6.6.4.2 Vaccine/Active Immunotherapy

The advent of recombinant DNA technologies has increased the available avenues for vaccine development. Although not related to rAbs, active immunotherapy is important for the prevention of illness due to infection by pathogenic microorganisms. Active immunity is the response generated by the immune system after exposure to a vaccine or microorganism. Both antibodies and cell-mediated immunity can be generated by active immunization. Because antibody therapy can be protective against an infectious disease, a vaccine that elicits similar antibodies should be protective against the relevant pathogen. Ideal vaccines should be safe, elicit the appropriate immune response, and provide long-term protection at low doses [147]. Vaccines against infectious organisms have been traditionally developed by administration of whole live attenuated or inactivated microorganisms [148]. Although live attenuated viral vaccines can elicit responses from cytotoxic T lymphocytes (CTLs) and from the humoral system, inactivated viruses and recombinant proteins are generally not potent inducers of CTLs [147]. However, subunit and recombinant vaccines hold promise for agents of bioterror because they deliver defined antigens, perhaps for multiple agents, and have the potential to reduce the immunogenicity of whole cell preparations [110]. Table 6.6-3 indicates a few infectious pathogens whose disease can be prevented, or minimized, by the use of recombinant antigens, recombinant viruses, or DNA vaccines.

Recombinant Antigens. Recombinant antigens are synthesized to represent the most immunogenic antigens from a particular pathogen. However, when purified

TABLE 6.6-3. Representative List of Pathogens Being Treated by Active Immunotherapy

Antibody Target	Type of Vaccine	Therapeutic Status	Reference
Chlamydia pneumoniae	DNA/Recomb Virus	Mouse; *In Vivo*	[149]
Cryptosporidium parvum	Recomb Antigen	Bovine; *In Vivo*	[150]
Entamoeba histolytica	Recomb Antigen	Mouse; *In Vivo*	[151]
HIV-1 Envelop Protein	Recomb Virus	Mouse: *In Vivo*	[152]
Listeria monocytogenes	DNA Vaccine	Mouse; *In Vivo*	[153]
Mycobacterium avium	Recomb Antigen	Lamb; *In Vivo*	[154]
Plasmdodium falciparum	Recomb Virus	Human; *In Vivo*	[155]
Vibrio anguillarum	Recomb Peptide	Piscine; *In Vivo*	[156]
Virulent infectious Bursal Disease Virus	DNA Vaccine	Chicken; *In Vivo*	[157]

recombinant antigen is administered using traditional immunization protocols, the levels of cellular immunity induced are generally low and not capable of eliciting complete protection against diseases caused by intracellular microbes [148]. Most injected proteins are not efficiently presented by major histocompatibility complex (MHC) class I, making this a major limitation for diseases in which cellular immune responses play a key role [147]. Recombinant antigens that have been used as vaccines are considered safe, but they do have limitations in their use. For example, a recombinant protein can have posttranslational modifications from the pro-tein present in the natural infection and may not elicit optimal responses. Immunization with recombinant antigens requires that parasite epitopes involved in invasion and attachment are known and available as well as amenable to re-combinant DNA technology, and they can be produced in a pure form. Molecular techniques for producing recombinant antigens that elicit neutralizing antibodies have been developed that may serve as a means to provide vaccination against pathogens.

Recombinant Viruses. This type of vaccination is based on the use of recombinant viruses encoding specific antigens as immunization tools. Recombinant viruses can express the foreign antigens directly inside cells of the host organism, as would happen in natural infection. Antigens so expressed are made available to the intracellular antigen-processing machinery. Displayed antigens can be bound by MHC molecules, thus favoring their presentation to T lymphocytes [148]. The poxviruses, adenoviruses, and influenza viruses are three of the most attractive and efficient vectors that can be used for vaccination purposes [148]. However, re-exposure of the immune system to the same recombinant antigens expressed by the viral vectors may not recall the memory T-cell responses induced during the primary exposure, as subsequent administrations of the same virus were cleared faster from the organism due to immune responses induced against the virus itself [158]. In cases where immunization with one viral vector does not elicit sufficient levels of immunity, researchers have successfully elicited immunization by the sequential administration of a different recombinant virus expressing the same antigen [158].

DNA Vaccines. DNA vaccines were introduced less than a decade ago, but they have already been applied to a wide range of infectious and malignant diseases, including those that are parasitic and difficult to control [159]. DNA vaccines involve the use of plasmids containing viral, parasitic, or bacterial genes that are expressing the protective antigen in mammalian cells after their introduction [160]. Uptake and expression of the DNA has been demonstrated in several species, for several parasitic and bacterial infections (reviewed in Ref. 147). DNA vaccination may also be useful to define key genes that play a role as antigens for diseases that are not well understood. Vaccination with DNA have been administered via (1) direct injection of naked DNA, (2) administration of DNA complexed with liposome formulations or other compounds that target specific receptors, or (3) compact DNA associated with gold particle bombardment [147].

The main safety issues for DNA vaccines include integration of the plasmid into the host genomic DNA, production of pathogenic anti-DNA antibodies to the plasmid that could induce or exacerbate diseases such as systemic lupus erythematosus, or immunologic tolerance to the antigen being expressed [147]. As a result,

to produce vaccines safely and efficiently, the use of plasmids that do not replicate in mammalian cells is desirable for gene expression. The risk of chromosomal integration and subsequent activation of an oncogene or disruption of a tumor suppressor gene or other regulatory gene is another safety issue [147].

6.6.5 CONCLUSIONS

With increased concern about the pathogen status in food and water, the application of antibodies in the detection of these pathogens also continues to increase. Design of new rAbs that are more specific and have a higher affinity for their target is becoming more commonplace. These new rAbs are making immunoassays more sensitive. When combined with advances in our understanding of the pathogenic nature of infectious diseases, rAbs are making immunotherapy more relevant in the prevention and treatment of diseases caused by pathogens. With the increased number of available antibody libraries and ease with which rAbs can be obtained, a rapid process exists for generation of specific, high-affinity rAbs against virtually any target. As the parameters for improving *in vivo* efficacy of rAbs becomes more understood, and bacterial fermentation provides a cost effective route to scale up production of many formats of engineered rAbs, their presence in pathogen diagnostic and therapies will be enhanced.

ACKNOWLEDGMENTS

We would like to thank the Canadian Water Network (CWN), the Natural Sciences and Engineering Research Council (NSERC) of Canada, Ontario Ministry of Agriculture and Food (OMAF), and Ontario Ministry of Environment for their support of our research on recombinant antibodies and *Cryptosporidium parvum*. We would also like to acknowledge GAP EnviroMicrobial Services and the NIH AIDS Research & Reference Reagent Program for their cooperation in our studies.

6.7.1 INTRODUCTION

Cancer is a major health problem worldwide. It is estimated that more than 10 million new cases of cancer are diagnosed annually around the globe and that more than 4 million individuals die each year from the disease [1]. Intense research over the past few decades has led to important discoveries by cancer biologists that are just now stimulating the development of potentially more effective and safer biologically targeted therapies for the disease. One promising strategy for treating malignancies that exploits their biological phenotype is targeted *in situ* radiotherapy [2]. In this approach, monoclonal antibodies (mAbs) that recognize tumor-associated antigens or peptide ligands that specifically bind to cell-surface growth factor receptors are used as targeting vehicles to selectively deliver radionuclides to cancer cells for *in situ* radiation therapy. These two approaches are known as radioimmunotherapy (RIT) or peptide-directed radiotherapy (PDRT), respectively. An extension of RIT or PDRT is to employ radiolabeled mAbs or peptides for imaging metastatic deposits for detection or to noninvasively characterize their phenotype *in situ*, known as molecular imaging [3]. Phenotypic characterization of tumors will be critical in the future to be able to appropriately select patients for treatment with new biologically targeted anticancer agents, including targeted radiotherapeutics. For example, it is known that breast cancers that exhibit high levels of amplification of the human epidermal growth factor receptor-2 (HER2/neu) gene respond best to treatment with the humanized anti-HER2/neu mAb, trastuzumab (Herceptin; Roche Pharmaceuticals Ltd., Nutley, NJ) [4]. HER2/neu gene amplification is currently evaluated in a primary breast cancer biopsy by immunohistochemical staining for the HER2/neu protein or by fluorescence *in situ* hybridization (FISH) for the gene copy number. A recent report, however, suggests that molecular imaging of HER2/neu expression in breast tumors using indium-111 (^{111}In)-labeled trastuzumab may reliably predict which patients respond to Herceptin as well as identify those who may be at risk for toxicity from the drug [5]. Moreover, imaging studies using radiolabeled forms of biopharmaceuticals could allow a noninvasive *in situ* assessment of their pharmacokinetic properties and, in particular, their tumor and normal tissue uptake and elimination. This may provide insight into their effectiveness as antitumor agents as well as their potential sites of normal organ toxicity. There have been many comprehensive reviews on the topics of imaging and targeted *in situ* radiotherapy of malignancies with radiolabeled mAbs and peptides [2, 3, 6]. In this chapter, the radiopharmaceutical science

that provides the foundation for these biomolecules for targeting radionuclides to tumors is discussed.

6.7.2 TUMOR AND NORMAL TISSUE TARGETING PROPERTIES OF MABS AND PEPTIDES

The tumor and normal tissue targeting properties of mAbs and their fragments and peptides must be considered when designing a radiopharmaceutical for molecular imaging or targeted *in situ* radiotherapy of cancer. Intact IgG mAbs (M_r = 150 kDa; Figure 6.7-1) are macromolecules that are cleared slowly from the blood with an elimination half-life of 2–3 days for murine forms and 4 days for chimeric and humanized mAbs [7]. This slow elimination provides multiple passes through a tumor at which extravasation and interaction with tumor cells may occur. Thus, the tumor accumulation [percent injected dose/g (% i.d./g)] of radiolabeled intact IgG mAbs is much greater than that of smaller and more rapidly cleared antibody fragments (e.g., Fab or scFv; Figure 6.7-1) or that of small peptides. This property renders intact IgG mAbs more attractive for RIT, because it maximizes the amount of radioactivity that is delivered to the tumor and, thus, the radiation absorbed dose delivered. However, the macromolecular properties of intact IgG mAbs severely restricts their tumor penetration. It has been shown that radiolabeled mAbs remain close to tumor blood vessels, whereas Fab and single-chain Fv (scFv) fragments penetrate more deeply into tumors [8]. This differential depth of penetration for intact IgG mAbs compared with their fragments may be related in part to antigen-binding affinity and avidity, because it has been hypothesized that a “binding-site barrier” restricts the penetration of antibodies into tumors as a consequence of interaction with antigens on cancer cells proximal to the blood vessels [9, 10]. Antibody fragments (Fab and scFv) are monovalent, which diminishes their avidity and affinity compared with divalent IgG mAbs. The poor tumor penetration

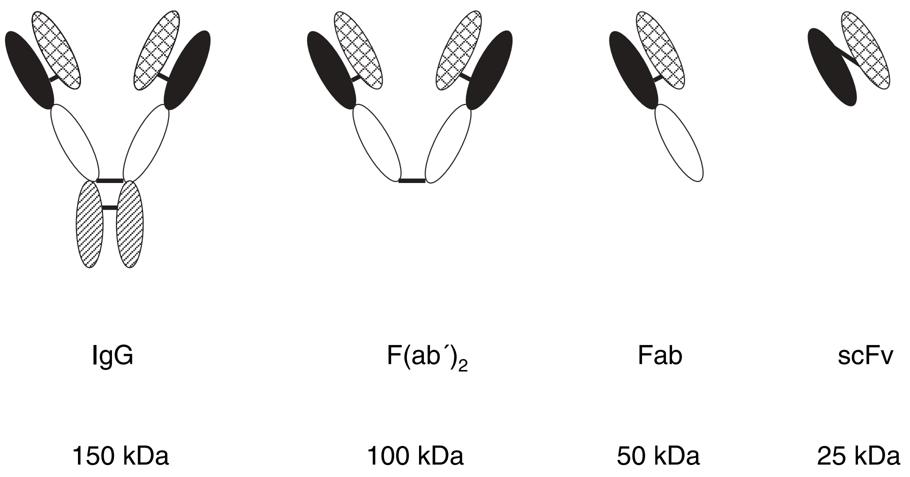

Figure 6.7-1. Structures and corresponding molecular weights of various antibody forms used for imaging or targeted *in situ* radiotherapy of cancer.

properties of intact IgG mAbs produces heterogeneous distribution of radioactivity within a tumor. Moreover, the Fc-domain of intact mAbs is recognized by asialoglycoprotein receptors on hepatocytes, which promotes liver accumulation of radioactivity [7]. Retention of radioactivity in the liver interferes with detection of hepatic metastases, especially when radiometal-labeled mAbs and peptides are used for imaging. This is less problematic for radioiodinated biomolecules due to their intracellular catabolism and release of radioiodine from hepatocytes.

For tumor imaging, antibody fragments [$F(ab')_2$, Fab, or scFv] or peptides are the most useful because they are rapidly eliminated from the blood and most normal tissues (except the kidneys), which minimizes circulating background radioactivity and yields high tumor/blood (T/B) and tumor/normal tissue (T/NT) ratios that occur at early times after injection. The major challenge with radiolabeled mAb fragments and peptides is their high accumulation in the kidneys. Kidney uptake is thought to be due to glomerular filtration of the fragments or peptides followed by charge interactions between cationic amino acid residues (e.g., lysine and arginine) in the proteins and the negatively charged renal tubular cell membrane [11]. High renal uptake of the somatostatin octapeptide analog, DOTATOC labeled with the β-emitter, ^{90}Y is associated with serious kidney toxicity in patients when used for PDRT of neuroendocrine malignancies [2]. However, renal toxicity can be avoided by co-administering intravenous solutions of lysine or arginine that competitively inhibit the interaction between renal tubular cells and radiolabeled mAb fragments or peptides [11, 12]. Furthermore, renal toxicity is not associated with the use of these radiopharmaceuticals for tumor imaging, because they are administered at much lower doses and labeled with low linear energy transfer (LET) γ-emitting radionuclides.

6.7.3 SELECTION OF A RADIONUCLIDE FOR TUMOR IMAGING

Radionuclides suitable for labeling mAbs or peptides for tumor imaging may be single γ-photon emitters (Table 6.7-1) or positron-emitters (Table 6.7-2). Images using single γ-photons are usually acquired in three-dimensional mode, known as single-photon emission computerized tomography (SPECT; Figure 6.7-2). The single γ-photons are detected by thallium-doped sodium iodide [NaI(Tl)] scintillation crystals that are housed in two opposing heads of a γ-camera. The heads are rotated 180° around the subject to obtain a series of images. Images of the body, organ, or tissue of interest are reconstructed by back-extrapolation of the lines of detection acquired by each camera head. This technique allows the reconstructed images to be "sliced" to visualize a single image plane separate from any overlying or underlying interfering planes. Optimal γ-energies for SPECT imaging are 100–300 keV. The corresponding imaging technique for positron-emitters is called positron-emission tomography (PET). Positrons are β^+ particles that are emitted when a proton is converted to a neutron in the decay scheme of certain radionuclides to stable elements. The positrons travel a distance (0.7 to 5 mm) that is directly proportional to their energy before they are annihilated through interaction with an electron in tissues. Positron annihilation creates two 511-keV γ-photons that travel out at approximately 180° from one another at the site of annihilation. PET relies on the simultaneous detection of these two γ-photons within a narrow

time window ("time of flight") by a ring of lutetium silicate (LSO) or bismuth subgerminate (BGO) scintillation crystals surrounding the subject (Figure 6.7-2). Back-extrapolation of the lines of detection allows accurate identification of the site of positron annihilation and yields high spatial resolution images. However, it is important to recognize that the spatial resolution of PET is impacted by the finite distance that the positron travels before its annihilation. This distance ranges from 0.7 mm for the low-energy, 0.6-MeV β^+ particles of ^{18}F to 5.3 mm for the higher energy 1.7-MeV β^+-particles emitted by ^{76}Br (Table 6.7-2) [13].

It is important to consider the pharmacokinetic properties of the vehicle in selecting an appropriate radionuclide for tumor imaging. Intact IgG mAbs require several days to reach maximum tumor uptake and to be cleared from the blood and normal tissues. Therefore, single γ-photon-emitters such as ^{111}In or ^{131}I with a half-life of 2.8 or 8 days, respectively (Table 6.7-1), or longer lived positron-emitters such as ^{124}I (half-life of 4 days; Table 6.7-2) are most suitable for labeling these vehicles for tumor imaging. Antibody fragments such as Fab or scFv are cleared more rapidly from the blood and most normal tissues (except the kidneys), yielding high T/B and T/NT ratios within 24 hours. Therefore, these vehicles may be labeled with short-to-intermediate half-life single γ-photon emitters such as ^{99m}Tc, ^{123}I, or ^{67}Ga for SPECT (Table 6.7-1) or with ^{64}Cu or ^{86}Y for PET (Table 6.7-2). The shorter half-life positron-emitters such as ^{18}F and ^{68}Ga are reserved for labeling peptides and scFv fragments of mAbs that exhibit very rapid tumor uptake and elimination from the blood and normal tissues. Ultra-short-lived positron-emitters such as ^{15}O, ^{13}N, or ^{11}C or (half-lives of 2, 10 or 20 minutes, respectively) that have been used for labeling small molecules for PET, are not feasible for imaging using mAbs or peptides.

6.7.4 SELECTION OF A RADIONUCLIDE FOR TARGETED *IN SITU* RADIOTHERAPY

Radionuclides suitable for targeted *in situ* radiotherapy of tumors (Table 6.7-3) emit either α-particles, β-particles, or Auger and conversion electrons [2]. The important differences between these different forms of radiation are their range in tissues and their LET. α-Particles consist of two protons and two neutrons and carry a 2^+ charge. These particles have the highest LET (100 keV/μm), are densely ionizing, and travel 50–100 μm (5–10 cell diameters) in tissues. α-emitters such as ^{211}At, ^{212}Bi, or ^{225}Ac are most useful for eradicating small clusters of cancer cells or micrometastases. β-particles are high-energy electrons that have a 1^- charge and travel 2–12 mm in tissues (200–1200 cell diameters). β-particles deposit most of their energy at the end of their track length in tissues. However, for comparison with α-particles, the average LET of the β-particles emitted by ^{131}I (Eβ = 0.6 MeV) over their 2-mm track length is 0.3 keV/μm. The average LET of the β-particles emitted by ^{90}Y (Eβ = 2.3 MeV) over their 10–12-mm track length is 0.2 keV/μm. Due to the long range of the β-particles emitted by ^{131}I, ^{90}Y, ^{186}Re/^{188}Re, or ^{175}Lu conjugated to mAbs or peptides that are targeted to tumor cells, it is possible to irradiate and kill more distant nontargeted tumor cells (“cross-fire” effect). This is advantageous for larger lesions (i.e., 2–10 mm in diameter) in which there is likely to be incomplete targeting of tumor cells. Inadequate targeting could allow some cells to survive. However, the “cross-fire” effect of the β-particles also contributes to dose-limiting bone marrow toxicity in RIT, due to nonspecific irradiation of hematopoietic stem cells by circulating radioactivity perfusing the bone marrow [2].

Auger electrons are very low-energy electrons emitted by radionuclides that decay by electron capture (EC). In EC, a proton in the nucleus captures an electron from an inner orbital shell, creating a vacancy in the shell. This vacancy is filled by the decay of an electron from a higher shell. The excess energy released is transferred to an outer orbital electron that is then ejected from the atom, creating a 2^+ atomic species. Because of their very low energy (<30 keV), Auger electrons travel only a few nanometers to at most a few micrometers in tissues (less than one cell diameter). Their LET approaches that of α-emitters (100 keV/μm). However, an antibody or peptide carrying an Auger electron-emitting radionuclide such as ^{125}I, ^{123}I, ^{111}In, or ^{67}Ga must be internalized and, ideally, translocated to the nucleus for the electrons to be the most damaging to DNA. Biomolecules that recognize peptide growth factor receptors [e.g., epidermal growth factor receptors (EGFRs) or somatostatin receptors (SMSRs)] are frequently internalized into cells and in some cases translocated to the nucleus, which allows them to be employed for targeted Auger electron radiotherapy of malignancies. The advantage of Auger electron-emitting radionuclides is that it is possible to restrict killing to cells that specifically bind and internalize radiolabeled mAbs or peptides. There is no “cross-fire” effect from Auger electron-emitting radionuclides, which should obviate any major nonspecific radiotoxicity to bone marrow stem cells, particularly if these cells do not express the target epitopes/receptors. On the other hand, in contrast to the more energetic β-emitters, the lack of a “cross-fire” effect from Auger electron-emitters does not permit killing of nontargeted cancer cells, although a “bystander effect” has been reported [14]. Auger electron-emitting radionuclides are therefore most useful for treating small tumor deposits or micrometastases for which delivery of radiolabeled biomolecules is more homogeneous.

TABLE 6.7-3. Radionuclides Suitable for Labeling Biomolecules for Targeted *in situ* Radiotherapy of Tumors

Radionuclide	Production Method	Particulate Emissions (Energy)	Maximum Range in Tissues	$T_{1/2}$phys	Labeling Methods
^{125}I	$^{124}Xe(n,\gamma)^{125}Xe \rightarrow ^{125}I$	Auger electrons (<30 keV)	<10 μm	59.4 days	Direct radio-iodination with chloramine-T or Iodogen; indirect conjugation using ATE, SIPC, SGMIB
^{123}I	$^{124}Xe(p,2n)^{123}Cs \rightarrow ^{123}Xe \rightarrow ^{123}I$	Auger electrons	<10 μm	13.2 hours	Same as for ^{125}I

^{225}Ac	$^{233}U \rightarrow ^{225}Ac$	α-particles (several duaghter radionuclides with different energies)	50–100 μm	10 days	Chelation by DOTA

6.7.5 LABELING MABS AND PEPTIDES WITH RADIOHALOGENS

6.7.5.1 Iodine Radionuclides

Radioiodination is one of the simplest ways to radiolabel a biomolecule. Several radionuclides of iodine are available for SPECT or PET (^{123}I, ^{124}I, ^{131}I; Tables 6.7-1 and 6.7-2) or for targeted *in situ* radiotherapy of cancer (^{125}I and ^{131}I; Table 6.7-3). Iodine is present in a valence state of 1^- in the alkaline solution in which it is supplied. It requires oxidation to a 1^+ valence state for electrophilic substitution into tyrosine amino acids in antibodies and peptides [15]. Reaction of radioiodine with histidine, cysteine, methionine, phenylalanine, and tryptophan residues is possible but less likely. The most commonly used oxidizing agents are chloramine-T (N-chloro-4-methylbenzene sulfonamide) [16] and Iodogen (1,3,4,6-tetrachloro-3α, 6α-diphenylglycouril; Pierce Chemical Co. Rockford, IL) [17]. Chloramine-T provides higher radiolabeling yields than Iodogen (70–90% vs. 40–60%) but because it is a stronger oxidizing agent, it may damage mAbs, especially if the conditions are not carefully controlled. A typical chloramine-T-mediated radio-iodination involves diluting the antibody or peptide in a slightly alkaline buffer and incubating it with radio-iodine and 10–20 µg of chloramine-T in a glass tube for 30–60 seconds at room temperature [18]. The radio-iodination reaction is stopped by adding 20–40 µg of the reducing agent, sodium metabisulfite. Radio-iodinated antibodies and peptides can be purified from free radioiodide by size-exclusion chromatography (SEC); alternatively, peptides may be purified by reversed-phase chromatography. Iodogen is a water-insoluble oxidizing agent that is dissolved in chloroform; 10–20 µg are then aliquoted into a glass tube and the chloroform is evaporated using a gentle stream of nitrogen to leave a coating of Iodogen on the inside surface of the tube. The biomolecule contained in a suitable buffer and radioiodide are then added to the tube and incubated for 1–2 minutes at room temperature. The reaction is stopped simply by transferring the radio-iodination mixture to a chromatography column for purification, leaving the water-insoluble Iodogen remaining in the tube. Iodogen is a more gentle oxidizing agent than chloramine-T and is preferred for radio-iodinating mAbs and their fragments.

The main challenge for radio-iodination of mAbs and peptides is their instability *in vivo* to proteolysis, deiodination, and loss of radioactivity from tumor cells. It is widely recognized that radio-iodinated biomolecules are proteolytically degraded in cells to radio-iodotyrosine, which is efficiently exported from the cells by membrane amino acid transporters. Released radio-iodotyrosine is deiodinated by deiodinases found in tissues, and the free radio-iodine redistributes and accumulates in organs with sodium iodide symporter expression, particularly the thyroid, stomach, and salivary glands. For tumor imaging applications, these catabolic processes diminish the tumor signal and increase normal tissue uptake of radioactivity. Moreover, in radiotherapeutic applications, these processes diminish the radiation absorbed dose to the tumor and increase the dose to normal tissues, thus narrowing the therapeutic index. To address this issue, several new radio-iodination methods have been developed that retain the radioactive catabolites within cells; these methods are known as “residualizing” techniques.

Zalutsky and Narula [19] first reported a method for residualizing radio-iodine in cells in 1987. This group synthesized the N-succinimidyl ester of 3-(tri-n-

butylstannyl) benzoate (ATE), a precursor that could be radio-iodinated in anhydrous chloroform by iodo-destannylation using anhydrous t-butylhydroperoxide (TBHP) as an oxidant. Radio-iodinated ATE, termed N-succinimidyl-3-iodobenzoate (SIB; Figure 6.7-3), was purified on a silica gel Sep-Pak (Waters) and conjugated to the N-terminus or ε-amino groups of lysine residues on IgGs through its reactive N-succinimidyl ester side chain. In this method, radio-iodine is situated at a position on the aromatic ring of ATE that is not ortho- to a phenolic hydroxyl group (as in the case of radio-iodotyrosine); this renders the molecule resistant to *in vivo* de-iodination. In mice, thyroid uptake of radioactivity was substantially decreased compared with IgGs labeled with radio-iodine using Iodogen. A paired-label experiment comparing the tumor and normal tissue uptake of an F(ab')$_2$ fragment of the OC125 mAb labeled with ^{125}I using SIB or ^{131}I using Iodogen in mice implanted with OVCAR-3 ovarian carcinoma xenografts, revealed that thyroid uptake of radio-iodine was reduced 100-fold using ATE [20]. There was also more rapid elimination of radioactivity from normal tissues, and at 96 hours post-injection (p.i.), T/NT ratios were fourfold higher. Similar promising results were observed in mice implanted with s.c. D-54 MG glioblastoma xenografts administered anti-tenascin mAb 81C6 labeled with ^{125}I using ATE compared with labeling with ^{131}I using Iodogen [21]. Zalutsky et al. [22] extended this residualizing strategy with an alternative radio-iodination agent, N-succinimidyl 5-[^{131}I]iodo-3-pyridinecarboxylate (SIPC; Figure 6.7-3). SIPC was used to radio-iodinate 81C6 mAb IgG and the

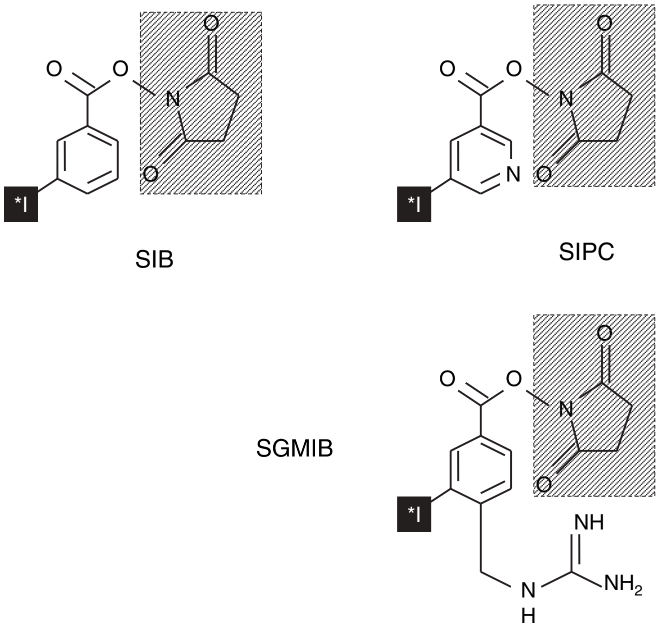

Figure 6.7-3. Precursors used for residualizing radio-iodination of monoclonal antibodies and peptides. Chemically reactive groups on the precursors are shaded, and site for radio-iodination of the precursor is indicated in black and with an asterisk. SIB: N-succinimidyl-3-iodobenzoate; SIPC: N-succinimidyl 5-iodo-3-pyridinecarboxylate; SGMIB: N-succinimidyl 4-guanidinomethyl-3-iodobenzoate.

F(ab')$_2$ fragment of anti-melanoma mAb Mel-14. It was hypothesized that SIPC, an iodopyridine, would be more dissimilar than SIB to iodotyrosine, and thus more resistant *in vivo* to de-iodination. The normal tissue distribution in mice of the 81C6 mAb and Mel-14 F(ab')$_2$ fragment radio-iodinated using SIPC or ATE were similar and there was very low thyroid uptake of radioactivity [<0.2–0.3% injected dose (% i.d.) at 7 days p.i.] using either reaagent. The tumor-specific anti-EGFRvIII mAb L8A4, which internalizes into receptor-positive cells and is highly susceptible to de-iodination, was radio-iodinated using SIPC resulting in improved tumor cell retention of radioactivity *in vitro* and increased accumulation in EGFRvIII positive tumor xenografts in mice providing enhanced T/NT ratios in comparison with L8A4 antibodies radio-iodinated using Iodogen [23, 24]. Radio-iodination using SIPC has also been applied to two 13-mer peptides: α-melanocyte-stimulating hormone (α-MSH) and its analog, [Nle^4, D-Phe^7]-α-MSH, resulting in preservation of receptor-binding properties *in vitro* and stability against de-iodination *in vivo* in mice [25]. However, conjugation of the peptides with SIPC increased their hydrophobicity. The catabolite of mAbs and peptides radio-iodinated with SIPC was found to be lysine-iodobenzoic acid (Lys-IBA).

One strategy that has been investigated to further enhance the retention of radio-iodine in cells is to use labeling techniques that generate a charged catabolite after intracellular proteolysis, which cannot traverse the lysosomal membrane and is thus resistant to exocytosis. Vaidyanathan et al. [26] synthesized N-succinimidyl 4-guanidinomethyl-3-[^{131}I]iodobenzoate (SGMIB; Figure 6.7-3), a radio-iodinating reagent that was expected to generate a positively charged catabolite at the acidic pH in lysosomes. They used this reagent to radio-iodinate anti-EGFRvIII mAb L8A4. There was three to fourfold greater retention of radioactivity in receptor-positive U87MG glioblastoma cells when these antibodies were radio-iodinated using SGMIB than when Iodogen was used. Analysis confirmed that the final catabolites were cationic. SGMIB has advantages over SIPC as a residualizing radio-iodination reagent, in that a twofold improvement in tumor retention of radioactivity was observed for L8A4 mAbs in mice implanted s.c. with D-256 glioblastoma xenografts expressing EGFRvIII. Again, similar to the SIPC reagent, thyroid radioactivity was very low (<0.35% i.d.) [27]. An analogous approach was reported by Shankar et al. [28] who used N-succinimidyl 3-[^{131}I]iodo-4-phosphonomethylbenzoate ([^{131}I]SIPMB) to radio-iodinate mAb L8A4; this reagent gen-erates an anionic catabolite that is retained within cells.

A different strategy for residualizing radio-iodine in cells uses radio-iodinated diethylenetriaminepentaacetic acid (DTPA)-containing peptides composed of one or more D-amino acids including D-tyrosine that are conjugated through a maleimide functional group to chemically reduced IgG mAbs [29]. Two such peptides: R–Gly–D–Tyr–D–Lys[1-(p-thiocarbonylaminobenzyl)DTPA], termed IMP-R1, and [R–D–Ala–D–Tyr–D–Tyr–D–Lys]$_2$(CA-DTPA), termed IMP-R2, were described by Govindan et al. [29]. The BOC-protected peptides were radio-iodinated at the D-tyrosine amino acid using chloramine-T and derivatized at their N-terminus with sulfo-SMCC to introduce maleimide groups. After deprotection, the maleimide-derivatized and radio-iodinated peptides were conjugated to thiol groups generated by dithiothreitol (DTT) reduction of some disulfide linkages on the anti-CD20 mAb LL2 or the anti-EGP-1 mAb RS7. The premise of including DTPA in the peptides was that as it had been shown that mAbs labeled with ^{111}In

through introduction of a DTPA metal chelator (see section 6.7.3) were catabolized to ^{111}In–DTPA–lysine, which was retained within the cells [30], it would be expected that radio-iodinated peptides containing this group would be trapped. The DTPA groups in the peptides are not used for radiolabeling. D-amino acids were included because these are more resistant to proteolysis than L-amino acids, and in particular, D-iodotyrosine is more resistant to *in vivo* de-iodination than L-tyrosine [31]. The immunoreactivity of the RS7 antibody was maintained using this labeling strategy (radio-iodinated LL2 was not tested for immunoreactivity), and both antibodies exhibited greater retention of radioactivity in tumor cells *in vitro* than antibodies radio-iodinated using chloramine-T. A series of radio-iodinated DTPA–D-amino acid peptides (IMP-R1 to IMP-R8) that differed in their hydrophobicity and charge was synthesized and conjugated to a DTT-reduced RS7 mAb [32]. These peptides varied in their DTPA content and extent of maleimide derivatization. Increasing the maleimide substitution in the peptides from one to two functional groups per molecule increased the conjugation efficiency with the R27 mAb from 30% to >80%. In mice implanted s.c. with Calu-3 lung carcinoma xenografts, tumor radioactivity was enhanced for mAb RS7 radio-iodinated using any of the DTPA–D-amino acid peptides compared with chloramine-T radioiodinated mAbs. However, normal tissue uptake was highest for the most hydrophobic peptides. IMP-R4: MCC–Lys(MCC)–Lys(1–((p-CSNH)benzyl)DTPA)–D–Tyr–D–Lys(3–((p-CSNH)benzyl)DTPA)–OH, where MCC represents the maleimide groups, provided the greatest retention of radio-iodine in tumors and the lowest normal tissue accumulation. This approach has been optimized using a one-vial kit labeling procedure under GMP conditions to yield at least 100 mCi of highly pure (>95%) ^{131}I-labeled humanized anti-CEA mAb hMN-14 that exhibits preserved immunoreactivity (>95%) for targeted *in situ* radiotherapy of malignancies [33]. A similar strategy was recently described by Foulon et al. [34]. This group used a polycationic peptide composed of D-amino acids: D–Lys–D–Arg–D–Tyr–D–Arg–D–Arg to radio-iodinate anti-EGFRvIII mAb L8A4. These peptides were first radio-iodinated using Iodogen and then conjugated in 60% overall yield via a maleimide group to mAb L8A4, which was thiolated using 2-iminothiolane. Paired label experiments in mice implanted s.c. with U87 glioblastoma xenografts expressing EGFRvIII and administered mAb L8A4 labeled with ^{125}I using this approach showed up to a fivefold higher tumor accumulation compared with L8A4 labeled directly with ^{131}I using Iodogen. However, use of the peptides for radio-iodinating L8A4 increased accumulation in the kidneys, perhaps because of binding of the positively charged catabolites to renal tubular cells [34].

Radio-iodine may also be residualized in cells by substitution onto an aromatic residue that is linked to a carbohydrate moiety attached to the biomolecule [35]. A sevenfold increase in tumor retention of radioactivity was observed in mice implanted with Calu-3 lung carcinoma xenografts at 7 days p.i. of radio-iodinated mAb RS7 using a dilactitol-tyramine (DLT) carbohydrate adduct compared with chloramine-T radio-iodination (38.0% vs. 5.5% i.d./g, respectively) [36]. Similar results were achieved using tyramine cellobiose (TCB)-radio-iodinated anti-EGFRvIII mAb L8A4 in mice bearing receptor-positive tumor xenografts [37]. However, a limitation of this approach seems to be the higher liver and spleen uptake of radioactivity of mAbs radio-iodinated using TCB [38]. Epidermal growth factor (EGF), a 53-amino acid peptide ligand for the EGFR present on many

epithelial malignancies, has been labeled using an analogous approach by radio-iodinating a tyrosine-modified dextran and then conjugating this dextran molecule to EGF [39]. Glioblastoma cells expressing EGFR showed significantly greater retention of radioactivity when incubated with dextran-EGF in which the radio-iodine was present on the dextran moiety compared with EGF or dextran-EGF where the radio-iodine was substituted into tyrosine amino acids on the EGF molecule itself.

Since the advent of high-resolution PET/computed tomography (CT) [40] and small animal PET tomographs [41] and building on the success of ^{18}F-fluorodeoxyglucose (^{18}F-FDG) for PET of malignancies [42], there has been a growing interest in labeling mAbs and peptides with positron-emitters. ^{124}I is a positron-emitter with a sufficiently long half-life of 4.2 days that is feasible for labeling mAbs and peptides for PET. Nevertheless, ^{124}I has limitations compared with ^{18}F. These limitations include its lower abundance of positron decay compared with ^{18}F (23% versus 100%); the higher β^+ energies for ^{124}I compared with ^{18}F (0.8–2.1 MeV vs. 0.6 MeV), which result in poorer spatial resolution (2.3 mm vs. 0.7 mm); and the emission of high-energy γ-photons by ^{124}I that degrade the PET image and contribute along with the higher positron energy and longer half-life to higher radiation absorbed doses [13]. Nevertheless, intact IgG mAbs [43–46], genetically engineered antibody fragments (e.g., minibodies and diabodies) [47, 48], and peptides [49] have been labeled with ^{124}I, in most cases using chloramine-T or Iodogen. It is important to add a small amount of ascorbic acid to the formulation after labeling biomolecules with ^{124}I in order to protect them from radiolytic decomposition caused by the high-energy positrons [46]. ^{124}I-labeled antibodies have been successfully used for PET imaging of receptor/antigen-positive tumors in mouse xenograft models [43, 45–48] and in one study in a child with neuroblastoma [44]. One advantage of PET using ^{124}I-labeled antibodies is that it allows accurate quantification of radioactivity uptake in tumors and normal tissues. This could be useful for predicting the radiation absorbed doses for subsequent RIT using the corresponding ^{131}I-labeled antibodies [47, 50].

6.7.5.2 Bromine Radionuclides

Although there has been interest in labeling mAbs and peptides with ^{124}I for PET, another attractive positron-emitter is bromine-76 (^{76}Br). ^{76}Br decays with a half-life of 16.2 hours, emitting positrons in 54% abundance with energy of 3.4 MeV. The almost sixfold higher positron energy of ^{76}Br compared with that of ^{18}F (0.6 MeV) provides poorer spatial resolution (>5 mm vs. 0.7 mm, respectively) and a higher radiation absorbed dose [13]. Nevertheless, ^{76}Br is more practical for labeling biomolecules for PET than ^{124}I due to its greater abundance of positron emissions, and because it can be produced using low-energy biomedical cyclotrons by the ^{76}Se(p,n)^{76}Br reaction [51]. Chloramine-T was initially studied for radiobromination of mAbs and peptides using ^{76}Br. The weaker oxidizing agent, Iodogen, does not seem to be useful for ^{76}Br labeling because of the greater resistance to oxidation compared with radio-iodine [52]. The colon cancer mAbs A33, 3S193, and 38S1 as well as EGF have been labeled with ^{76}Br using chloramine-T in yields of 63–77% and with good preservation of antigen/receptor-binding characteristics [53]. Nevertheless, in one study, the immunoreactivity of ^{76}Br-mAb 38S1 was diminished to

45% and only radiobromination using bromoperoxidase was found to generate radiolabeled antibodies with preserved immunoreactivity [52]. Human colon cancer xenografts implanted into nude rats have been visualized by PET using ^{76}Br-mAb 38S1 [54, 55].

Despite the ability to directly radiobrominate some antibodies using chloramine-T, many investigators obtained inconsistent and low yields and as mentioned, in some cases, decreased immunoreactivity using this approach. Therefore, newer strategies were explored for labeling mAbs with ^{76}Br using N-succinimidyl para-[^{76}Br]bromobenzoate (^{76}Br-SPBrB; Figure 6.7-4) [56]. ^{76}Br-SPBrB was generated by bromodestannylation of N-succinimidyl-para-tri-n-butylstannylbenzoate (SPMB) using chloramine-T [56, 57]. The resulting ^{76}Br-SPBrB was purified by high-performance liquid chromatography (HPLC) and conjugated through the activated N-succinimidyl moiety to ε-amino groups of lysines on the antibodies. Using this approach, mAb 38S1 was labeled with ^{76}Br in 49% yield and with good preservation of immunoreactivity (69–76%) [56]. Building on the strategy described by Vaidyanathan et al. [26] to radio-iodinate antibodies using reagents (e.g., SGMIB) that yield positively charged catabolites that are retained in cells, Mume et al. [58] synthesized N-succinimidyl 5-[^{76}Br]bromo-3-pyridinecarboxylate (Figure 6.7-4) by bromodestannylation of N-succinimidyl-5-(tributylstannyl)3-pyridinecarboxylate and conjugated it to the HER-2/neu mAb trastuzumab (Herceptin). The labeling yield was 45%, but after purification, the immunoreactivity with HER2/neu positive SKOV-3 ovarian carcinoma cells was >75%. However, this method of radiobromination did not improve cellular retention of radioactivity compared with trastuzumab labeled with ^{76}Br–SPBrB. A site-specific radiobromination technique was recently reported for labeling the affibody molecule $(Z_{HER2\text{-}4})_2$–Cys with ^{76}Br at a cysteine residue [59]. $(Z_{HER2\text{-}4})_2$–Cys affibodies are small recombinant proteins [$M_r = 7$ kDa (monomer) or 15 kDa (dimer)] that bind with high specificity to HER2/neu receptors, similar to antibody fragments but produced by phage display techniques [60]. A bifunctional reagent, ((4-hydroxy-phenyl)ethyl)maleimide (HPEM; Figure 6.7-4), reactive with thiols was synthesized and radiobrominated with ^{76}Br using chloramine-T. The radiobrominated HPEM was conjugated through its maleimide group to the free thiol on the cysteine residue of the $(Z_{HER2\text{-}4})_2$–Cys affibodies. ^{76}Br–$(Z_{HER2\text{-}4})_2$–Cys exhibited preserved binding to HER2/neu-positive SKOV-3 cells *in vitro* and achieved high tumor uptake (5% i.d./g) and T/NT ratios (up to 31 : 1) at 4 hours p.i. *in vivo* in mice implanted with SKOV-3 tumor xenografts.

Finally, a totally new approach to labeling antibodies with ^{76}Br employed derivatives of polyhedral boron clusters such as *closo*-dodecaborate (2^-) or *nido*-undecaborate (1^-) anions (Figure 6.7-4) [61, 62]. These structures form strong boron–bromine bonds and were labeled with ^{76}Br using chloramine-T. Once labeled with ^{76}Br, they were conjugated through their benzylisothiocyanato side chain to ε-amino groups of lysine residues on mAbs. The idea was that, as ^{76}Br is attached through a bromine–boron bond to a charged molecular structure that is completely foreign to the body, enzymatic debromination and exocytosis of radioactivity from cells would be substantially reduced. Bruskin et al. [61] labeled trastuzumab (Herceptin) with ^{76}Br in >80% yield using this approach, resulting in a preparation that was immunoreactive with HER2/neu-positive SKBR-3 human breast cancer cells. Trastuzumab has also been labeled with ^{76}Br using the related *nido*-undecaborate (1^-) anion [62].

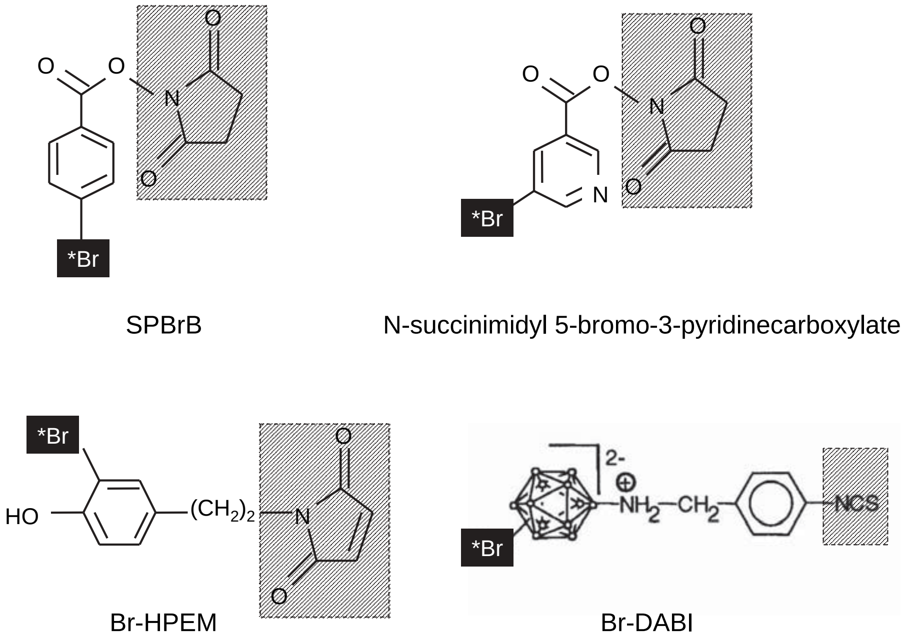

Figure 6.7-4. Precursors used for residualizing radiobromination of monoclonal antibodies and peptides. Chemically reactive groups on the precursors are shaded, and site for radiobromination of the precursor is indicated in black and with an asterisk. SPBrB: N-succinimidyl para-bromobenzoate; Br-HPEM: bromo-((4-hydroxy-phenyl)ethyl) maleimide; Br-DABI: bromo-(4 isothiocyanatobenzyl-ammonio)-bromo-decahydro-closo-dodecaborate.

6.7.5.3 Fluorine Radionuclides

Fluorine-18 (^{18}F) is the most widely used radionuclide for PET of tumors, usually in the form of ^{18}F-FDG [42]. Due to its relatively low positron energy (0.6 MeV), ^{18}F provides excellent spatial resolution (0.7 mm); it also is associated with lower radiation absorbed doses compared with ^{124}I or ^{76}Br [13]. There has been considerable interest in labeling mAb fragments and peptides with ^{18}F [63]. The pharmacokinetics of intact IgG mAbs, in particular their slow elimination from the blood, do not lend themselves to the use of ^{18}F, due to its short half-life of 110 minutes. In contrast, antibody fragments (e.g., F(ab')$_2$, Fab, and scFv) and peptides are accumulated rapidly in tumors and eliminated quickly from the blood and most normal tissues. Antibody fragments and peptides labeled with ^{18}F could therefore be useful for PET. The principal challenge in labeling biomolecules with ^{18}F is that nucleophilic substitution reactions are required; direct electrophilic radiofluorination of biomolecules requires carrier fluoride that yields low specific activity that is unsuitable for imaging epitopes/receptors on tumor cells [63]. To solve this problem, biomolecules are labeled with ^{18}F by first substituting ^{18}F onto a prosthetic group and then chemically linking this group through a reactive side chain to the biomolecules [63]. One primary consideration in designing methods for labeling antibody fragments and peptides with ^{18}F is the amount of time required to complete the labeling and conjugation procedures due to the short 110-minute half-life of ^{18}F. It

is desirable that the labeling procedure, including quality control testing, be completed in 1–1.5 hours, to minimize losses in yield, simply due to the physical decay of ^{18}F.

Garg et al. [64] described an approach for labeling F(ab')$_2$ and Fab fragments of the antimyosin antibody R11D10 using 4-[^{18}F]fluorobenzylamine succinimidyl ester ([^{18}F]SFBS; Figure 6.7-5). Although this method was rapid with a total labeling time of 1.5 hours, synthesis of [^{18}F]SFBS required three separate reactions followed by HPLC purification of the reagent; the yield of [^{18}F]SFBS was 25–40%. Conjugation of [^{18}F]SFBS to antibody fragments through reaction of the succinimidyl ester with ε-amino groups on lysines was performed in a fourth step, which required purification of the ^{18}F-labeled fragments from excess [^{18}F]SFBS by SEC. The immunoreactivity of the ^{18}F-labeled F(ab')$_2$ and Fab fragments of R11D10 were relatively preserved (89% and 75%, respectively). Using [^{18}F]SFBS as a prosthetic group, Garg et al. [65] labeled F(ab')$_2$ fragments of the anti-glioma mAb Mel-14 and obtained high T/NT ratios (up to 14:1 at 4 hours p.i.) in a s.c. glioblastoma mouse tumor xenograft model. They also labeled Fab fragments of the TP-3 antibody with [^{18}F]SFBS, which permitted PET of osteosarcoma tumors in dogs [66]. An analogous approach for labeling biomolecules with ^{18}F uses the prosthetic group, [^{18}F]-N-succinimidyl 4-(fluoromethyl)benzoate ([^{18}F]SFB; Figure 6.7-5)

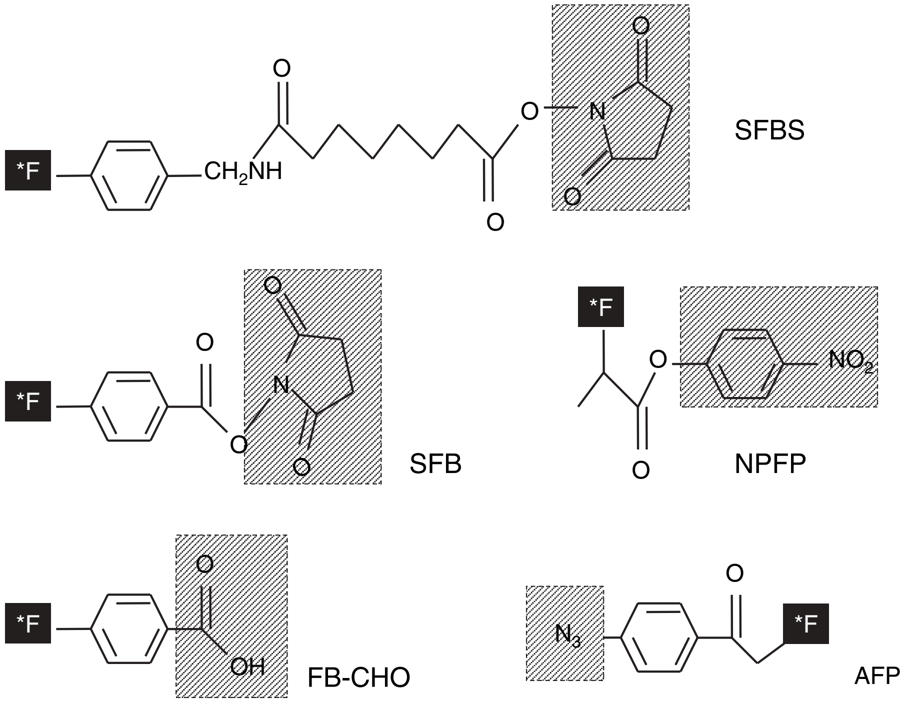

Figure 6.7-5. Prosthetic precursors used for radiofluorination of monoclonal antibody fragments and peptides. Chemically reactive groups on the precursors are shaded, and site for radiofluorination of the precursor is indicated in black and with an asterisk. SFBS: 4-fluorobenzylamine succinimidyl ester; SFB: N-succinimidyl 4-(fluoromethyl)benzoate; NPFP: 4-nitrophenyl 2-fluoropropionate; FB-CHO: 4-fluorobenzaldehyde; AFP: 4-azidofluorophenacyl.

[67]. The synthesis of [^{18}F]SFB was optimized [68], and the reagent was used for labeling F(ab')$_2$ fragments of the anti-glioma mAb Mel-14. The immunoreactivity of ^{18}F-labeled Mel-14 F(ab')$_2$ fragments using [^{18}F]SFBS or [^{18}F]SFB was indistinguishable (65% vs. 64%, respectively), and the radiolabeled fragments demonstrated similar tissue distribution and pharmacokinetics in dogs [69]. The 13-amino acid α-MSH peptide analog, N-acetyl-Ser-Tyr-Ser-NorLeu-Glu-His-D-Phe-Arg-Trp-Gly-Lys-Pro-Val-NH_2, has been labeled with [^{18}F]SFB with good preservation of receptor-binding affinity [70].

Another reagent that has been used for labeling biomolecules with ^{18}F is 4-nitrophenyl 2-[^{18}F]fluoropropionate ([^{18}F]NPFP; Figure 6.7-5) [71]. [^{18}F]NPFP is a smaller prosthetic group that may have less impact on the receptor-binding properties and/or physico-chemical properties of peptides than [^{18}F]SFBS or [^{18}F]SFB. Accordingly, [^{18}F]NPFP was used for labeling the octreotide peptide analog, SDZ 223-228, with ^{18}F resulting in full retention of biological activity [72]. It was necessary to Boc-protect the ε-amino group on lysine-5 in SDZ 223-228 during labeling with [^{18}F]NPFP and then deprotect afterward, because this residue is critical for SMSR-binding. Nevertheless, a radiofluorination technique using 4-[^{18}F]fluorobenzaldehyde ([^{18}F]FB–CHO; Figure 6.7-5) that allows site-specific labeling of aminoxyacetic acid functionalized octreotide analogs without the need to protect/deprotect the ε-amino group on lysine-5 has been recently reported [73]. This method allowed PET imaging of s.c. transplantable AR42J rat pancreatic tumors in athymic mice at 1 hour p.i. of the ^{18}F-labeled octreotide derivatives. In another study, D–Phe^1–octreotide labeled with ^{18}F using [^{18}F]NPFP exhibited higher liver accumulation and hepatobiliary clearance of radioactivity than the corresponding radio-iodinated derivative in Lewis rats bearing pancreatic islet cell tumors, suggesting that [^{18}F]NPFP may increase the hydrophobicity of peptides [74]. Nevertheless, T/B ratios were 5.2:1 at 1 hour p.i. and 4.2:1 at 2 hours p.i., due to the rapid blood clearance of the ^{18}F-D-Phe^1-octreotide. [^{18}F]NPFP and [^{18}F]SFB have also been employed for ^{18}F labeling of peptides that contain the arginine-glycine-aspartic acid (RGD) sequence that binds to the αvβ3 integrin implicated in tumor angiogenesis [75, 76]. In a study comparing labeling of proteins with [^{18}F]NPFP, [^{18}F]SFB, and another fluorinating reagent, 4-azidofluorophenacyl-[^{18}F]AFP (Figure 6.7-5), it was found that [^{18}F]NPFP-conjugated human serum albumin was partially unstable under slightly basic conditions [77]. It was concluded that [^{18}F]SFB may be the most suitable radiofluorinating agent. Finally, [^{18}F]FB-CHO (Figure 6.7-5) has been used to site-specifically label human serum albumin with ^{18}F at hydrazinenicotinamide (HYNIC) functional groups introduced into the protein using HYNIC N-hydroxysuccinimide ester [78]. This method has similarities with the use of HYNIC for labeling biomolecules with ^{99m}Tc (section 6.7.6.1).

6.7.5.4 Astatine Radionuclides

Astatine-211 (^{211}At; Table 6.7-3) is an α-particle emitter with a half-life of 7.2 hours that is useful for labeling mAbs and peptides for targeted *in situ* radiotherapy of malignancies [2, 79]. ^{211}At is produced in a cyclotron using the ^{209}Bi(α,2n)^{211}At reaction. However, the astatine–carbon bond is unstable [80] and direct electrophilic astatination of biomolecules at tyrosine residues using oxidizing agents such as chloramine-T or hydrogen peroxide results in low yield [81] and susceptibility

in vivo to de-astatination [82]. Zalutsky and Narula [83] addressed this problem by labeling N-succinimidyl 3-(tri-n-butylstannyl) benzoate (ATE) with ^{211}At. The N-succinimidyl 3-[^{211}At]astatobenzoate (SAB; Figure 6.7-6) was conjugated to ε-amino groups on lysine residues in antibodies, which is similar to the strategy used for radio-iodination. Using SAB, intact mAb 81C6 IgG and F(ab')$_2$ fragments of mAb Mel-14 directed against glioblastoma were labeled with ^{211}At with preservation of immunoreactivity *in vitro* and excellent targeting *in vivo* to s.c. D-54 MG human glioblastoma xenografts in mice [84]. Due to its short half-life (7.2 hours) and the short range of the α-particles (50–100 μm), F(ab')$_2$ fragments are more suitable for labeling with ^{211}At than intact mAb IgG's because they penetrate deeper into tumors and are cleared more quickly from the blood [7]. Despite their more rapid blood clearance than F(ab')$_2$, Fab fragments are not appropriate for labeling with ^{211}At because they accumulate to high levels in the kidneys, thus posing a potential radiotoxicity hazard. Paired label experiments in normal mice of the anti-CEA mAb C110 or its F(ab')$_2$ fragment labeled with ^{211}At or ^{131}I using the ATE method revealed that there was greater tissue retention of ^{211}At than for ^{131}I [85]. In another study, mice implanted s.c. with TK-82 human renal cell carcinoma xenografts showed similar tumor and normal tissue uptake after administration of ^{211}At or ^{125}I-labeled A6H F(ab')$_2$ [86]. Tumor uptake in this mouse xenograft model was 30% i.d./g for ^{211}At-A6H F(ab')$_2$ versus 19% i.d./g for ^{125}I-A6H F(ab')$_2$ at 19 hours p.i. T/B ratios were 3:1 for both ^{211}At and ^{125}I. ^{211}At-labeled anti-tenascin mAb 81C6 has been produced using the SAB reagent in sufficient quantities (2–10 mCi) under GMP conditions for use in a phase I clinical trial in glioblastoma patients [87]. Radiolytic decomposition of SAB due to the α-particles emitted by ^{211}At and subsequent low radiolabeling yields is nevertheless a major challenge in producing clinical quality ^{211}At-labeled mAbs [88, 89]. It seems that radiolytic decomposition is especially problematic when chloroform is used as a solvent for synthesizing SAB; benzene and methanol are alternatives that are less susceptible to the radiolytic effects of ^{211}At.

Reist et al. [90] extended their previous residualizing radio-iodination approach using N-succinimidyl 5-[^{131}I]iodo-3-pyridinecarboxylate (SIPC) to ^{211}At. Anti-EGFRvIII mAb L8A4 was labeled by conjugation with N-succinimidyl 5-[^{211}At]astato-3-pyridinecarboxylate (SAPC; Figure 6.7-6). Again, the premise is

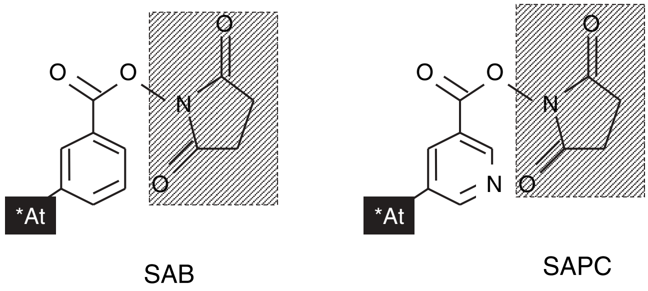

Figure 6.7-6. Precursors used for residualizing radio-astatination of monoclonal antibodies and peptides. Chemically reactive groups on the precursors are shaded, and site for radio-astatination of the precursor is indicated in black and with an asterisk. SAB: N-succinimidyl 3-astatobenzoate; SAPC: N-succinimidyl 5-astato-3-pyridinecarboxylate.

that proteolysis of the ^{211}At-labeled antibodies would yield a positively charged ^{211}At catabolite that would be unable to traverse the lysosomal membrane or be exocytosed. Immunoreactivity was maintained, and ^{211}At- and ^{131}I-labeled L18A4 showed similar tumor and normal tissue accumulation in mice implanted s.c. with EGFRvIII-positive U87MG glioblastoma xenografts. Other biomolecules that have been labeled with ^{211}At include octreotide [91] and the anti-CD20 mAb rituximab (Rituxan; Roche Pharmaceuticals Ltd.) directed against non-Hodgkin's B-cell lymphomas [92].

6.7.6 LABELING MABS AND PEPTIDES WITH RADIOMETALS

6.7.6.1 Technetium Radionuclides

Technetium-99m (^{99m}Tc; Table 6.7-1) is the most widely available, least expensive, and most commonly used radionuclide in nuclear medicine and is thus an attractive candidate for labeling mAbs, their fragments, as well as peptides for tumor imaging. ^{99m}Tc is a metastable form of ^{99}Tc, which decays by internal conversion to its ground state (^{99}Tc) with a half-life of 6 hours, emitting a γ-photon of 140 keV that is easily imaged by gamma cameras available in all nuclear medicine facilities. ^{99m}Tc is produced from the decay of molybdenum-99 (^{99}Mo) using a commercially available ^{99}Mo/^{99m}Tc generator at very low cost (less than $0.50 per mCi). Its relatively short half-life minimizes the radiation exposure to patients undergoing imaging procedures, but it necessitates rapid labeling procedures for biomolecules. There are several approaches to labeling antibodies and peptides with ^{99m}Tc [93, 94]. These approaches include (1) direct methods that rely on the binding of ^{99m}Tc to endogenous thiols generated by reduction of disulfide linkages in mAbs or introduced chemically by reaction with thiolating agents such as 2-iminothiolane, and (2) indirect methods that involve binding of ^{99m}Tc to a chelating agent that is then conjugated to the mAb or peptide ("pre-formed chelator" approach) or to a chelator already incorporated into the biomolecule. There are advantages and disadvantages of each of these strategies with respect to ease of use, *in vivo* stability, and amenability to kit formulation.

Intact mAb IgGs can be labeled simply and directly with ^{99m}Tc by reduction of a small proportion (<5%) of the inter- or intrachain disulfide bonds to free thiols by treatment with a 2000-fold molar excess of 2-mercaptoethanol (2-ME) for 30 minutes (Figure 6.7-7) [94]. The reduced IgGs are purified from excess 2-ME by SEC and labeled to high efficiency (>90%) by transchelation of ^{99m}Tc from ^{99m}Tc-glucoheptonate or ^{99m}Tc-methylene diphosphonate (^{99m}Tc–MDP). ^{99m}Tc-glucoheptonate or ^{99m}Tc–MDP are prepared from commercial kits and ^{99m}Tc pertechnetate ($^{99m}TcO_4^-$) eluted from a ^{99}Mo/^{99m}Tc generator. This method of labeling mAbs with ^{99m}Tc was introduced by Schwartz and Steinstrasser in 1987 [95] and later optimized by Mather and Ellison in 1990 [96]. A recent modification of the Schwartz method employed exposure of the anti-CD20 mAb rituximab (MabThera; Roche) to ultraviolet (UV) light of wavelength 320 nm for 20 minutes to photoreduce some disulfide linkages to thiols, which were then labeled wth ^{99m}Tc by transchelation from ^{99m}Tc–MDP [97]. This photoreduction method was originally described by Stalteri and Mather in 1996 [98]; it does not require removal of any chemical reducing agents and is somewhat simpler and potentially more controllable than chemical

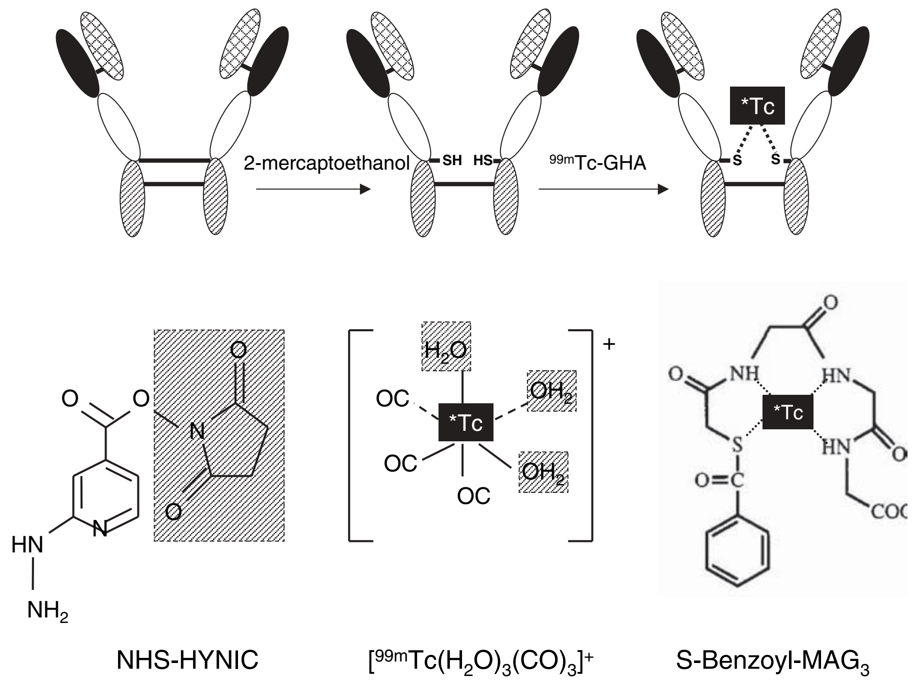

Figure 6.7-7. *Top Panel*: Method for direct labeling of intact monoclonal antibodies with ^{99m}Tc. Some disulfide linkages between the antibody chains are chemically reduced with 2-mercaptoethanol. The free thiols produced are sites for binding ^{99m}Tc-glucoheptonate (^{99m}Tc-GHA). *Bottom Panel*: Metal chelators that can be conjugated to monoclonal antibodies or peptides for labeling with ^{99m}Tc. Chemically reactive groups on the precursors are shaded, and complexation of ^{99m}Tc is indicated in black and with an asterisk. NHS-HYNIC: N-hydroxysuccinimide ester of hydrazinenicotinamide; $[^{99m}Tc(H_2O)_3(CO)_3]^+$: ^{99m}Tc(I)-carbonyl complex; S-benzoyl-MAG$_3$: S-benzoyl-mercaptoacetyl-glycyl-glycyl-glycine.

reduction with 2-ME. The advantage of the Schwartz technique is that purified reduced IgGs can be dispensed into vials and stably maintained either frozen or lyophilized until required for labeling with ^{99m}Tc, thus generating a kit formulation [99]. The major disadvantage of the method is that if too great an amount of reducing agent is used, too many disulfide linkages are reduced, increasing the risk for disrupting key linkages needed to maintain protein folding, integrity, and immunoreactivity. This is especially a problem for mAb fragments such as F(ab')$_2$, Fab, and scFv. Likewise the method cannot be used for labeling small peptides with ^{99m}Tc that harbor disulfide bonds required for maintaining biological activity (e.g., somatostatin analogs). Careful control and optimization of reduction conditions through measurement of the number of free thiols generated using Ellman's reagent [100, 101] is needed to successfully apply this method for labeling biomolecules with ^{99m}Tc. Another disadvantage is that IgGs labeled with ^{99m}Tc through direct binding to thiols are subject to loss of the radiolabel *in vivo* over time by exchange with endogenous thiol containing molecules such as cysteine and glutathione [94]. Nevertheless, the Schwartz method has been used for labeling several mAbs with ^{99m}Tc providing preserved immunoreactivity and the ability to target and image human cancers in mouse xenograft models [102, 103] and in patients [104, 105].

Due to the limitations of the Schwartz method for labeling mAb fragments (e.g., F(ab')$_2$ or Fab) and peptides with ^{99m}Tc, alternative strategies have been investigated. One method uses hydrazinenicotinamide (HYNIC) and coligands such as ethylenediaminodiacetic acid (EDDA), ethlenediaminetetraacetic acid (EDTA), tricine, or glucoheptonate to form a stable ^{99m}Tc complex with the biomolecule (Figure 6.7-7) [106]. This method was described by Abrams et al. in 1990 [107]. HYNIC is conjugated to the mAb (or its fragments) or peptides using an excess of HYNIC N-hydroxysuccinimide ester (or other chemically reactive form), which forms an amide linkage with the N-terminus or ε-amino groups in lysines. After chromatographic purification, the HYNIC-derivatized biomolecule is labeled with ^{99m}Tc by incubation with $^{99m}TcO_4^-$ in the presence of $SnCl_2$ and coligand. Coligands are needed because HYNIC occupies only one or two of the six coordination sites of ^{99m}Tc [106]. $SnCl_2$ is included to reduce ^{99m}Tc from its 7^+ valence state in $^{99m}TcO_4^-$ to a valence of 4^+ or 5^+ for complexation with HYNIC-coligands. Our group has labeled Fab fragments of the HER2/neu mAb trastuzumab (Herceptin) with ^{99m}Tc using HYNIC [108]. ^{99m}Tc-HYNIC-trastuzumab Fab showed preserved binding affinity for HER2/neu receptors on SKBR-3 human breast cancer cells *in vitro* ($K_d = 1.6 \times 10^{-8} M^{-1}$) and demonstrated good tumor targeting *in vivo* in mice implanted s.c. with HER2/neu-positive BT-474 breast cancer xenografts (T/B ratio = 3:1 at 24 hours p.i.). BT-474 tumors were visualized by imaging. Others have labeled mAb Fab fragments with ^{99m}Tc using HYNIC achieving preserved immunoreactivity and good tumor targeting [109, 110]. As mentioned, the Schwartz method is not amenable to labeling peptides that harbor key intramolecular disulfide linkages. However, the somatostatin analog, D-Phe^1-Tyr^3-octreotide (TOC), which contains a disulfide bond essential for somatostatin receptor (SMSR)-binding, has been labeled with ^{99m}Tc by conjugation to HYNIC using a variety of coligands [111–113]. Similarly, the 53-amino-acid peptide, EGF, which harbors three disufide bonds required for maintenance of its tertiary structure and receptor-binding properties has been labeled with ^{99m}Tc using HYNIC and tricine as a coligand [114]. In each case, receptor-binding was preserved *in vitro*, allowing tumor imaging in mouse xenograft models [113, 114] or in patients [111, 112].

An interesting finding is that the choice of coligand for HYNIC drastically affects the plasma protein binding, elimination from the blood, and tissue distribution of the ^{99m}Tc-labeled biomolecules. This effect was first reported by Babich and Fischman in 1995 [115] who noted differences in radioactivity accumulation in the lungs, kidneys, liver, spleen, and gastrointestinal tract of rats for the chemotactic peptide (N–For–Met–Leu–Phe–Lys) conjugated to HYNIC and labeled with ^{99m}Tc using glucarate, glucoheptonate, mannitol, or glucamine as coligands. Use of EDDA as a coligand instead of tricine for ^{99m}Tc labeling of the somastatin analogs HYNIC–TOC or RC160 produced a more hydrophilic complex that cleared more quickly from the blood in rats and favored renal over hepatobiliary clearance [116]. However, substitution of the backbone of EDDA with dimethyl, diethyl, or dibenzyl moieties increased the hydrophobicity of ^{99m}Tc–HYNIC–RC160, resulting in a fivefold to sixfold increased plasma protein binding *in vitro* and substantially increased liver uptake and hepatobiliary elimination in rats [117]. Tricine as a coligand for ^{99m}Tc–HYNIC–RC160 produced liver and intestinal radioactivity uptake intermediate between that of the EDDA and substituted EDDA derivatives. HYNIC–TOC labeled with ^{99m}Tc using EDDA as a coligand showed excellent

tumor localization in a study of 10 patients with SMSR-positive tumors allowing imaging of lesions at 4 hours p.i. [112]. Similarly, in a study of 13 patients, 12 of whom had SMSR-positive malignancies, administered ^{99m}Tc–HYNIC–TOC labeled using tricine as a coligand, tumors were imaged as early as 10 minutes p.i. [111]. A comparison between these two studies revealed that the circulating blood background radioactivity was higher and that urinary excretion of radioactivity was lower in patients receiving ^{99m}Tc–tricine–HYNIC–TOC than those administered ^{99m}Tc–EDDA–HYNIC–TOC, likely due to the increased plasma protein binding of ^{99m}Tc–tricine–HYNIC–TOC [118]. In almost all cases, the ^{99m}Tc–HYNIC-labeled analogs detected the same lesions as ^{111}In–DTPA–D–Phe^{1}–octreotide, the "gold standard" for SMSR tumor imaging, but the images were clearer and lesions were detected earlier using the ^{99m}Tc analogs. ^{99m}Tc–tricine–HYNIC–TOC missed one liver lesion in a patient, which was detected with ^{111}In–DTPA–D–Phe^{1}–octreotide, probably due to its higher liver uptake [111]. The effect of a coligand on plasma protein binding and blood clearance does not seem to be restricted to small peptides such as ^{99m}Tc–HYNIC–TOC. Ono et al. [119] found that 3-benzoylpyridine (BP) ternary complexes of ^{99m}Tc–HYNIC-conjugated Fab fragments [^{99m}Tc–HYNIC–Fab(tricine)(BP)] exhibited lower plasma protein binding *in vitro* than the corresponding binary complexes [^{99m}Tc–HYNIC–Fab(tricine)$_2$] and were cleared more quickly from the blood in mice (0.35% vs. 0.98% i.d./g at 24 hours p.i., respectively). ^{99m}Tc–HYNIC–Fab(tricine)(BP) also exhibited lower liver uptake than ^{99m}Tc–HYNIC–Fab(tricine)$_2$. They concluded that the ^{99m}Tc–tricine coligand exchanges *in vivo* with plasma proteins as well as lysosomal proteins in tissues, causing slow blood clearance and high liver retention of radioactivity. This loss of radioactivity was decreased using the more stable ternary ^{99m}HYNIC–Fab(tricine)(BP) complexes. Our group similarly found a slower blood clearance in mice for trastuzumab Fab labeled with ^{99m}Tc through HYNIC using glucoheptonate as a coligand than for ^{111}In-labeled trastuzumab Fab (3.2% vs. 1.4% i.d./g at 24 hours p.i., respectively) [108, 120]. There was also higher liver uptake for ^{99m}Tc–HYNIC–trastuzumab Fab than for ^{111}In–trastuzumab Fab at 24 hours p.i. (3.8% vs. 2.4% i.d./g, respectively). As ^{99m}Tc labeling efficiencies for antibodies and peptides are high (>90%) using HYNIC, kit formulation is possible, and indeed kits have been created for labeling HYNIC–TOC with ^{99m}Tc [111].

A particularly useful method for labeling biomolecules with ^{99m}Tc, especially those produced by protein engineering techniques and that contain polyhistidine affinity tags, employs a ^{99m}Tc(I)–carbonyl complex (Figure 6.7-7) [121, 122]. This method, described by Waibel et al. in 1999 [122], involves a simple one-vial synthesis of the organometallic aqua–ion complex [^{99m}Tc$(H_2O)_3(CO)_3]^+$, which then efficiently complexes through release of its water molecules with imidazole nitrogens in histidine-containing biomolecules. The [^{99m}Tc$(H_2O)_3(CO)_3]^+$ complex is formed by heating $^{99m}TcO_4^-$, Na_2CO_3, and $NaBH_4$ flushed with carbon monoxide (CO) at 75°C for 30 minutes. The yield of [^{99m}Tc$(H_2O)_3(CO)_3]^+$ is >95%. A commercial kit for producing the [^{99m}Tc$(H_2O)_3(CO)_3]^+$ complex (Iso-Link; Mallinckrodt, Petten, Belgium) is available. Labeling with ^{99m}Tc is achieved simply by mixing the [^{99m}Tc$(H_2O)_3(CO)_3]^+$ complex with the histidine-containing protein or peptide and heating for 20–30 minutes at 37°C. An scFv containing a polyhistidine tag was labeled with the ^{99m}Tc(I)–carbonyl complex resulting in a stable complex *in vitro* in human serum and retaining 87% of its radioactivity over 24

hours at 37°C [122]. It was also stable to challenge *in vitro* with a 5000-fold molar excess of histidine, retaining 94% of its radioactivity [122]. This technique is attractive because recombinant antibodies and peptides often incorporate polyhistidine affinity tags for their purification, thus allowing them to be directly and easily labeled using the ^{99m}Tc(I)–carbonyl complex. Moreover, Re(I)–carbonyl complexes have also been prepared for this method, allowing extension to radionuclides of rhenium (e.g., ^{186}Re or ^{188}Re; Table 6.7-3) for targeted *in situ* radiotherapy of malignancies [123].

Finally, tetradentate chelators such as N_3S (triamidothiols), N_2S_2 (diamidodithiols), or N_2S_4 (diaminotetrathiols) have been used for labeling mAbs and peptides with ^{99m}Tc (Figure 6.7-7) [106]. The advantage of these chelators is that they form stable, well-defined ^{99m}Tc complexes, but they require introduction into biomolecules through reaction of a chemically reactive ester in a side chain with ε-amine groups on lysines. This conjugation step is nonspecific and has the potential to target a key lysine required for maintenance of antigen or receptor-binding. This problem can be solved in the case of small peptides by incorporating the tetradentate chelator at a specific position into the biomolecule during its solid phase synthesis using sequences of amino acids such as cysteine-glycine-glycine-glycine (N_3S) [124]. Moreover, there is the possibility that ^{99m}Tc will bind to low-affinity endogenous metal-binding sites in antibodies in addition to the high-affinity sites introduced with the tetradentate chelator. Therefore, to avoid this possibility, a "preformed chelator" approach was reported by Fritzberg et al. [125]. In this preformed chelator approach, a stable ^{99m}Tc–N_2S_2 complex is synthesized first and then conjugated to the mAbs through a reactive tetrafluorophenyl ester side chain. However, this strategy is complex and time consuming; the conjugation step is inefficient; and it does not lend itself easily to kit formulation. Despite these limitations, tetradentate chelators have been employed for labeling various mAbs and peptides with ^{99m}Tc [94, 106]. An interesting application of a tetradentate chelator was described for ^{94m}Tc labeling of the somatostatin analog, demotate [126]. ^{94m}Tc is a positron-emitter (β^+ 72%; Eβ^+ max 2.5 MeV; Table 6.7-2) with a half-life of 52 minutes. Demotate incorporating the 1,4,8,11-tetraazaundecane (N_4) tetradentate chelator was labeled with ^{94m}Tc in the presence of $SnCl_2$. ^{94m}Tc-demotate exhibited preserved receptor-binding to A-427 non-small cell lung cancer cells infected with the AdHASSTR2 adenovirus encoding the SMSR subtype 2. A-427 xenografts infected with AdHASSTR2 implanted s.c. into athymic mice were visualized by PET at 1 hour p.i. of ^{94m}Tc-demotate.

6.7.6.2 Rhenium Radionuclides

Methods for labeling antibodies and peptides with radionuclides of rhenium have been developed from techniques used for labeling with ^{99m}Tc, due to the similarity in the chemistry of technetium and rhenium [127]. Two radionuclides of rhenium (^{186}Re and ^{188}Re) are useful for targeted *in situ* radiotherapy of cancer (Table 6.7-3). ^{186}Re decays with a half-life of 3.7 days emitting a β-particle with maximum energy (E_{max}) of 1.07 MeV as well as a low abundence (9%) γ-photon of 137 keV, which is useful for imaging. ^{188}Re decays with a 17-hour half-life emitting a β-particle with E_{max} of 2.12 MeV and a low abundance (15%) γ-photon of 155 keV that can be

imaged. The twofold higher β-particle energy of ^{188}Re compared with ^{186}Re provides a threefold longer range in tissues (8 vs. 3 mm, respectively), making it more useful for treating larger tumors (i.e., >1 cm in diameter) or tumors in which there is incomplete targeting of radiolabeled mAbs or peptides to cancer cells. On the other hand, the relatively short half-life of ^{188}Re (17 hours) may limit its feasibility for labeling intact IgG mAbs for radiotherapeutic applications due to their slow kinetics of tumor uptake and clearance from the blood and normal tissues. Antibody fragments and peptides may be more suitable for labeling with ^{188}Re. A major advantage of ^{188}Re is that it can be produced carrier-free and in high purity using a $^{188}W/^{188}Re$ generator system [128], which would make the radionuclide available at low cost in any nuclear medicine facility.

Both direct and indirect methods have been used for labeling antibodies with $^{186}Re/^{188}Re$ [127]. Direct methods rely on the binding of reduced $^{186}Re/^{188}Re$ to free thiols on the antibodies generated by reduction with 2-ME as described for ^{99m}Tc (Section 6.7.6.1). However, the chemistries of technetium and rhenium are not identical. In particular, rhenium is more difficult to reduce from its 7^+ valence state to its lower valence states of 4^+ or 5^+ for labeling biomolecules, and it is more easily re-oxidized [129, 130]. Thus, a greater amount of $SnCl_2$ reducing agent is required. The optimal pH for labeling with $^{186}Re/^{188}Re$ is also lower than that for ^{99m}Tc-labeling (pH 4.5–5.0 vs. pH 7.0–7.5, respectively) and pH values >5.0 can result in re-oxidation of rhenium [129]. Moreover, radiolysis of antibodies and peptides caused by the high-energy β-particles emitted by $^{186}Re/^{188}Re$ can be a problem, and thus, radioprotectants such as ascorbic acid, gentisic acid or human serum albumin are often incorporated into the formulations. In one study, ascorbic acid was employed as both a radioprotectant and a reducing agent for the disulfide bonds for labeling IgG with ^{186}Re [130]. Much longer incubation times (17–24 hours) have been used for direct labeling of mAbs with $^{186}Re/^{188}Re$ [130, 131] than for ^{99m}Tc labeling (30 minutes) [132]. However, in one study [133], a kit formulation was developed for labeling the anti-CD20 mAb ritiximab (Rituxan; Roche) with ^{188}Re. A labeling efficiency >97% was obtained in only 1–1.5 hours after the addition of ^{188}Re perrhenate eluted from a $^{188}W/^{188}Re$ generator to the kit.

Tetradentate chelators (e.g., N_3S; Figure 6.7-7) have also been used for labeling mAbs and their F(ab')$_2$ fragments [134, 135] as well as the somatostatin peptide RC-160 [136] with $^{186}Re/^{188}Re$. In the case of antibodies, the "preformed chelate" approach was used, whereas for RC-160, the N_3S chelator was introduced during solid phase peptide synthesis. One method that has been used for direct labeling of antibodies using ^{188}Re employs the hydroxamic acid, trisuccin. Trisuccin differs from most tetradentate ligands (e.g., N_3S structures) in that it does not contain a free thiol. Therefore, it can be conjugated directly to a mAb and used for labeling with $^{186}Re/^{188}Re$ without the risk of the free thiol reacting with disulfides on the antibodies. Safavy et al. [137] labeled two different humanized forms of the tumor-associated glycoprotein-72 (TAG-72) mAb CC49 with ^{188}Re using trisuccin conjugated through a 6-oxoheptanoic acid linker molecule. The labeling efficiency ranged from 80% to 98%, and the immunoreactivity ranged from 69% to 77%. High tumor uptake of radioactivity (18%–23% injected dose/g) was found in mice implanted with s.c. TAG-72-positive LS174T human colon cancer xenografts. Finally, bombesin, a 14-amino acid analog of gastrin-releasing peptide (GRP) that binds to GRP receptors on prostate, breast, lung, and pancreatic cancers, has been

labeled using a $^{188}Re(H_2O)(CO)_3$–carbonyl complex similar to that described for labeling biomolecules with ^{99m}Tc (Section 6.7.6.1) [138]. Targeting of PC-3 prostate cancer xenografts in mice was achieved with ^{188}Re-labeled bombesin.

6.7.6.3 Indium Radionuclides

Indium-111 (^{111}In; Table 6.7-1) is a γ-emitting radionuclide (Eγ = 172 and 245 keV) with a half-life of 67 hours that is routinely used for labeling mAbs and peptides for SPECT imaging of tumors. The positron-emitter, ^{110m}In (Table 6.7-2), has a half-life of 69 minutes and is useful for labeling peptides for PET. The β^+ energy of ^{110m}In (2.26 MeV) provides a spatial resolution of 3.0 mm compared with 0.7 mm for ^{18}F [13]. Octreotide was labeled with ^{110m}In and used for PET of a patient with a SMSR-positive intestinal carcinoma metastasis [139]. ^{114m}In and its daughter product, ^{114}In, are long-lived radionuclide impurities in ^{111}In, but they have potential for targeted *in situ* radiotherapy of malignancies. ^{114m}In decays to ^{114}In with a half-life of 49.5 days emitting an imageable γ-photon of 190 keV, as well as Auger and conversion electrons that can kill cancer cells. ^{114}In decays to ^{114}Cd (0.5%) or ^{114}Sn (99.5%) with a half-life of 72 seconds emitting β^- particles (E_{max} = 1.98 MeV) that are also useful for treatment of tumors. Octreotide has been labeled with ^{114m}In [140]. Antibodies and peptides are labeled with ^{111}In by introducing the chelator, diethylenetriaminepentaacetic acid (DTPA), by reaction of ε-amino groups on lysine residues or the N-terminal amine of the biomolecules with reactive forms of DTPA (Figure 6.7-8), such as DTPA dianhydride (cDTPAA) [141], DTPA mixed anhydride [142], or DTPA p-benzylisothiocyanate (SCN-Bz-DTPA) [143, 144]. Conjugation with cDTPAA involves suspending cDTPAA in anhydrous chloroform, dispensing an

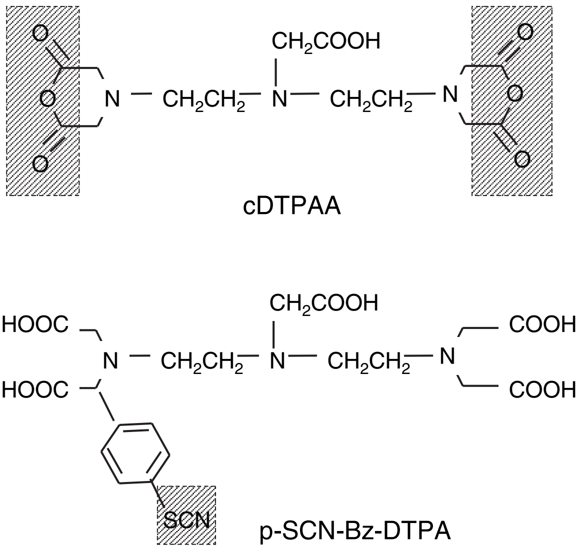

Figure 6.7-8. Metal chelators that can be conjugated to monoclonal antibodies or peptides for labeling with ^{111}In. cDTPAA: Bicyclic anhydride of diethylenetriaminepentaacetic acid; p-SCN-Bz-DTPA: p-isothiocyanatobenzyl-diethylenetriaminepentaacetic acid. Chemically reactive groups for conjugation to the antibodies or peptides are shaded.

aliquot of the suspension containing a known amount of cDTPAA into a clean, dry glass tube, and evaporating the chloroform to dryness using a gentle stream of nitrogen to leave a film of cDTPAA on the inside surface of the tube. The antibody or peptide dissolved in 50-mM sodium bicarbonate buffer, pH 7.5, is then added to the tube. Reaction with cDTPAA occurs rapidly within 1–2 minutes, although 15–30 minutes are often allowed. DTPA conjugation efficiency is dependent on protein concentration, pH, and the molar ratio of cDTPAA: antibody/peptide. The DTPA-derivatized biomolecule is separated from excess DTPA by SEC and/or by ultrafiltration. Pure DTPA-conjugated antibodies or peptides can be dispensed into unit-dose vials to produce kits that can be labeled to high radiochemical purity (RCP > 90%) simply by adding ^{111}In to the vial and incubating at room temperature for 15–30 minutes [145]. Radiolabeling is achieved by transchelation of ^{111}In from acetate or citrate complexes to DTPA. The acetate or citrate counterions are used to maintain the solubility of ^{111}In at pH 5–7.5 used for labeling. ^{111}In–acetate or –citrate complexes are formed by mixing $^{111}InCl_3$ with 0.5–1-M sodium acetate or citrate buffer, pH 5.0. One critical parameter that must be considered for labeling biomolecules with ^{111}In is the presence of trace amounts of divalent or trivalent metal ions (e.g., Fe, Al, Cd, and Zn) in the labeling reaction. These trace metals may exist at even higher levels than ^{111}In, which is in commercial $^{111}InCl_3$ solutions [146], and can interfere with labeling by occupying the small number of DTPA metal-binding sites present in biomolecules. Trace metal contamination is minimized by acid-washing of glassware, by using trace-metal-free plasticware, through storing DTPA-conjugated proteins frozen (to avoid leaching of metals into the solution from the glass container), and by purification of conjugation buffers on a cation-exchange column (e.g., Chelex-100) [147]. A method has been reported for ultra-purification of ^{111}In from trace metals in $^{111}InCl_3$ solution by selective extraction of ^{111}In as an iodide complex into anhydrous diethyl ether [146].

Hnatowich et al. [141] found that the reaction between cDTPAA and IgG is dependent on pH (optimum between pH 7.5 and 8.5) and protein concentration (optimum >15 mg/mL). There was an inverse relationship between the molar ratio of cDTPAA : IgG and the conjugation efficiency with the greatest efficiency (>70%) found at a 1 : 1 ratio using a protein concentration of 15 mg/mL. However, it may not always be possible to achieve these high protein concentrations, and thus, greater molar ratios of cDTPAA : antibody/peptide (e.g., 5 : 1 to 20 : 1) are used to compensate for the lower conjugation efficiency at lower concentrations (e.g., 2–5 mg/mL). One limitation of the cDTPAA method is that the reagent contains two anhydride moieties that can react with ε-amino groups on lysines or the N-terminal amine of biomolecules. Reaction of cDTPAA with lysines on two biomolecules causes intermolecular cross-linking, leading to the formation of dimers and higher molecular weight polymers. Reaction of cDTPAA with two lysines on the same biomolecule generates intramolecularly cross-linked species. This latter possibility is especially troublesome because in contrast to intermolecularly linked species, intramolecularly cross-linked biomolecules are not easily detected or measured by chromatographic techniques but may significantly diminish immunoreactivity or receptor-binding properties due to protein misfolding [148]. The proportion of intermolecularly linked molecules is directly proportional to the molar ratio of cDTPAA : IgG and protein concentration in the conjugation reaction, and the resulting substitution level (moles DTPA/mole biomolecule) of the conjugate.

Hnatowich et al. [141] reported that the proportion of polymers increased from 0.3% when IgG was conjugated with cDTPAA at a 1:1 molar ratio (cDTPAA:IgG) to as much as 40% at a molar ratio of 10:1 when the IgG concentration was 15 mg/mL. Our group found less than 11% IgG dimers when the HER-2/neu mAb trastuzumab (Herceptin) was modified with a fourfold molar excess of cDTPAA using a protein concentration of 5 mg/mL. In this instance, there were two DTPA molecules/trastuzumab IgG [149]. Another limitation of the cDTPAA method is that one of the five carboxylic acid groups of DTPA is used to form an amide linkage with the antibody or peptide. This converts DTPA to diethylentriaminetetraacetic acid (DTTA), which forms a much less stable heptadentate complex with ^{111}In. This instability is manifested by a moderate rate of transchelation *in vivo* (7–10% per day) of ^{111}In from DTPA-conjugated antibodies to transferrin, which then causes deposition of radioactivity in the liver and bone marrow [150, 151]. In contrast, the transchelation rate from an octadentate ^{111}In–DTPA complex to transferrin is 1–2% per day [151, 152]. Despite these limitations of cDTPAA as a bifunctional chelator, its has been used for ^{111}In labeling of intact IgG mAbs [18, 120, 147, 151], single-chain Fv fragments [153], and peptides [18, 154, 155]. In the case of peptides that harbor critical lysine residues necessary for receptor-binding, these amino acids must be Boc-protected during conjugation of the N-terminal amine with DTPA, and then deprotected afterward [155].

To address the limitations of cDTPAA, other forms of DTPA have been synthesized that position a reactive group on the methylene carbon of one carboxymethyl arm instead of using one carboxylic acid group to link with an antibody or peptide [143, 144]. One of these DTPA bifunctional chelators is the p-benzylisothiocyanate derivative of DTPA (p–SCN–Bz–DTPA; Figure 6.7-8). The p–SCN–Bz–DTPA chelator reacts with ε-amino groups or the N-terminus of biomolecules to form a thiourea linkage. As there is only one reactive moiety on the p–SCN–Bz–DTPA chelator, there is no possibility of inter- or intramolecular cross-linking, which helps to preserve immunoreactivity or receptor-binding affinity [143, 144]. Our group found that the immunoreactive fraction of mAb 2G3 reactive with a 330-kDa glycoprotein on breast and ovarian cancer was 0.52 when conjugated with 0.5–1.5 moles of DTPA using cDTPAA, but it was 0.77 when conjugated with p–SCN–Bz–DTPA [151]. Importantly, the retention of all five carboxylic acid groups in the DTPA molecule for binding ^{111}In preserves the highly stable octadentate ^{111}In–DTPA complex, which diminishes the loss of ^{111}In to transferrin in plasma. The B-cell lymphoma antibody Lym-1 conjugated with p–SCN–Bz–EDTA (a chelator similar to p–SCN–Bz–DTPA) and labeled with ^{111}In showed a lower rate of loss of ^{111}In in serum than Lym-1 conjugated with DTPA using cDTPAA (<1% vs. 14% over 5 days, respectively) [156]. Similar results were obtained *in vitro* in serum and *in vivo* in plasma in mice for other ^{111}In–SCN–Bz–EDTA or SCN–Bz–DTPA immunoconjugates [157]. However, our group did not observe increased stability of ^{111}In-labeled mAb 2G3 conjugated to SCN–Bz–DTPA *in vitro* in serum compared with ^{111}In–DTPA–mAb 2G3 (both had transchelation rates of 7% per day), but we did find a lower rate of loss of ^{111}In from ^{111}In–SCB–Bz–DTPA–2G3 to ascites fluid from ovarian cancer patients (5% vs. 11% per day) [151]. Avoidance of polymerization and increased serum stability of p–SCN–Bz–DTPA conjugated biomolecules decreases liver uptake and retention of radioactivity, a common problem with ^{111}In-labeled mAbs and peptides [158].

Methods have been developed to site-specifically conjugate DTPA to the Fc domain of antibodies for labeling with ^{111}In in order to better preserve their immunoreactivity [159]. Site-specific conjugation of DTPA was achieved by reaction of the N-terminal amine of the tripeptide, glycine–tyrosine–lysine–DTPA (GTK–DTPA) with aldehydes generated in the Fc-domain by sodium periodate oxidation [160]. Stabilization of the resulting Schiff base linkage between GTK–DTPA and the antibodies was achieved by sodium borohydride reduction. This approach positions the DTPA chelator at a position that is remote from the Fab antigen-binding region. Nevertheless, the sodium periodate oxidation step can diminish antibody immunoreactivity if not controlled [161]. The number of aldehydes generated by sodium periodate oxidation can be measured by a spectrophotometric assay that relies on the reaction of the aldehyde groups with dinitrophenylhydrazine (DNPH), generating a derivative that absorbs at 360 nm [162]. Our group recently reported a novel strategy for site-specific labeling of recombinant biomolecules with ^{111}In that takes advantage of its high affinity for transferrin ($K_a = 10^{28}$ L/mole). We fused the gene for the n-lobe of human transferrin (hn-Tf) through a DNA sequence that encoded a flexible polypeptide linker [$(GGGGS)_3$] to the gene for vascular endothelial growth factor ($VEGF_{165}$) and expressed the recombinant fusion protein in *Pichia pastoris* [163]. The hnTf–VEGF protein bound ^{111}In directly through its hnTf moiety and retained its binding affinity for VEGF receptors on human umbilical vascular endothelial cells (HUVECs). The protein did not bind to transferrin receptors on cells, because such binding requires both the n- and the c-lobes of transferrin. ^{111}In–hnTf–VEGF localized specifically in angiogenic U87MG glioblastoma xenografts implanted s.c. in athymic mice permitting tumor imaging at 72 hours p.i. However, ^{111}In–hnTf–VEGF exhibited relatively high liver uptake and there was a moderately rapid loss of ^{111}In *in vitro* from the protein to transferrin in plasma (21% per day). This transchelation was not likely due to a lower affinity of the hnTf moiety for ^{111}In, but it was caused by competition with the higher concentrations of transferrin present in plasma.

Limiting the metal chelator substitution of a biomolecule to one to two DTPA or EDTA groups per molecule in order to preserve its immunoreactivity or receptor-binding affinity restricts the specific activity that can be achieved for labeling with ^{111}In. For example, monosubstitution of EGF with DTPA restricts the maximum specific activity that can be practically achieved with ^{111}In to 40 MBq/μg (2.4×10^5 MBq/μmole). At this low specific activity, only one in eight EGF molecules carries an ^{111}In atom and almost 90% of EGFRs in a tumor would be targeted by non-radiolabeled EGF. To address this issue, Remy et al. [164] conjugated maleimide-derivatized EGF with a thiol-containing multibranched peptide containing four EDTA-like metal chelators for ^{111}In. However, the MCP–4–EDTA–S–MB–EGF conjugate showed a 40-fold decrease in receptor-binding affinity in a competition assay with MDA–MB–468 human breast cancer cells compared with unmodified EGF. In contrast, our group found that derivatization of EGF directly with one to two DTPA metal chelators and labeling with ^{111}In yielded a radiopharmaceutical with receptor-binding affinity identical to that of ^{125}I-labeled EGF ($K_a = 7.3 \times 10^8$ L/mole) [18]. Greater success was achieved by our group in maximizing the specific activity of ^{111}In–EGF by conjugating maleimide-derivatized EGF to thiolated human serum albumin (HSA), which presents 60 lysine residues for DTPA conjugation [165]. Conjugation of EGF to HSA diminished its receptor-

binding affinity 15-fold ($K_a = 5.1 \times 10^7$ L/mole), but there were no further decreases in affinity when up to 23 DTPA chelators were preferentially substituted into the HSA moiety. The specific activity of ^{111}In–DTPA–HSA–EGF was increased 10-fold compared with ^{111}In–DTPA–hEGF. ^{111}In–DTPA–HSA–EGF retained its receptor-mediated internalization and nuclear translocation properties in MDA–MB–468 cells and was fourfold more growth-inhibitory toward the cells. An analogous strategy was reported by Manabe et al. [166] that used a polylysine peptide carrier to conjugate as many as 42 DTPA molecules to the anti-HLA mAb H-1 with > 90% retention of immunoreactivity. Similarly, starburst dendrimers that display 64 amine groups on their surface were derivatized with up to 43 1B4M DTPA-like chelators, and then were conjugated through a maleimido bond to mAb OST7 [167]. The maximum specific activity achieved for labeling these starburst dendrimer immunoconjugates with ^{111}In (8.4 MBq/μg; 1.3×10^6 MBq/μmole) was 48-fold higher than directly conjugated 1B4M-OST7. In another study, poly(ethylene glycol) (PEG) containing an amine functional group was used to conjugate DTPA chelators to the anti-EGFR mAb C225 with good preservation of immunoreactivity [168]. This approach provides a method of labeling with ^{111}In while minimizing nonspecific retention of radioactivity in the liver due to conjugation with PEG [169].

High retention of radioactivity in the liver with ^{111}In–DTPA-conjugated mAbs is thought to be due to intracellular trapping of ^{111}In-catabolites. ^{111}In–DTPA-labeled IgG antibodies interact with glycoprotein receptors on hepatocytes through their Fc-domain and are internalized into endosomes. The antibodies are routed to lysosomes for proteolytic degradation. The ultimate catabolite of proteolysis has been identified as ^{111}In–DTPA–ε–Lys [30, 170]. This catabolite cannot easily cross the lysosomal membrane due to its positive charges or be exocytosed due to its poor recognition by cell membrane amino acid transporters and, thus, becomes trapped. An analogous mechanism has been proposed for retention of ^{111}In-labeled mAb fragments and peptides by renal tubular cells. ^{111}In-labeled mAb fragments or peptides are filtered by the glomerulus and reabsorbed by renal tubular cells. Proteolytic catabolism within renal tubular cells of ^{111}In–DTPA–F(ab′)$_2$ fragments yields ^{111}In–DTPA–ε–Lys, which is trapped within the cells [171]. Proteolysis of ^{111}In–DTPA–D–Phe^1–octreotide or ^{111}In–DTPA–L–Phe^1–octreotide similarly results in retention of ^{111}In–DTPA–D–Phe^1–OH or ^{111}In–DTPA–L–Phe^1–OH catabolites, respectively, in renal tubular cells [172, 173].

The macrocyclic chelator, 1,4,7,10-tetraazacyclododecane N,N′,N″,N‴-tetraacetic acid (DOTA) (Section 6.7.6.4) has been less commonly used for labeling mAbs and peptides with ^{111}In because the kinetics of binding ^{111}In by DOTA are much slower than those of DTPA. Elevated temperatures of 37–43°C for mAbs [174] and heating at 100°C for peptides [175] combined with longer incubation times (30–45 minutes) are required to obtain complete incorporation of ^{111}In into DOTA-conjugated biomolecules. Nevertheless, intact IgG mAbs [174, 176], Fab fragments [177] and diabodies [178], as well as octreotide [175] have been labeled with ^{111}In using DOTA. The stability of ^{111}In–DOTA-conjugated mAbs in serum is greater than that of ^{111}In–DTPA-conjugated antibodies. Lewis et al. [174] found that there was less than 0.8% loss of ^{111}In in serum from ^{111}In–DOTA–cT84.66 mAb over 10 days compared with 13.0% for ^{111}In–DTPA–cT84.66. The advantage of conjugating mAbs or peptides with DOTA for labeling with ^{111}In is that it provides an analog

for the corresponding yttrium-90 (^{90}Y)–DOTA–biomolecule used for targeted *in situ* radiotherapy. Imaging with the ^{111}In–DOTA–biomolecule can be used to predict radiation dosimetry estimates to tissues for the ^{90}Y–DOTA–biomolecule [179, 180]. Use of an ^{111}In–DTPA–conjugated mAb or peptide for this purpose may yield inaccurate dosimetry estimates because of major differences in stability *in vivo* between ^{111}In– and ^{90}Y–DTPA complexes.

6.7.6.4 Yttrium Radionuclides

Two radionuclides of yttrium, ^{86}Y and ^{90}Y, are available for labeling biomolecules for imaging or radiotherapeutic purposes, respectively. ^{86}Y (Table 6.7-2) is a positron-emitter with a half-life of 14.7 hours that is produced in a cyclotron using the ^{86}Sr(p,n)^{86}Y reaction [181]. The spatial resolution for detection of the positron annihilation from ^{86}Y is 1.8 mm compared with 0.7 mm for ^{18}F [13]. ^{90}Y (Table 6.7-3) is a pure β-emitter with a half-life of 2.7 days that is produced by a strontium-90 (^{90}Sr)/^{90}Y generator [182]. ^{90}Y is an attractive radionuclide for *in situ* radiotherapy of cancer because it does not emit γ-radiation, which minimizes the radiation exposure to health-care personnel and family members from a patient-administered ^{90}Y-labeled mAb or peptide. For example, patients with non-Hodgkin's B-cell lymphoma treated with ^{90}Y-ibritumomab tiuxetan (Zevalin; Biogen Idec, Cambridge, MA) do not need to be isolated for radiation safety reasons and can be treated as outpatients, whereas patients receiving ^{131}I-labeled tositumomab (Bexxar; GlaxoSmithKline, Uxbridge, Middlesex, UK) require special radiation safety precautions to be taken [183]. However, as ^{90}Y does not emit γ-radiation, the tissue distribution of ^{90}Y-labeled mAbs and peptides cannot be easily imaged (only poor-resolution Bremstrahlung images can be acquired). Therefore, the radiation absorbed doses to tissues in patients from ^{90}Y-labeled biomolecules are often estimated by imaging studies with ^{111}In-labeled analogs [179, 180]. However, as mentioned (see Section 6.7.3), differences in the *in vivo* stability of ^{111}In- and ^{90}Y-labeled biomolecules can produce discrepancies in their pharmacokinetics and normal organ distribution, yielding inaccuracies in the dosimetry estimates. PET imaging using ^{86}Y-labeled analogs has been suggested as a means of more accurately estimating the radiation absorbed doses from ^{90}Y-labeled biomolecules [184].

The macrocyclic chelator, DOTA (Figure 6.7-9), is the chelating agent of choice for labeling mAbs and peptides with yttrium-90 (^{90}Y) due to the high stability of ^{90}Y-DOTA complexes ($K_a = 10^{24}$ L/mole) [185]. Initially, DTPA was used as a chelator for ^{90}Y-labeling [186], but it was discovered that ^{90}Y–DTPA complexes were unstable *in vivo*, which caused bone accumulation of free ^{90}Y released from the immunoconjugates. The stability of ^{90}Y-labeled biomolecules is of paramount importance because even a small amount of free ^{90}Y sequestered in the bone can contribute significantly to bone marrow toxicity due to the long range (10–12 mm) of the β-particles ("cross-fire" effect). This is one reason that the maximum tolerated dose of ^{90}Y-labeled mAbs (e.g., Zevalin) is 32 mCi, whereas up to 150 mCi of ^{131}I-labeled mAbs can be safely administered [2]. Bz–SCN–DTPA (Figure 6.7-8) yields more stable ^{90}Y complexes than those formed with DTPA, but the complexes are not as stable as ^{90}Y–DOTA complexes. In one study [187], the bone uptake of radioactivity in mice implanted s.c. with SK–RC–52 renal cell carcinoma xenografts at 7 days p.i. of ^{90}Y–DOTA-conjugated chimeric G250 mAbs was only 0.4% i.d./g,

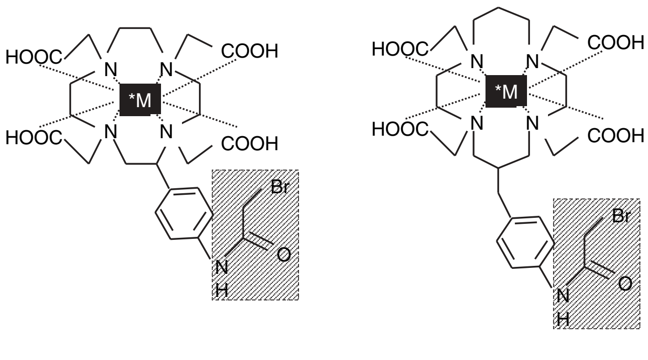

Figure 6.7-9. Chemically reactive forms of two macrocyclic chelators that can be conjugated to monoclonal antibodies or peptides for labeling with radiometals. Groups for conjugation to the antibodies or peptides are shaded. BAD: p-bromoacetamidobenzyl-DOTA complexes ^{90}Y, ^{67}Ga, ^{177}Lu, ^{212}Pb, ^{212}Bi or ^{225}Ac. BAT: bromoacetamidobenzyl-TETA complexes ^{64}Cu or ^{67}Cu.

compared with 1.2% i.d./g for Bz–SCN–DTPA- and 10.7% i.d./g for DTPA-conjugated antibodies. Similarly, a threefold lower bone uptake of radioactivity at 10 days p.i. in mice was observed for ^{88}Y–DOTA–hLL2 anti-CD22 mAbs compared with ^{88}Y–Mx–DTPA–hLL2 mAbs [188].

DOTA, which was first described by McCall et al. in 1990 [189], can be conjugated to mAbs by conversion to its reactive form, p-bromoacetamidobenzyl–DOTA (BAD; Figure 6.7-9) followed by reaction of BAD with free thiols introduced into the antibodies by reaction with 2-iminothiolane (2-IT) [190]. 2-IT also creates a spacer between the mAbs and the DOTA chelator that allows more efficient labeling with ^{90}Y. An alternative approach involves reaction of an N-hydroxysuccinimidyl ester of DOTA with ε-amino groups on lysine residues or the N-terminus of biomolecules [191]. Labeling of DOTA-conjugated mAbs is achieved by incubation with ^{90}Y chloride ($^{90}YCl_3$) mixed with 0.5-M ammonium acetate buffer, pH 7.0–7.5, for 30 minutes at 37°C [192]. Similar conditions have been employed for labeling DOTA-conjugated peptides with ^{90}Y, except that a temperature of 80–100°C was used to accelerate the incorporation of ^{90}Y [193]. Labeling of biomolecules with ^{90}Y using DOTA is highly susceptible to the effects of divalent trace metal ion contamination, especially Ca^{2+}, Fe^{2+}, and Zn^{2+}. In fact, the affinity constant (K_a) for binding of Fe^{2+} by DOTA is 100,000 times higher than that for binding ^{90}Y [185]. It is critical to exclude trace-metals as much as possible from the ^{90}Y labeling reaction. One recent Letter to the Editor even suggests that minor trace-metal contamination of pipette tips can seriously diminish the labeling efficiency of DOTA-conjugated peptides with ^{90}Y [194]. Another important issue in labeling biomolecules with ^{90}Y is the potential for radiolysis. Interaction of the moderate energy (E_{max} 2.2 MeV) β-particles emitted by ^{90}Y with water molecules in the buffers used to formulate the radiopharmaceuticals generates highly reactive free radicals that degrade the metal chelator as well as the biomolecules themselves. The radiolysis effect is dependent on specific activity and on radioactivity concentration. For example, ^{90}Y–BAD–2–IT–Lym–1 antibodies formulated at a specific

activity of 1–2 mCi/mg remained pure and relatively immunoreactive (>75%) in storage over a 3-day period [195]. However, at a specific activity of 4 mCi/mg, the radiochemical purity (RCP) of ^{90}Y–BAD–2–IT–Lym–1 dropped to 65% and the immunoreactivity decreased to 28%. At a specific activity of 9.4 mCi/mg, the RCP of ^{90}Y–BAD–2–IT–Lym–1 decreased to 21% and the immunoreactivity was virtually abolished (3%). Radiolysis can be minimized by inclusion of radioprotectants such as ascorbic acid, gentisic acid, or human serum albumin in the formulation and by freezing the radiolabeled biomolecules to minimize diffusion of free radicals in the aqueous solutions [195, 196]. In one study, it was shown that ascorbic acid may also act as a suitable buffering agent, thereby removing the need for the ammonium acetate buffer [197].

A controversial issue with respect to the use of DOTA as a metal chelator for ^{90}Y and other radiometals is its potential immunogenicity in humans. In a phase I/II clinical trial in which six ovarian cancer patients received ^{90}Y–DOTA–HMFG1 murine mAbs intraperitoneally, all patients developed anti-DOTA antibodies and three patients developed serum sickness [198]. Four of eight patients who received ^{111}In–DOTA-conjugated mAbs intravenously developed anti-DOTA antibodies. The immune response seems to be directed against the DOTA ring structure and not the benzyl-containing side chain. The immune response to DOTA is also dependent on the antigenicity of the biomolecule to which it is conjugated, because rabbit IgG conjugated to DOTA did not induce anti-DOTA antibodies in rabbits, whereas mouse IgG–DOTA immunoconjugates administered to rabbits stimulated an immune response toward the chelators [199]. Moreover, an immune response to DOTA has not been found with all mAbs. Anti-DOTA antibodies were not detected in the serum of 18 lymphoma patients administered multiple doses of ^{111}In–BAD–2–IT–Lym–1 mAbs, although these patients typically do not mount a strong immune response to radioimmunoconjugates [200]. Similarly, ^{90}Y–DOTATOC, an octapeptide somatostatin analog, does not seem to be immunogenic, again suggesting that the biomolecule carrier must be considered in assessing the potential immunogenicity of DOTA [201].

6.7.6.5 Gallium Radionuclides

Gallium-67 (^{67}Ga; Table 6.7-1) is a cyclotron-produced radionuclide with a half-life of 78.2 hours that has been used for many years in nuclear medicine as ^{67}Ga citrate for tumor imaging [202]. Despite its history of use, the properties of ^{67}Ga are not ideal for imaging, however, due to the high energy of two of its γ-photons ($E\gamma = 300$ and 393 keV), which make it difficult to collimate. Nevertheless, ^{67}Ga has recently received attention as a radiolabel for mAbs for *in situ* radiotherapy of cancer, exploiting its abundent Auger and conversion electron emissions [203]. Most of the recent interest in gallium radionuclides has been focused on labeling peptides with ^{68}Ga for PET (Table 6.7-2) [204]. Antibodies have not been labeled with ^{68}Ga for PET, because their kinetics of tumor uptake and elimination from the blood and normal tissues is too slow. ^{68}Ga is conveniently produced using a germanium-68 (^{68}Ge)/^{68}Ga generator system that could allow production of the radionuclide for up to one year in a nuclear medicine facility using a single generator, due to the long half-life of ^{68}Ge (270 days) [205]. ^{68}Ga decays with a half-life of 68 minutes to ^{68}Zn. Its positron energy is 1.92 MeV, which provides a spatial resolution of 2.4 mm

versus 0.7 mm for ^{18}F [13]. ^{66}Ga is a longer lived positron-emitting radionuclide (half-life of 9.5 hours), which has also been studied for labeling peptides for PET [206].

Initially, desferrioxamine (DFO) was used as a chelator for labeling peptides with ^{68}Ga [74, 207], but more recently DOTA has been used (Figure 6.7-9) [204, 208]. Most PET tumor imaging studies with ^{68}Ga-labeled peptides have focused on DOTATOC, a synthetic octapeptide analog of somatostatin. Labeling DOTATOC involves adjusting the pH of $^{68}GaCl_3$, which is eluted in 0.5-M HCl from the ^{68}Ge/^{68}Ga generator to pH 4.8 with 50-mM sodium acetate buffer. The required amount of ^{68}Ga acetate complex is then mixed with DOTATOC (10–20 nmols) and heated at 95°C for 15 minutes in a heating block. Early studies in which DOTATOC was labeled with ^{68}Ga using this technique yielded labeling efficiencies that were about 50%, thus requiring postlabeling purification on a C-18 Sep-Pak cartridge [208, 209]. The final radiochemical purity was >95%. The large volumes of ^{68}Ga eluates eluted from the ^{68}Ge/^{68}Ga generator system as well as contamination with trace metals were believed to be responsible for the low labeling efficiencies for DOTATOC with ^{68}Ga. Improvements in the concentration of ^{68}Ga eluates using an ion-exchange cartridge combined with more homogeneous microwave heating of the labeling reaction for 10–20 minutes have recently yielded almost complete incorporation of ^{68}Ga in to extremely small quantities (<1 nmole) of DOTATOC, thus increasing the specific activity by almost 100-fold [210].

Interestingly, DOTATOC labeled with ^{68}Ga has a fivefold higher binding affinity for SMSR subtype 2 (IC_{50} = 2.5 nmol/L) compared with ^{90}Y–DOTATOC (IC_{50} = 11 nmol/L) and a ninefold higher affinity than that of ^{111}In–DTPA–octreotide (IC_{50} 22 nmol/L) [211]. Combined with the high spatial resolution and sensitivity of PET, this provided a greater sensitivity for imaging small meningioma lesions (100% vs. 85%) in patients compared with SPECT imaging with ^{111}In–DTPA–octreotide [209, 212]. The somatostatin analog DOTANOC, which binds to SMSR subtypes 2 and 5, has been labeled with ^{68}Ga and used for PET of a patient with metastases from a neuroendocrine tumor [213]. Preclinical studies have been performed in mouse tumor xenograft models using ^{68}Ga–DOTA–α–melanocyte-stimulating hormone (α-MSH) for imaging melanoma [214] or ^{68}Ga–DOTA–EGF to image gliomas or epidermoid carcinoma xenografts [215]. Due to the convenient availability of a generator system for ^{68}Ga, it is not necessary for a nuclear medicine facility to have access to a cyclotron, and therefore, it is likely that more studies ultimately leading to clinical application of many different ^{68}Ga-labeled peptides for PET imaging of tumors will be performed in the near future.

6.7.6.6 Copper Radionuclides

Several radionuclides of copper are suitable for labeling mAbs, their fragments, or peptides for PET (e.g., ^{60}Cu, ^{61}Cu, or ^{64}Cu; Table 6.7-2) [216]. ^{64}Cu decays with a half-life of 12.7 hours by three different pathways: (1) electron capture (41%) emitting Auger and conversion electrons, (2) positron (β^+) emission (19%), and (3) β^- emission (40%). The β^- emissions make the radionuclide useful not only for PET but also for radiotherapy of tumors. Indeed, in one study, ^{64}Cu-labeled octreotide inhibited the growth of CA20948 rat pancreatic tumors in Lewis rats [217]. In another study, ^{64}Cu-labeled 1A3 mAbs were used to treat hamsters implanted s.c.

with GW39 human colon carcinoma xenografts [218]. ^{64}Cu is most commonly produced in a biomedical cyclotron by the ^{64}Ni(p,n)^{64}Cu reaction using a ^{64}Ni-enriched target [219, 220]. The positron energy of ^{64}Cu is almost identical to that of ^{18}F (0.657 MeV vs. 0.635 MeV, respectively), and the intrinsic spatial resolution is indistinguishable (0.73 vs. 0.70 mm, respectively) [13, 221]. However, due to the lower abundance of positron emission with ^{64}Cu compared with ^{18}F (19% vs. 97%), the sensitivity for PET with ^{64}Cu is about fivefold lower than that with ^{18}F [221]. The short-lived positron-emitter, ^{61}Cu (half-life 3.32 h), has a greater abundance of positron emission than ^{64}Cu (60% vs. 19%) and has been used for labeling octreotide for PET of CA20948 tumors in rats [222]. ^{67}Cu (Table 6.7-3) can be used for labeling mAbs and peptides for targeted *in situ* radiotherapy. ^{67}Cu decays with a half-life of 2.6 days emitting β^- particles with energies of 0.395 (51%), 0.484 (28%), and 0.577 (20%) MeV as well as several γ-photons with energies ranging from 91 to 300 keV that are imageable [223]. ^{67}Cu is produced in a biomedical cyclotron using the ^{nat}Zn(p,2p)^{67}Cu or ^{68}Zn(p,2p)^{67}Cu reactions or in a nuclear reactor using the ^{nat}Zn(n,p)^{67}Cu reaction [223].

DTPA (Figure 6.7-8) and benzyl-EDTA were initially examined for chelating ^{67}Cu, but it was soon found that these complexes formed were unstable, releasing 70–95% of their radiolabel *in vitro* in serum over 5 days [224]. In contrast, the macrocyclic chelator, 1,4,8,11-tetraazacyclotetradecane-N′,N″,N‴-tetraacetic acid (TETA; Figure 6.7-9), provided a more stable ^{67}Cu complex that lost only 2–6% of the radiolabel in serum when conjugated to Lym-1 antibodies [224]. This greater stability of ^{67}Cu–TETA vs. ^{67}Cu–DTPA or Bz–EDTA complexes is not due to a higher thermodynamic stability, but it is believed to be due to the structural rigidity of the ^{67}Cu–TETA complex, which shields the radionuclide from attack by endogenous copper binding proteins. Copper is bound in plasma by albumin and transcuprein, which transport the metal to hepatocytes [216]. Copper internalized by hepatocytes is used to synthesize metalloenzymes such as superoxide dismutase (SOD), is stored bound to metallothionein (MT), or is secreted back into the plasma complexed to ceruloplasmin. DOTA (Figure 6.7-9) and its analogs form stable complexes with copper radionuclides, but TETA is the most widely used chelator [216].

BAT (Figure 6.7-9) is a modified form of TETA, which contains a bromoacetamidobenzyl side chain that is reactive with antibodies modified with 2-minothiolane (2-IT) to present a free thiol. The inclusion of the 2-IT spacer improves the labeling efficiency of the antibodies with ^{67}Cu and ^{64}Cu [225]. DOTA and TETA chelators can be introduced into peptides during solid phase synthesis for labeling with ^{64}Cu/^{67}Cu [226, 227]. Labeling of TETA-conjugated mAbs or peptides is achieved by incubation with ^{64}Cu/^{67}Cu in a 100-mM ammonium citrate buffer, pH 5.5, at room temperature for 30–60 minutes [226, 228]. Disodium EDTA is added to chelate any unbound radiometal, and the ^{64}Cu/^{67}Cu-labeled biomolecules are purified by SEC. ^{64}Cu/^{67}Cu labeled peptides are usually purified on a C-18 Sep-Pak (Waters Associates Inc., Milford, MA). Using TETA, mAb1A3 IgG and its $F(ab')_2$ fragments were labeled with ^{64}Cu for PET in a phase I/II trial of 36 patients with colorectal carcinoma [229] and Lym-1 antibodies were labeled with ^{67}Cu for RIT of 12 patients with non-Hodgkin's lymphoma [228]. Several different peptides have been labeled with ^{64}Cu using DOTA or TETA for PET of tumors, including octreotide analogs [226, 227, 230, 231], RGD peptides that recognize $\alpha_v\beta_3$

integrins [232], vasoactive intestinal polypeptide (VIP) analogs [233], and bombesin derivatives [234].

$^{64}Cu/^{67}Cu$ labeled intact IgG antibodies exhibit high accumulation in the liver, whereas $^{64}Cu/^{67}Cu$-labeled F(ab′)$_2$ fragments and peptides are retained by the kidneys. In rats administered 1A3 mAbs labeled with ^{67}Cu using four different chelators, including 1-[(1,4,8,11-tetraazacyclotetradec-1-yl)methyl]benzoic acid (CPTA), a macrocycle related to TETA, it was found that there was a slow rate of transchelation of ^{67}Cu to SOD in the liver [235]. In contrast, ^{67}Cu-labeled F(ab′)$_2$ fragments of mAb 1A3 were rapidly catabolized to ^{67}Cu–CPTA–ε–lysine. Similarly, transchelation of radiometal to SOD in the liver was observed for ^{64}Cu–TETA–octreotide in rats [236]. However, in a clinical study, in which 10 patients received ^{67}Cu–2IT–BAT–Lym-1 antibodies [237], only a small fraction (0.8–7.8%) of the injected dose of ^{67}Cu was recycled by the liver and, in this case, mostly to ceruloplasmin. There was no transchelation to SOD detectable. The higher concentration of SOD in the liver of rats compared with humans may account for this species-dependent catabolic route for $^{64}Cu/^{67}Cu$-labeled biomolecules [236].

6.7.6.7 Lutetium Radionuclides

Lutetium-177 (^{177}Lu; Table 6.7-3) is a β-emitting radionuclide (Eβ = 0.495 MeV) with a half-life of 6.7 days that is useful for labeling mAbs and peptides for targeted *in situ* radiotherapy of tumors. In addition, ^{177}Lu emits γ-photons of energies 113 and 208 keV that can be imaged. ^{177}Lu is produced in a nuclear reactor by neutron irradiation of $^{176}Lu_2O_3$. Several chelators have been employed for labeling mAbs and peptides with ^{177}Lu including derivatives of DOTA (e.g., PA–DOTA and CA–DOTA) and analogs of DTPA (e.g., CHX–A–DTPA and SCN–Bz–DTPA) [238]. The difference between the two DOTA chelators is that in PA–DOTA, the benzylisothiocyanate side chain used for conjugation is attached to one nitrogen in the macrocycle, whereas in CA–DOTA, it is attached to a methylene carbon. PA–DOTA forms a less stable complex with ^{177}Lu than CA–DOTA or CHX–DTPA [238]. The instability of the ^{177}Lu–PA–DOTA complex may account for the prolonged retention of radioactivity in the reticuloendothelial system (RES), including the bone marrow of patients administered ^{177}Lu–PA–DOTA–CC49 mAbs for RIT of TAG-72 positive malignancies and, consequently, the observed dose-limiting hematopoietic toxicity [239]. ^{177}Lu released from biomolecules is expected to be sequestered in the skeleton because lutetium competes with calcium for bone deposition [240]. It has been shown that by adding DTPA to ^{177}Lu–DOTA^0–Tyr^3]octreotate used for PDRT of SMSR-positive tumors, the small amount (<2–5%) of free ^{177}Lu impurity in the radiopharmaceutical can be rapidly eliminated from the body by renal excretion as ^{177}Lu–DTPA, thus minimizing bone uptake of radioactivity [241]. In addition to labeling intact IgG CC49 mAbs with ^{177}Lu [239, 242], dimeric scFv fragments of this antibody have been labeled with ^{177}Lu for radiotherapeutic purposes [243].

6.7.6.8 Lead, Bismuth, and Actinium Radionuclides

DOTA (Figure 6.7-9) is a also useful bifunctional chelator for labeling antibodies with radionuclides of lead, bismuth, and actinium for targeted *in situ* radiotherapy

[2]. Lead-212 (^{212}Pb) decays to the α-emitter, bismuth-212 (^{212}Bi). The α-emitter, actinium-225 (^{225}Ac), decays to a series of daughter radionuclides that are α-emitters (^{221}Fr, ^{217}At, ^{213}Bi) or β-emitters (^{213}Po, ^{209}Tl, ^{209}Pb, ^{209}Bi). The use of ^{225}Ac as a radiolabel for mAbs has been termed an "atomic nanogenerator" because the decay of ^{225}Ac generates the daughter radionuclides locally in tumors that then emit several different forms of radiation that kill cancer cells [244]. The main concern for employing radionuclides such as ^{212}Pb or ^{225}Ac that do not decay directly to stable elements is that the decay process may decrease the stability of the metal chelate complex due to the transformation of one element into another (i.e., ^{212}Pb is converted into ^{212}Bi). In particular, bismuth has an affinity for the kidneys, and it was shown that even low doses of ^{225}Ac-labeled HuM195 antibodies caused severe renal toxicity and anemia in monkeys, likely due to release of ^{213}Bi from the antibodies and redistribution of the radionuclide to the kidneys [245]. Bismuth radionuclides are also stably bound by CHX–A–DTPA and CHX–B–DTPA, two analogs of DTPA [246, 247]. HER2/neu mAbs AE1 and trastuzumab (Herceptin) have been labeled with ^{212}Pb or ^{225}Ac, respectively, using DOTA as the metal chelator [248, 249].

6.7.7 CHARACTERIZATION OF RADIOLABELED MABS AND PEPTIDES

It is important to fully characterize the properties of radiolabeled mAbs and peptides intended for tumor imaging or targeted *in situ* radiotherapy of malignancies. Characterization includes (1) analytical tests that evaluate homogeneity and radiochemical purity; (2) radioligand binding assays that assess the ability to specifically bind target antigens/receptors *in vitro*; (3) stability studies that assess the loss of radiolabel *in vitro* in biologically relevant media; and (4) biodistribution, pharmacokinetic, dosimetry, and imaging studies that reveal tumor and normal tissue uptake *in vivo* in an animal model and predict radiation absorbed doses in humans.

6.7.7.1 Evaluation of the Homogeneity of Radiopharmaceutical Bioconjugates

Evaluation of homogeneity is especially important for mAbs or peptides conjugated to chelators for labeling with radiometals (Section 6.7.6). Substitution of these biomolecules with too many chelators may significantly decrease their immunoreactivity or receptor-binding affinity [159]. The substitution level (moles chelators/mole of biomolecule) may be measured by spectrophotometric, fluorescence, or radiochemical assays. For example, HYNIC substitution in biomolecules intended to be labeled with ^{99m}Tc or ^{186}Re/^{188}Re (see sections 6.7.1 and 6.7.2) can be measured by a colorimetric assay that relies on reaction of the HYNIC groups with p-nitrobenzaldehyde to form a complex that absorbs at 385 nm [162]. DTPA substitution for labeling biomolecules with ^{111}In (see Section 6.7.6.3) can be measured by several different techniques: (1) radiochemical assays that rely on the binding of ^{111}In or ^{57}Co by DTPA [141, 250]; (2) spectrophotometric assays that generate a colored arsenazo III DTPA complex [251]; (3) fluorescence assays that measure the binding of europium(III) by DTPA [252]; or (4) immunoelectrofocusing (IEF)

that reveals changes in pI associated with DTPA substitution [253]. The most common method is simply to radiolabel an aliquot of the impure DTPA conjugation mixture with a trace amount of ^{111}In and separate the resulting ^{111}In–DTPA–biomolecule from free ^{111}In–DTPA by silica gel instant thin-layer chromatography (ITLC–SG) developed in 100-mM sodium citrate, pH 5.0. The conjugation efficiency is then calculated from the ITLC–SG results and multiplied by the molar ratio of cDTPAA:antibody/peptide used in the reaction to estimate the average number of moles of DTPA per mole of biomolecule. Typically, a substitution level of one to two moles DTPA per mole of biomolecule is desirable to minimize polymerization and/or interference in immunoreactivity or receptor-binding affinity [159]. The number of DOTA chelators introduced into antibodies or peptides for labeling with ^{90}Y, ^{68}Ga, ^{177}Lu, ^{212}Bi, or ^{225}Ac (see Sections 6.7.4, 6.7.5, 6.7.7, and 6.7.8) can be measured by a spectrophotometric assay, which measures the decrease in absorbance at 656 nm for a Pb(II)–arsenazo III complex upon transchelation of Pb^{2+} to DOTA [254].

The polymerization of biomolecules as a consequence of metal chelator substitution may be assessed by size-exclusion HPLC with UV detection (Figure 6.7-10) or by sodium dodecylsulfonate–polyacrylamide gel electrophoresis (SDS–PAGE; Figure 6.7-10). Polymerization is most commonly due to cross-linking of mAbs or

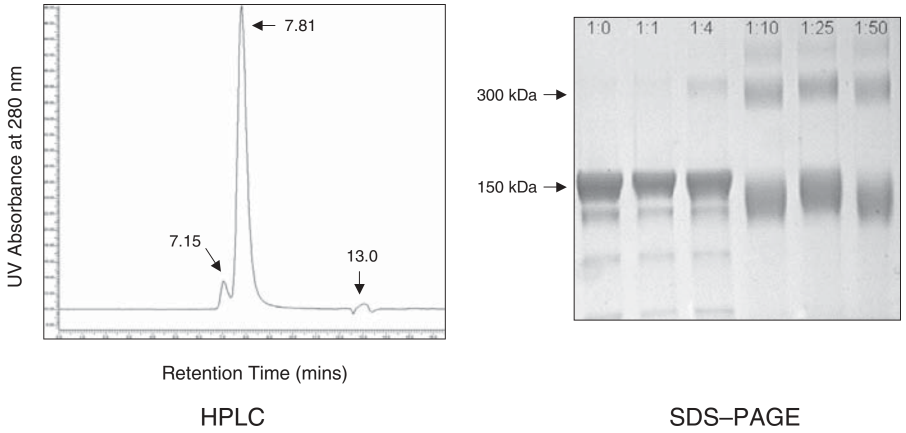

Figure 6.7-10. Two analytical methods used to assess the purity and homogeneity of metal-chelated monoclonal antibodies or peptides. *Left Panel*: Size-exclusion HPLC analysis of trastuzumab (Herceptin) IgG conjugated with the bicyclic anhydride of DTPA (cDTPAA) on a BioSep-SEC-S2000 column eluted with 150-mM sodium chloride/10-mM sodium phosphate buffer, pH 6.8, at a flow rate of 0.6 mL/min with UV detection at 280 nm. The molar ratio of cDTPAA:IgG was 4:1. Peak with a retention time (t_R) of 7.81 minutes represents a DTPA-conjugated trastuzumab monomer. Peak with t_R of 7.15 minutes represents a DTPA–trastuzumab dimer caused by cross-linking of the antibody molecules through the two chemically reactive groups on cDTPAA. Peak with t_R of 13.0 minutes represents a small amount of unconjugated DTPA (detected through a change in refractive index). Right Panel: SDS–PAGE analysis of trastuzumab (Herceptin) IgG conjugated with cDTPAA on a 4–10% Tris HCl gradient mini-gel stained with Coomassie Brilliant Blue. There is an increase in the proportion of dimerized (300 kDa) and polymerized (>300 kDa) IgG species as the molar ratio of cDTPAA:IgG is increased from 1:1 to 50:1. (Data generously provided by Kristin McLarty.)

peptides by bifunctional chelators such as cDTPAA that contain two reactive groups that interact with ε-amino groups on lysines on two separate biomolecules (intermolecular linkage) or within one biomolecule (intramolecular linkage) [141, 151]. Such polymerization can be eliminated by using a bifunctional chelator that contains only a single reactive group (e.g., SCN–Bz–DTPA). The level of polymerization that is tolerable depends on the biomolecule, but less than 10% of higher molecular weight species is desirable to avoid diminishing immunoreactivity or receptor-bindng affinity, as well as to minimize sequestration by the reticuloendothelial system (RES) [158].

6.7.7.2 Measurement of Radiochemical Purity (RCP)

In our laboratory, we determine the radiochemical purity (RCP) of radiolabeled mAbs or peptides by size-exclusion HPLC on a BioSep SEC-S 2000 column (Phenomenex, Canada) eluted with 100-mM sodium phosphate buffer, pH 7.4 at a flow rate of 1.0 mL/minute, and interfaced with a PerkinElmer diode array detector set at 280 nm and an FSA radioactivity detector (Figure 6.7-11). The RCP of radiolabeled peptides could also be measured by reversed-phase HPLC on a C-18 column eluted with trifluoroacetic acid/methanol/water combinations. Through overlaying the UV and radioactivity traces, these HPLC chromatograms confirm that the biomolecule is radiolabeled. Furthermore, they identify and quantify any radiochemical impurities, such as free radiolabeled chelators or radionuclides. However, for rapid measurement of RCP, paper chromatography or ITLC systems are more commonly used. The level of RCP purity required for radiolabeled mAbs and peptides depends on their intended clinical application and the toxicity associated with the impurities. An RCP > 90% would be acceptable for mAbs or peptides labeled with a single γ-photon-emitter (e.g., ^{99m}Tc or ^{111}In) or a short-lived positron-emitter (e.g., ^{18}F or ^{68}Ga) and intended for tumor imaging. On the other hand, biomolecules labeled with α-emitters (e.g., ^{211}At) or β-emitters (e.g., ^{131}I or ^{90}Y) for targeted *in situ* radiotherapy of malignancies require a higher RCP (>95%) because of the larger amounts of radioactivity administered and the inherent toxicity of the radiochemical impurities, particularly if they concentrate in a sensitive organ (e.g., bone or thyroid). For example, free ^{90}Y is sequestered *in vivo* by bone, increasing the risk for bone marrow toxicity [255].

6.7.7.3 Measurement of Immunoreactivity or Receptor-Binding Properties

The immunoreactivity or receptor-binding characteristics of mAbs or peptides conjugated to chelators for radiometal labeling must be assessed because these effect tumor uptake *in vivo* [159]. Similarly, these properties should be evaluated for the final radiolabeled biomolecules. Two parameters are measured: (1) the antigen/receptor-binding affinity and (2) the immunoreactive fraction (IRF) or receptor-binding fraction (RBF). The affinity constant (K_a) or dissociation constant (K_d) are measured in direct or indirect competition antigen/receptor-binding assays and compared with those of the unmodified mAbs or peptides. Direct binding assays (previously known as Scatchard assays) are performed by incubating increasing concentrations of radiolabeled mAbs or peptides with tumor cells that express the target epitopes/receptors. These assays may also be performed by incubating the

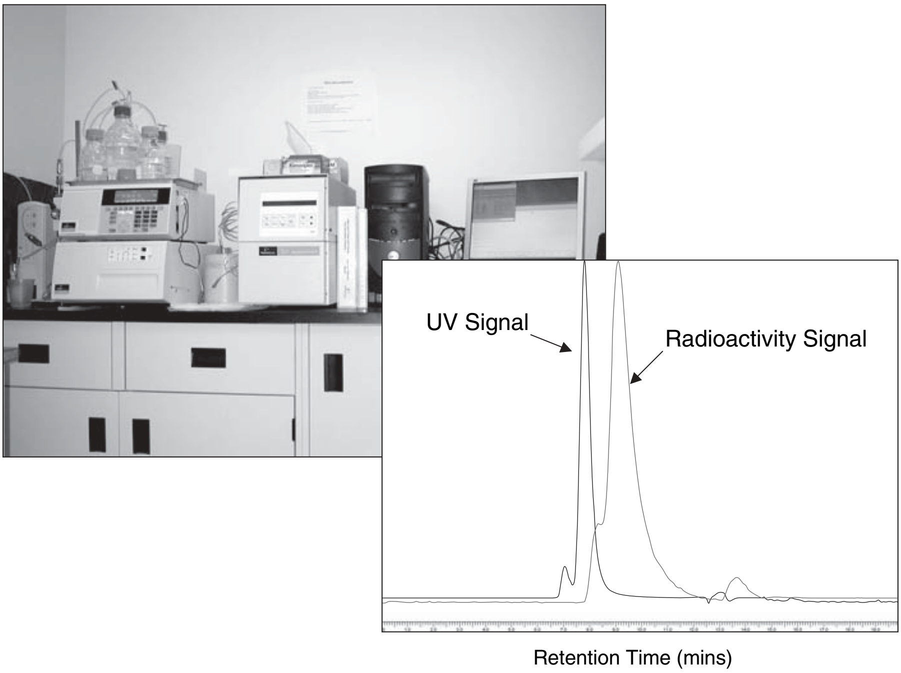

Figure 6.7-11. *Left Panel*: A size-exclusion HPLC system with a diode array UV detector and FSA flow-through radioactivity detector for evaluating the radiochemical purity and homogeneity of radiolabeled monoclonal antibodies and peptides. *Right Panel*: Typical HPLC chromatograms obtained for analysis of ^{111}In–DTPA-conjugated trastuzumab (Herceptin). The radioactivity signal is offset from the UV signal because of the distance of tubing between the two detectors, which are in sequence. The radioactivity signal has less resolution than the UV signal due to its larger flow cell. ^{111}In–DTPA–trastuzumab IgG in this example has less than 5% free ^{111}In–DTPA impurity (indicated by small peak on the radioactivity trace at t_R = 13.8 minutes). The major peak with t_R of 7.7 minutes in the UV trace and 9.5 minutes in the radioactivity trace represents a ^{111}In–DTPA–trastuzumab IgG monomer. The smaller peak with t_R of 7.1 minutes in the UV trace and 8.25 minutes in the radioactivity trace represents a ^{111}In–DTPA–trastuzumab IgG dimer. (Data generously provided by Kristin McLarty.) (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_med/pharmaceutical_biotech/.)

radiolabeled biomolecules with purified antigens/receptors coated onto wells in a microELISA plate. The binding of the radiolabeled biomolecules to the cells is measured in the absence [total binding (TB)] or presence [nonspecific binding (NSB)] of an excess (e.g., 100 nM) of non-radiolabeled biomolecules to saturate the epitopes/receptors on the cells. Specific binding (SB) is obtained by subtracting NSB from TB and is plotted versus the concentration of radiolabeled mAbs or peptides (Figure 6.7-12). The curve is fitted to a direct antigen/receptor-binding model using nonlinear fitting software (e.g., Prism; Graphpad Software, San Diego, CA) and the K_a and maximum number of binding sites/cell (B_{max}) estimated. Competition radioligand binding assays can be performed by measuring the binding of radiolabeled mAbs or peptides to cells displaying the target epitopes or receptors in the presence of increasing concentrations of unmodified biomolecules. The K_d is

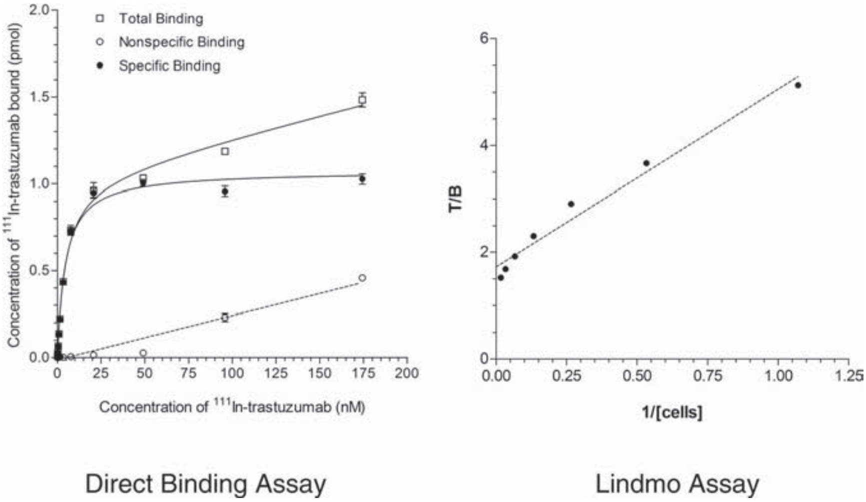

Figure 6.7-12. *Left Panel*: Results for a direct binding assay for a ^{111}In–DTPA–trastuzumab (Herceptin) IgG incubated with SK–BR-3 human breast cancer cells overexpressing HER2/neu. The K_a and B_{max} in this example were 1.2×10^8 L/mole and 1.0×10^6 receptors/cell, respectively. *Right Panel*: Results for measurement of the immunoreactive fraction (IRF) of a ^{111}In–DTPA–trastuzumab IgG incubated with SK–BR-3 cells using the Lindmo method [256]. In this example, the intercept on the ordinate (1/IRF) was 1.7 and the IRF was therefore 0.59. (Data generously provided by Kristin McLarty.)

then estimated from the concentration of unmodified antibodies or peptides required to displace 50% of the initial binding of the radiolabeled biomolecules to the cells. Finally, the IRF or RBF of radiolabeled mAbs or peptides may be measured by the Lindmo assay [256]. In this assay, a small amount of radiolabeled biomolecules (e.g., 5–10 ng) is incubated with increasing concentrations of cancer cells that display the target epitopes/receptors. The total radioactivity counts added divided by the bound counts (T/B) is plotted versus the inverse of the cell concentration (1/[cells]). The intercept on the ordinate of this plot is 1/IRF or 1/RBF (Figure 6.7-12, right panel). The IRF or RBF provides information that is different than that of K_a or K_d, in that these parameters describe the fraction of radiolabeled biomolecules that can bind their target epitopes/receptors at "infinite antigen excess," irrespective of their binding affinity. Ideally, measurement of K_a or K_d as well as determination of IRF or RBF should be performed to assess immunoreactivity or receptor-binding characteristics.

6.7.7.4 Evaluation of *In Vitro* and *In Vivo* Stability

Studies to evaluate the *in vitro* and *in vivo* stability of radiolabeled mAbs and peptides are an integral part of their development. Kits used to prepare radiolabeled biomolecules (Section 6.7.7.7) must meet specifications established for labeling efficiency, immunoreactivity/receptor binding, homogeneity, sterility and apyrogenicity, and other quality control tests over the expected storage period [145]. Similarly, the radiolabeled biomolecule must maintain the specified level of RCP over the interval from the time of labeling until it is administered. The results

of these stability studies will define the expiry times for the kits and/or radiolabeled mAbs or peptides [145]. The stability of the radiolabeled biomolecules *in vitro* in biologically relevant media such as plasma or serum must also be determined. The anticipated mechanism of loss of radiolabel *in vivo* should be taken into account in designing these studies. For example, studies examining the transchelation of radiometal to transferrin in serum/plasma are necessary for ^{111}In- or ^{67}Ga-labeled biomolecules [151], whereas studies that measure transchelation to albumin or other copper-binding proteins are required for ^{64}Cu/^{67}Cu-labeled biomolecules [224]. Cysteine-challenge studies are required for ^{99m}Tc-labeled biomolecules, especially those labeled using the Schwartz technique [94, 257]. Frequently, stability *in vitro* does not predict stability *in vivo*, because the radiolabeled biomolecules may be catabolized in tissues, resulting in release and redistribution of the radionuclide. For example, radioiodinated proteins are stable *in vitro* in serum/plasma but *in vivo* may be internalized by tumor and normal cells, in which they are rapidly catabolized by lysosomal proteases and deiodinases, resulting in release and redistribution of free radioiodine. This instability *in vivo* can be addressed by employing residualizing radio-iodination techniques (Section 6.7.5.1). Nevertheless, due to the limitations of *in vitro* stability studies, it is important to evaluate the stability of radiolabeled mAbs and peptides *in vivo* by chromatographic analysis of plasma/serum samples to identify any circulating radioactive catabolites, as well as by monitoring changes in tissue distribution of radioactivity over time by imaging or biodistribution studies (see Section 6.7.7.5). In these studies, it is critical to sample tissues that are known to sequester the radionuclide, should it be released from the biomolecule, i.e., bone for ^{90}Y or ^{177}Lu and thyroid and stomach for iodine radionuclides. Noninvasive SPECT or PET imaging studies in humans allow these stability studies to be continued into clinical trials of the radiolabeled biomolecules.

6.7.7.5 Preclinical Biodistribution, Tumor Imaging, and Dosimetry Studies

It is important to evaluate the tumor and normal tissue distribution of radiolabeled biomolecules in an animal model. For radiolabeled mAbs and peptides intended to target solid tumors, these studies are performed in athymic mice implanted subcutaneously (s.c.) with human tumor xenografts [18, 108, 120, 132, 258]. In the case of hematological malignancies (e.g., B-cell lymphoma or leukemias), athymic or non-obese diabetic severe combined immunodeficient (NOD-scid) mice may be engrafted s.c. or inoculated intravenously (i.v.) with malignant cells to establish a tumor model [259–261]. Tumor-bearing mice are injected i.v. with 25–100 μCi (0.9–3.7 MBq) of radiolabeled mAbs or peptides. Control groups may consist of (1) mice bearing the same tumors but injected with radiolabeled nonspecific biomolecules that do not recognize the target epitopes/receptors, (2) mice bearing these tumors but injected with the radiolabeled mAbs or peptides mixed with a large excess of unlabeled biomolecules to saturate the epitopes/receptors, or (3) mice implanted with a tumor that does not express the target epitopes/receptors and receiving the radiolabeled mAbs or peptides. Goups of five to six mice are sacrificed at selected times postinjection (p.i.) depending on the anticipated pharmacokinetics. The tumor and samples of blood and normal tissues are obtained and weighed, and the radioactivity in each is measured by γ-scintillation counting. For pure β-emitters (e.g., ^{90}Y), liquid scintillation counting may be used to measure the radioactivity

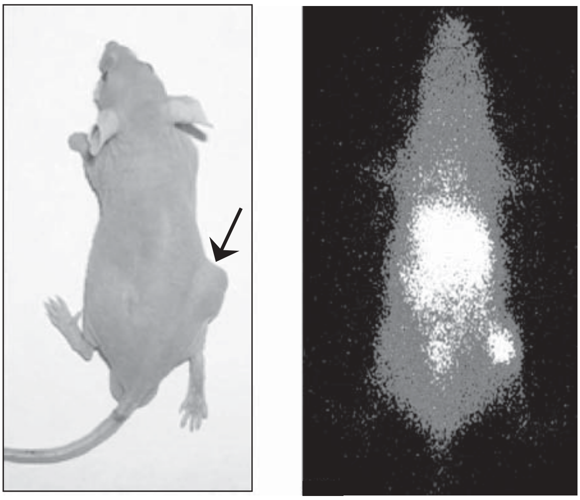

Figure 6.7-13. Imaging of an athymic mouse bearing a subcutaneous HER2/neu-positive BT-474 human breast cancer xenograft (arrow) at 72 hours postintravenous (tail vein) injection of ^{111}In-DTPA-trastuzumab (Herceptin). The tumor is clearly visualized using the radiopharmaceutical. (Image generously provided by Kristin McLarty and Deborah Scollard.) (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_ med/pharmaceutical_biotech/.)

in tissues, or alternatively, the Bremstrahlung radiation caused by interaction of the β-particles with the tissues can be measured in a γ-counter. The tumor and normal tissue uptake is expressed as the percent injected dose per gram of tissue (% i.d./g). The tumor/blood (T/B) and T/NT ratios are calculated. Tumor uptake varies from 1% to 2% i.d./g for radiolabeled peptides to as high as 10% to 20% i.d./g for intact IgG mAbs [18]. Tumor uptake should be significantly greater than that in control groups of mice. The T/B ratio should be >2:1 and, ideally, as high as 5:1 to 10:1. In addition to biodistribution studies, imaging studies of γ-emitting or positron-emitting biomolecules may be performed using dedicated high-resolution (1–2 mm) microSPECT or microPET small animal imaging devices (Figure 6.7-13) [262, 263]. These images can be quantified by region-of-interest (ROI) analysis and are useful to follow any changes in the biodistribution of radioactivity in an individual animal over time. In addition, preclinical small animal imaging studies provide "proof-of-principle" for radiolabeled biomolecules intended for tumor imaging applications in humans. The results of biodistribution and imaging studies can be used to predict the radiation absorbed doses to organs in humans for subsequent clinical trials using computer software such as OLINDA [264, 265].

6.7.7.6 Preclinical Studies to Evaluate Anti-Tumor Effects and Normal Tissue Toxicity

Radiolabeled mAbs and peptides intended for RIT or PDRT of malignancies need to be first evaluated preclinically in mouse tumor xenograft models. These studies involve administration of increasing doses of the radiolabeled biomolecules to mice

and monitoring the tumor growth or survival of the animals over time [258]. Control groups of mice receive either the formulation vehicle (e.g., saline) or the nonspecific radiolabeled mAbs of the same class and isotype or peptides that do not recognize the target epitopes/receptors. Generalized and gastrointestinal toxicity is monitored by weighing the animals every few days to identify any weight loss (>10%), whereas bone marrow toxicity is assessed by determining leukocyte, red blood cell, and platelet counts in blood samples. Liver toxicity is evaluated by following serum transaminases, whereas kidney toxicity is determined by measuring serum creatinine. Hematopoietic toxicity, if present, is usually observed within 2–3 weeks after injection of the radiolabeled biomolecules and normalizes within 6–8 weeks, whereas liver and kidney toxicity may require an extended observation period (4–8 weeks). An ideal radiotherapeutic agent will exhibit clearly evident and specific antitumor effects with minimal–moderate and manageable normal tissue toxicity [258].

6.7.7.7 Kit Formulation and Associated Pharmaceutical Testing

Labeling methods for mAbs and peptides that involve the chelation of radiometals (e.g., ^{99m}Tc, ^{111}In, ^{68}Ga, ^{90}Y, ^{177}Lu, and ^{64}Cu) allow formulation of radiopharmaceutical kits [99, 145]. These kits consist of a unit dose of a solution of the metal chelator–biomolecule conjugates dispensed into a glass vial sealed with a rubber septum and aluminum crimp. The kits may be stored at 2–8°C, kept frozen at −10°C, or lyophilized, depending on the particular mAb or peptide. Radiolabeling is performed simply by adding a buffered solution of the radionuclide to the vial and incubating for a predetermined period of time and temperature. The kits are designed such that the labeling efficiency is >90–95%, thus requiring no post-labeling purification and only minimal quality control testing (e.g., assay for total radioactivity, pH measurement, and RCP testing). Other quality control testing procedures are performed on the kit formulation before its use for labeling biomolecules. These tests include protein/peptide purity and homogeneity, evaluation of immunoreactivity or receptor-binding properties, estimation of the level of chelator substitution, measurement of protein concentration and pH, and stability studies. Key pharmaceutical tests such as the USP Sterility Test and USP Bacterial Endotoxins Test also need to be performed on the kits. The radiolabeled biomolecules may be tested retrospectively for sterility and apyrogenicity, provided that the kits have been validated using trial batches to produce a sterile, apyrogenic product.

6.7.8 SUMMARY

Radiolabeled mAbs and peptides offer the opportunity for molecular imaging of tumors in order to probe their phenotypic properties. Various strategies have been developed for labeling these biomolecules with single γ-photon-emitters or positron-emitters for SPECT and PET imaging, respectively. These approaches can be extended for labeling biomolecules with α- or β-emitters or radionuclides that emit Auger and conversion electrons for targeted *in situ* radiotherapy of malignancies. Establishment of specifications for radiolabeled mAbs and peptides supported by comprehensive characterization testing procedures assures the quality of these novel biopharmaceuticals for human evaluation in clinical trials.

ACKNOWLEDGMENT

The author would like to acknowledge the financial support for research originating in his laboratory at the University of Toronto described in this chapter. Funding was received from the U.S. Department of Defense Breast Cancer Research Program, the Canadian Institutes of Health Research, the Canadian Breast Cancer Research Alliance, the Canadian Breast Cancer Foundation, the Cancer Research Society, Inc., the Susan G. Komen Breast Cancer Foundation, the Natural Sciences and Engineering Research Council of Canada, the James Birrell Neuroblastoma Research Fund, and the Ontario Cancer Research Network through funding provided by the Province of Ontario. The author would also like to acknowledge the outstanding contributions by the graduate students, post-doctoral fellows, and research technicians who have been members of his research group over the years.

7.1.1 INTRODUCTION

Human gene therapy (HGT) is defined as the transfer of nucleic acids (DNA or RNA) to somatic cells of a patient, which results in a therapeutic effect, by either (1) correcting genetic defects, (2) overexpressing proteins that are therapeutically useful, or (3) inhibiting the production of "harmful" proteins (e.g., by shRNA).

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

Although it has several theoretical advantages, so far HGT has not delivered the promised results: Convincing clinical efficacy in pivotal phase III clinical trials has not yet been demonstrated in the United States or Europe (although two gene therapy products for cancer treatment have recently been approved and marketed in China). HGT is a complex process, involving multiple steps in the human body (delivery to organs, tissue targeting, cellular trafficking, regulation of gene expression level and duration, biological activity of therapeutic protein, safety of the vector and gene product, to name just a few), most of which are not completely understood.

In most applications, gene therapy represents a new, innovative drug delivery system making use of the technical and scientific advances of the last two decades in microbiology, virology, organic chemistry, molecular biology, biochemistry, cell biology, genetics, genomics, and genetic engineering. It is more than "gene transfer," which is only a part of the complex, multiphase process of identification, manufacturing, preclinical testing, and clinical development of gene therapy products (see Section 7.1.3).

The prerequisites of successful HGT include therapeutically suitable genes (with a proven role in pathophysiology of the disease either by its lack, mutation, or overexpression), appropriate gene delivery systems (e.g., viral and nonviral vectors), proof of principle of efficacy and safety in appropriate preclinical models, and suitable manufacturing and analytical processes to provide well-defined HGT products for clinical investigations.

The principle of gene therapy has specific therapeutic advantages over existing therapeutic modalities (such as small molecules or biologics) in certain disease indications. These include (1) correction of the genetic cause of a disease, (2) selective treatment of affected (diseased) cells and tissues (the cells and tissues produce their own "remedy"), and (3) long-term treatment after a single application. It may be best suited for so-called "nondrugable" targets (i.e., the modulation of target molecule is not feasible with small-molecule or protein drugs). Based on these theoretical principles, at the time of its first introduction more than 17 years ago, gene therapy promised to be an effective and safe treatment modality, which will soon cure diseases and replace classic therapies.

Over the past few years, significant progress has been made in various enabling technologies and in the molecular understanding of diseases and the manufacturing of vectors. These advances, combined with the growing experience with gene transfer in humans, promises to contribute to the ultimate success of this new class of therapeutics.

7.1.2 BASIC PRINCIPLES

7.1.2.1 From Nucleic Acid Delivery to Therapeutic Effects

Gene therapy consists of multiple biological processes in the body, the exact nature of which is in most cases still unknown (Figure 7.1-1). Gene therapy is initiated with the introduction of an appropriate vector (viral or nonviral) either into the body locally (direct tissue injection), into body cavities (e.g., peritoneum or cerebrospinal fluid), or into the bloodstream (systemic delivery). The vector needs to "find"

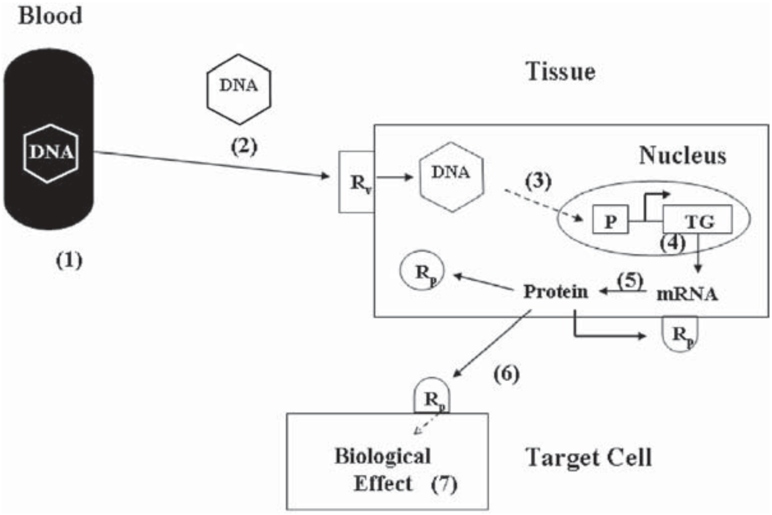

Figure 7.1-1. Multiple biological processes of in vivo gene transfer. The following main steps are required for successful gene transfer in the human body: (1) vector (viral, nonviral, cell-based) delivery (localized tissue delivery or systemic delivery via blood circulation) of a gene (DNA); (2) vector "recognition" by specific receptors (Rv) on cells in target tissue; (3) uptake of the vector by cells, trafficking to the nucleus and delivery of vector DNA in to the nucleus; (4) transcription (expression) of therapeutic (trans) gene in the nucleus; (5) translation of mRNA into therapeutic protein in the cytoplasm; (6) interaction of therapeutic protein with its receptors (Rp) within the "producing" cell (intracrine mechanism), on the surface of "producing" cell (autocrine mechanism) or on neighboring "target" cell (paracrine mechanism). For some applications, the therapeutic protein enters the circulation and acts distant from the target tissue (endocrine mechanism) (e.g., erythropoietin, coagulation factors VIII and IX, and growth hormone); and (7) after interaction with its receptor, the protein induces a biological effect, which results in therapeutic benefits. (Reproduced with permission from Pergamon Press.)

its target tissue, after which it enters the target cell membrane and traffics through the cytoplasm to reach and enter the nucleus. Once there, the therapeutic (trans) gene needs to be transcribed and the formed mRNA needs to be appropriately translated into the therapeutic protein. The protein then acts on its receptor(s) either on the cell that produced it (intracrine or autocrine mechanism), on neighboring cells (paracrine mechanism), or at distant sites after entering the blood circulation (endocrine mechanism, e.g., erythropoietin, coagulation factors, and growth hormone). Finally, after interacting with its receptor, the protein needs to induce an appropriate biological effect that results in therapeutic benefits. For gene correction or gene knock-down approaches, the steps are similar to those outlined above, except that the last step is modification of the genome ("gene correction") or blockade of mRNA transcription (siRNA/shRNA) of endogenous genes, respectively.

Although the factors needed for successful gene therapy are not different from any new therapeutic modality (which include technical [gene delivery and expression], clinical [therapeutic efficacy and safety], and socioeconomic factors), the specific technical success factors are unique for gene therapy approaches. They

include the choice of appropriate therapeutic gene(s) (with a proven role in the pathomechanism of the disease, specifically targeted and of sufficient potency), gene delivery systems (of sufficient targeting ability, transfection efficiency, and safety), and gene expression regulation systems to control the level and timing of transgene expression.

The therapeutic and socioeconomic success of gene therapy products includes the requirement that the benefits of gene therapy should outweigh the risks and should offer advantages over conventional (usually less expensive) treatments, before this new approach will become accepted in the general medical practice.

7.1.2.2 Essential Components and Selected Technical Features of a Gene Therapy Product

Gene Delivery Vectors. The goal in the discovery and development of most gene therapy vectors is to deliver and express genes at the appropriate site and at therapeutically meaningful levels in a controlled manner. The first-generation gene therapy vectors have used the ability of viral systems to deliver genetic information to human cells. Attempts are also made to develop nonviral synthetic vectors and hybrid synthetic-viral systems that are potentially safer alternatives for gene delivery. A third approach uses isolated human cells (stem cells, progenitor cells, or somatic cells) as a means to introduce the therapeutic genes into specific human cell populations where the therapeutic product is required.

Viral Vectors. Viruses "acquired" numerous biological properties over millions of years of evolution that allow them to effectively recognize and enter cells, traffic within the cytosol to the nucleus, translocate into the nucleus, and express their genes in the host cell (Figure 7.1-2).

The most frequently used viral vectors in clinical trials so far are retroviruses and adenoviruses (Table 7.1-1). Several other viral vectors are in preclinical development or are under clinical evaluation, including adeno-associated virus (AAV), lentivirus, herpes simplex virus (HSV), and others.

Retroviruses can lead to a stable integration of the transfected gene into the host genome and therefore produce long-lasting gene transfer. Replication-deficient retroviruses are produced *in vitro* in specific packaging cells transfected previously with retroviral genes (G, P, E) that have been deleted from the genome of the therapeutic retroviruses. Major limitations of the retroviruses are their low titers, their inability to infect nondividing cells, and the potential risk of insertional mutagenesis. The development of new pseudotyped retroviruses has increased virus titers that will permit more efficient gene transfer.

There are more than 50 known serotypes of *adenoviruses*, but until recently, serotype 5 (Ad5) and to a lesser extent serotype 2 (Ad2) (both class C adenoviruses) have been used as recombinant, nonreplicating gene delivery vectors. *Recombinant Ad5* can be produced in high titer. Ad5 vectors do not lead to stable integration of the transgene into the host genome (only at very low frequency in cell culture [2]), and they usually remain extrachromosomal and cause only a transient transgene expression. Replication-deficient adenoviruses are produced *in vitro* in specific packaging cells that complement gene products (e.g., *E1* and *E3*) deleted from the genome of the therapeutic adenoviruses. They give effective tran-

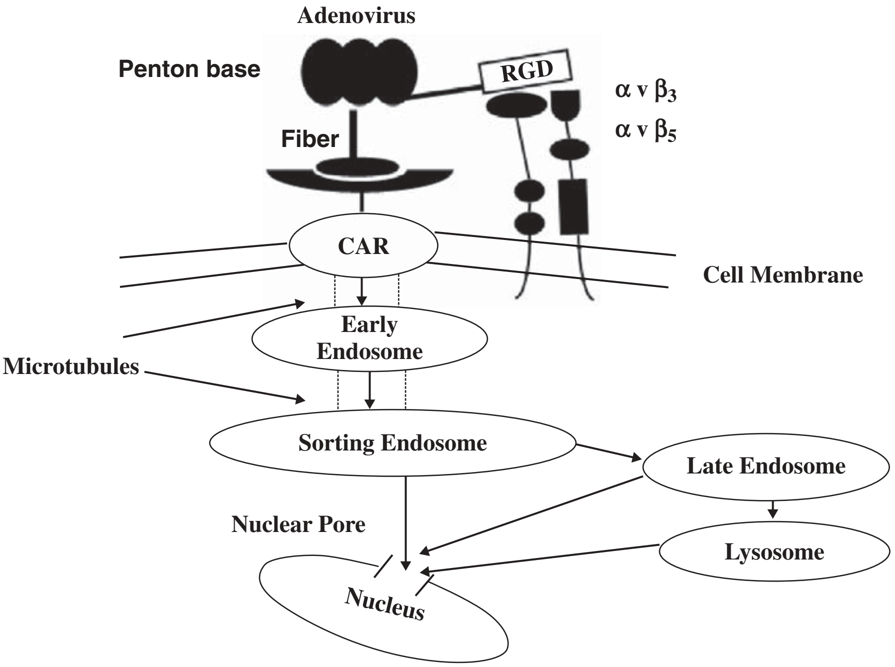

Figure 7.1-2. Cellular recognition, uptake, and trafficking of adenoviral gene delivery vectors. Receptor-mediated entry of adenovirus into cells depends on interaction of two of its coat proteins with two different cell-surface receptors. The viral fiber knob protein mediates attachment to the cell via the CAR. After attachment, an RGD tripeptide motif in the penton base protein binds to intergrins (αvβ3 or αvβ5), which mediates internalization. Knowledge of these domains and processes helped to design novel strategies to change the natural tropism of adenoviral vector ("re-targeting"; see text for details.) Once inside the cell, the adenovirus effectively and quickly (within less than 60 minutes) reaches the nucleus (via the endosome, microtubules, and the lysosome) and translocates into the nucleus via nuclear pores with the help of the nuclear localization signal (NLS) peptide in the viral coat protein. (Reproduced with permission from Pergamon Press.)

TABLE 7.1-1. Gene Delivery Systems (Vectors) Used in Gene Therapy Clinical Trials (1989–Present)[1]

Delivery System	Number of Trials
Retrovirus	254
Adenovirus	240
Naked DNA	132
Lipofection	85
Poxvirus	52
Vaccinia virus	30
Herpes simplex virus	26
Adeno-associated virus	19
RNA transfer	10

[1] From Ref. 1.

sient gene expression in proliferating and nonproliferating cells, but first-generation adenoviruses have the disadvantage of producing immunological and inflammatory reactions. These complications should be lessened with second-generation adenoviral vectors [3].

Some adenoviruses are human pathogens (wild-type Ad5, for example, causes the "common cold" syndrome), and most patients have already been exposed to them during their lifetime, resulting in the presence of various levels of circulating neutralizing anti-viral antibodies (NABs). This exposure may hinder the effectiveness of their systemic application. Use of viral vectors that are not human pathogens (e.g., various serotypes of adenoviruses, AAV, or nonhuman adenoviruses) can avoid this problem. Immune response evoked by the first application of the viral vector (human or nonhuman) may interfere with their repeated application (although the immune response may depend on the route of delivery and dose used). First- and second-generation adenoviral vectors have limited cloning size (<10 kb), which prevents the use of large therapeutic genes, multiple genes, or complex gene regulatory elements. The use of "gutless" adenovirus avoids this problem, allowing a cloning capacity of up to ~30 kb, but filling the vector with "useless" DNA is a challenge, and so is the proper manufacturing of these modified vectors, which require the presence of helper viruses.

AAVs have been used for effective gene transfer to muscle [4]. Numerous AAV serotypes have been identified (AAV1–9) recently, with a different tissue tropism, which gives us hope for using them in a tissue-specific manner [5].

In addition to pseudotyping (retroviruses) or deletion of nonessential viral genes (adenoviruses), several other strategies are pursued to improve viral vectors for human therapeutic use. This is a very active field, the overview of which is beyond the scope of this chapter. Some notable activities include changing viral coat proteins (fibers, pentons, etc.) to redirect the tropism of the virus and incorporation of specific gene regulatory systems (gene-switches, tissue-specific promoters, etc.) to allow proper timing, duration, extent, and localization of therapeutic gene expression.

Nonviral Vectors. The existing synthetic vectors (naked DNA, cationic liposomes, etc.) are far from being perfect delivery systems. Although they are less pathogenic and may have reduced toxicity compared with some existing viral vectors, depending on the dose injected, liposomes may aggregate in the blood and can cause severe toxic reactions [6].

Plasmid and liposome complexes are easy to produce and are safer, but they have low gene-transfer efficiency. However, novel lipid formulations and synthetic cationic polymer carriers have clearly improved the effectiveness of plasmid-mediated gene transfer [7–9].

In the future, the "perfect" gene delivery vector may be synthetic, incorporating many advantages of viruses (which over their evolution acquired the perfection of gene delivery to host organisms, such as dense DNA "packaging," cell recognition, cellular uptake, cytosolic trafficking, efficient nuclear uptake, and gene expression in the host cell nucleus, Figure 7.1-3), but avoiding the unwanted properties of viruses (e.g., off-target tropism, pathogenicity, cell toxicity, and immune and inflammatory reactions).

Dense DNA packaging (a prerequisite for efficient gene transfer) can be achieved by using, for example, protamine sulfate (a "trick" borrowed from sperm cells,

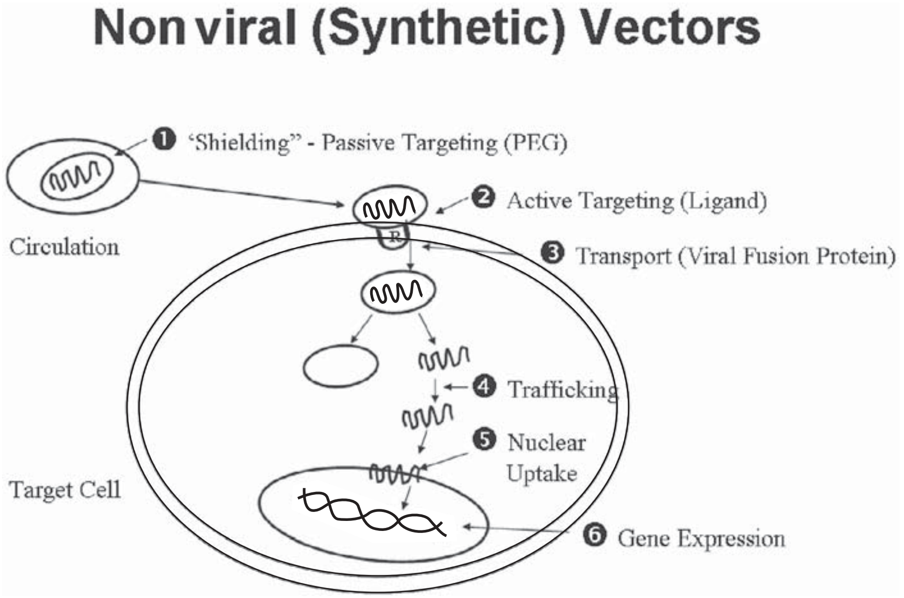

Figure 7.1-3. The "ideal" synthetic (nonviral) gene delivery vector. After dense DNA packaging is accomplished (e.g., by protamine sulfate), the surface of synthetic particles (which is usually positively charged) needs to be "shielded" (e.g., by poly (ethylene-glycol) [PEG]) so that they do not attach to blood elements or to each other and, therefore, have an extended circulating plasma half-life (1) (passive targeting to "leaky" vessels"). The surface of the particles will contain specific ligands for active targeting to selected cells/tissues (2). By engineering viral fusion proteins to the particle coat, cell entry is facilitated (3). Cellular trafficking will be enhanced and intracellular degradation of DNA prevented (4). Nuclear uptake will be facilitated by viral nuclear localization signal (NLS) peptides (5). Chromosomal localization will be augmented (e.g., by the *rep* gene, which allows targeting to chromosome 19) and gene expression regulated by specific transcriptional control elements (6). (Reproduced with permission from Pergamon Press.)

which similar to viruses package DNA efficiently). The particle should be "shielded" from binding to plasma proteins, blood cells, or to each other to allow longer circulating plasma half-life and more efficient uptake in target tissues (e.g., at the site of leaky vessels in tumors) ("passive" targeting). They will be engineered to contain cell recognition ligands (e.g., transferring for proper "active" targeting of cancer cells), cell membrane fusion proteins, and nuclear localization signals (all "borrowed" from viruses) for efficient cellular trafficking. Chromosomal localization and insertion for long-term expression of the therapeutic gene will be achieved by adding, for example, the *rep* gene, which allows targeting and insertion of the DNA to chromosome 19 [10]. These examples are just a few that are being tested today. However, even more sophisticated systems can be expected in the future, along with appropriate manufacturing and analytical processes, which will allow their introduction to human subjects.

Cell-Based Delivery of Therapeutic Genes. Although cell therapies have been used in medicine for several decades (e.g., blood transfusion), the use of cells

manipulated *ex vivo* with therapeutic genes and then reintroduced into patients offers a new strategy by which to deliver therapeutic genes.

Human hematopoietic stem cells, mesenchymal stem cells, neuronal stem cells, embryonic stem cells, and peripheral T cells are the focus of ongoing research efforts [11, 12]. The panel of stem cells available for gene therapy purposes will increase as isolation and culturing procedures improve and appropriate factors are identified that can be used to drive their differentiation along distinct cell lineage pathways. Issues currently being addressed include the development of vectors (e.g., lentiviruses) for efficient stem cell gene transduction, expression and regulation of therapeutic genes during lineage progression from stem cells to differentiated cells, control of stem cell growth, expansion *ex vivo*, and engraftment and differentiation *in vivo*. Genetically engineered stem cells or less pluripotent progenitor cells are currently being tested for therapeutic angiogenesis (endothelial cell progenitors), Parkinson's disease (neuronal stem cells), bone marrow transplantation (hematopoiectic stem cells), and AIDS (e.g., hematopoietic stem cells transfected with the *RevM10* gene) [11–13].

"Customized" Gene Delivery Vectors. It is important to emphasize that there will not be a "universal" vector that is optimally useful for all indications. On the contrary, each disease target will have a specific set of technical requirements, and the "perfect" vector for a specific disease should be optimized according to these specific criteria. For example, some diseases will require local delivery (e.g., ischemia, retinitis pigmentosa, and Parkinson's disease), whereas others necessitate systemic delivery (e.g., cancer). For certain diseases, the gene of a secreted protein (e.g., coagulation factors VIII and IX for hemophilia A and B, respectively; growth hormone; and erythropoietin) can be expressed in almost any tissue of the body. Sometimes only transient, short-lived gene expression will be needed (e.g., therapeutic angiogenesis and cancer), whereas in other cases long-term (sometime lifelong) gene expression duration will be necessary (e.g., most monogenic diseases, such as familial hypercholesterolemia, hemophilia, and SCID). For certain disease targets, most, if not all, target cells need to be transfected (cancer), whereas in other cases, this will not be necessary (e.g., with most secreted therapeutic proteins).

In certain diseases, tight control of gene expression will not be important (e.g., coagulation factors), whereas in others very tight regulation of the gene expression will be essential (e.g., insulin). Some diseases will require specific targeting of the vector for efficient and safe delivery after systemic application (e.g., cancer). Other disease targets will require tissue-or disease-specific promoter elements (e.g., arteriosclerosis and cancer). In some instances, conditionally inducible gene expression regulation (gene-switch) will allow precise dosing and timing of gene expression, which will also be an essential element for safety reasons (i.e., ability to "turn off" the gene if serious side effects occur).

Most vectors optimized for a certain disease target will consist of multiple "components," each fulfilling some necessary technical, biological, or therapeutic need. As the different elements will probably be perfected (and patented) by different companies, the introduction of the optimal multicomponent vector may be difficult because of intellectual property rights and commercial obstacles.

Gene Delivery Targeting. The effectiveness of gene therapy is determined by a combination of the effects of gene delivery into the target tissue, the entry of the new genetic material into cells, and the expression of the transfected gene in the target tissue (Figure 7.1-1). When specific physical or biological targeting methods are available, they generally improve the expression of the transfected gene in the target organ and reduce gene expression in off-target tissues, which may lead to unwanted side effects.

Physical Targeting. A variety of physical gene delivery methods has been introduced to achieve better local tissue targeting of vectors. An example of the effective physical targeting is catheter-mediated gene transfer to various regions of the body (e.g., feed arteries of organs, such as leg muscles, heart, and liver, or retrograde injection via veins) [14–16]. Intramuscular injection of plasmid DNA or viral vectors encoding angiogenic growth factors has been used in ischaemic myocardium [17] and peripheral vascular disease [18, 19]. Another approach to local delivery to small arterioles and capillaries is injection of biodegradable microspheres coated with recombinant growth factors or plasmid DNA [20]. Ultrasonography [21], alone or in combination with microbubbles [22], can also potentially be used to improve the efficiency of gene transfer. For facilitation of intramuscular, intratumoral, or intradermal delivery of naked, plasmid, or cationic liposome-carried DNA, gene gun technology [23] and electroporation [24] can be used. Although these delivery methods offer certain advantages in specific disease targets, they are being progressively replaced by more specific biological targeting methods.

Biological Targeting. Biological vector targeting uses modification of viral coat proteins (for viral vectors) or surface properties of synthetic vectors (e.g., liposomes).

Passive targeting makes use of alteration of the pharmacokinetics of vectors by "shielding" them from binding to blood cells, plasma proteins, immunoglobulins, unwanted tissues, or to each other, allowing them to circulate for longer periods of time in the blood and accumulate in specific tissues with "leaky" blood vessels (such as tumors).

Active (vector) targeting aims at directing vector binding and uptake to specific cells in the body by selective "targeting" molecules attached to the surface of the vectors by a variety of technologies (e.g., chemical and genetic). Recent advances in the biological understanding of adenovirus structure and adenovirus receptor interactions have lead to the development of targeted adenovirus vectors. Receptor-mediated entry of adenovirus serotype 5 (Ad5) into cells has been found to depend on two of its coat proteins. The fiber knob protein mediates primary attachment to the cell via the coxsackie-adenovirus receptor (CAR) protein [25]. After cell attachment via fiber–CAR interaction, an RGD tripeptide motif in the penton base protein binds to integrins ($\alpha_v\beta_3$ and $\alpha_v\beta_5$) that mediate cellular internalization [26, 27] (Figure 7.1-2). Other adenovirus serotypes use different cell-surface receptors (e.g., the group B adenoviruses bind to CD46 [28]), most of which have not been identified yet.

Two basic requirements are necessary to create a (re)targeted Ad5 vector: Interaction of adenovirus with its native receptors (e.g., CAR) must be first removed,

and novel, tissue-specific ligands must be added to the virus [29–31]. Three general approaches have been used to achieve these basic requirements. In the "two-component" approach, a bispecific molecule is complexed with the adenovirus [29, 32]. The bispecific component simultaneously blocks native receptor (CAR) binding and redirects virus binding to a tissue-specific receptor (e.g., to integrins using the RGD motif). In the "one-step" approach, the adenovirus is genetically modified in the fiber protein domains to remove native receptor interactions and a novel ligand is genetically incorporated into one adenovirus coat protein [31–33]. The third approach is to use specific polymers to cover the entire virus and "shield" it from unwanted interactions. This method creates a truely "stealth" virus, preventing its interaction, not only with its primary (CAR, via fiber) and secondary cell-surface receptors (integrins, via penton RGD), but also with plasma proteins (including neutralizing antibodies), blood cells, and most tissue sites, providing an ideal situation for extended persistence in the circulation and *passive targeting* [34]. The polymer coat allows covalent attachment of specific "ligands" of choice to its surface, effectively retargeting the vector to a desired tissue (*active targeting*) [35].

Transcriptional Targeting. Receptor targeting technology can be combined with "transcriptional targeting" approaches (by the use of cell-, tissue- or disease-specific promoters).

A tissue- or disease-specific promoter will allow therapeutic gene expression only in cells that express transcription factor proteins binding to these specific promoter sites. Some tissue- or disease-specific promoters, identified and tested in animal models to date, include the promoter of the prostate-specific antigen (PSA) gene [36], osteocalcin gene [37], glucose "sensing" molecules for insulin gene delivery, and hypoxia response element (HRE) activated by hypoxia inducible factors (HIFs) in hypoxic/ischemic tissues (e.g., tumors) [38].

Gene Expression Control Systems. Regulating therapeutic gene expression will be necessary for both the clinical efficacy and the safety of most HGT applications. Gene therapy offers the promise of replacing frequent injections of an expensive therapeutic protein or antibody with an infrequent or even one-time administration of a gene delivery vector, which would then provide continuous therapeutic protein production at the desired site. An appropriate system of gene expression will control and allow titration of protein levels, dosing to be adjusted as the disease evolves, and therapy to be initiated repeatedly or terminated at will. Regulation can be achieved by a physiological/pathological signal (e.g., glucose and hypoxia) [39, 40] or via dose-dependent ligand binding and activation of chimeric transcription factor proteins, which then interact with DNA elements incorporated into the vector and regulate therapeutic gene expression [41].

Much progress has been made on control systems, where gene expression is regulated pharmacologically by a small-molecule drug. Four major systems are known to date that have already been tested in animals: those regulated by the antiobiotic tetracycline (Tet) [42], the insect steroid ecdysone or its analogs [43], the anti-progestin mifepristone (RU486) [44], and chemical dimerizers such as the immunosuppressant rapamycin and its analogs [45–47]. They all involve small-molecule-dependent recruitment of a transcriptional activation domain to a basal

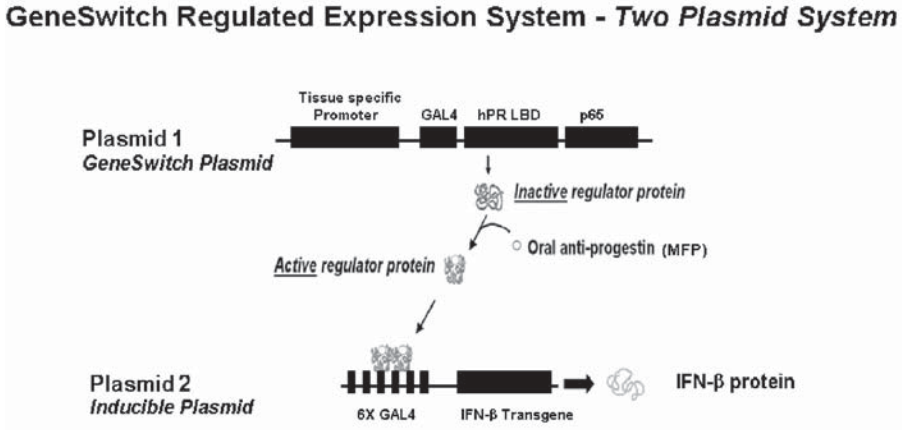

Figure 7.1-4. The two-plasmid GeneSwitch gene expression control system. Plasmid 1 contains the DNA of the mutated ligand binding domain (LBD) of the human progesterone receptor (hPR) driven by a tissue specific promoter (e.g., actin promoter for muscle applications). It also contains the GAL4 DNA-binding domain and the p65 activator domain (all combined called the "regulator protein"). After expression, the regulator protein remains inactive until an anti-progestin small molecule compound (e.g., mifepriston, MFP) binds to it, and initiates conformation change and dimerization. The active regulator protein binds to the promoter region of Plasmid 2, which induces the expression of the therapeutic gene of interest (in this example interferon β, IFNβ).

promoter driving the gene of interest, but they differ in the mechanism of recruitment. Such a pharmacological gene expression regulation system should meet the following criteria. Basal expression should be very low and inducible to high levels over a wide dose range. Induction should be a positive effect (adding rather than removing a drug) and use an orally active small molecule that has no untoward pharmacological effects in humans. The regulatory protein(s) should have no effects on endogenous gene expression and should be of human origin to minimize immunogenicity. An example of one of the most advanced systems (GeneSwitch), developed by Valentis, Inc. (Burlingame, CA) is shown in Figure 7.1-4. It has been successfully used for the timing (Figure 7.1-5) and dosing (Figure 7.1-6) of circulating plasma levels of therapeutic proteins (such as IFNβ) expressed in the hind limb muscle of mice after i.m. delivery of their DNA in the form of AAV-1 (Figure 7.1-5) or naked plasmid combined with electroporation (Figure 7.1-6).

7.1.2.3 Disease Targets for Gene Therapy

Ever since the first clinical attempt of gene transfer more than 17 years ago, numerous monogenic (Table 7.1-2) and complex (multigenic) diseases (Table 7.1-3) were targeted with a large variety of gene therapy strategies.

In 1989, Rosenberg et al. performed the first human gene therapy trial [49] when they used a retrovirus to introduce the gene coding for resistance to neomycin into human tumor-infiltrating lymphocytes before infusing them into five patients with advanced melanoma.

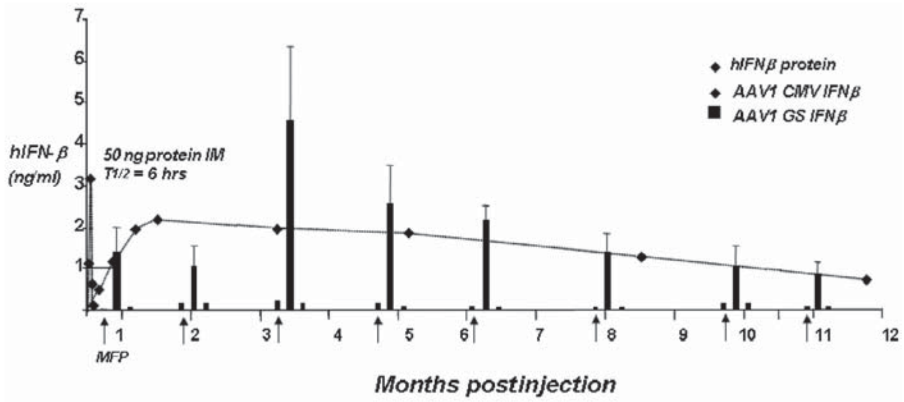

Figure 7.1-5. Long-term regulated expression of human Interferon β (hIFNβ) in mice. Three groups of male C57B16/J mice (n = 10 each) were injected with hIFNβ protein (50 ng, intramuscular, i.m.; diamonds), adeno-associated virus serotype 1 (AAV1) carrying the hIFNβ gene driven by the constitutive CMV promoter (10^{10} vp/animal; i.m.; dotted line), or AAV1 carrying the hIFNβ gene regulated by the GeneSwitch (GS) inducible promoter (columns). Circulating plasma hIFNβ level (ng/mL) was measured by ELISA. I.m. injection of IFNβ protein resulted in transient increase in plasma IFNβ levels with very rapid clearance (T1/2: 6 hours). In contrast, single i.m. injection of AAV1 CMV IFNβ resulted in long-term (at least up to 12 months) elevation of plasma hIFNβ protein levels. IFNβ protein expression could be repeatedly induced by intraperitoneal (i.p.) administration of MFP (once every 6 weeks up to 12 months; arrows) after single i.m. administration of AAV1GS IFNβ. The induced plasma hIFNβ levels from the GS construct were similar to the sustained plasma levels produced by the constitutive (CMV) promoter.

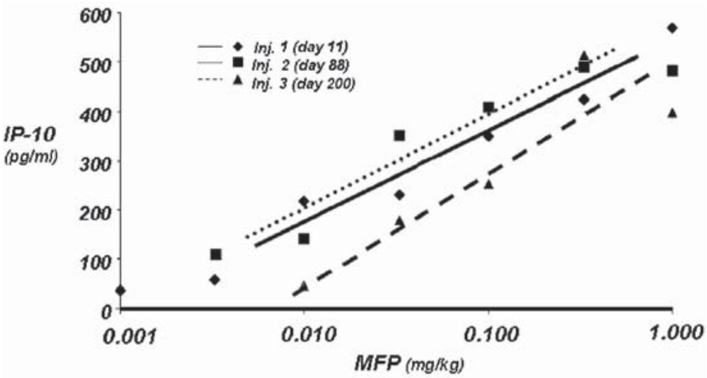

Figure 7.1-6. Reproducible dose-dependent induction of IFNβ by Mifepristone (MFP). C57B16/J mice (n = 35) were injected intramuscularly (followed by electroporation) with a plasmid (250 μg) containing the murine (m) IFNβ gene regulated by GeneSwitch upon induction by MFP. Groups of mice (n = 5 each) were given different doses (0 to 1 mg/kg) of MFP intraperitonally (i.p.). Plasmid injection and MFP dose-response were repeated three times, every other month, for 6 months. The level of mIFNβ protein in plasma was estimated by the IFNβ-induced marker protein, IP-10. Note the linear dose-response to MFP over a two log dose-range (0.01–1.0 mg/kg), which was reproducible upon readministration of the plasmid.

TABLE 7.1-2. Disease Targets for Gene Therapy: Monogenic Diseases

Disease	Gene(s)	Number of Clinical Protocols/Trials (1990–1999)[1]
Cystic fibrosis	CFTR, α-1-anti-trypsin	24
Severe combined immunodeficiency (SCID)	ADA	3
Gaucher disease	Glucocerebrosidase	3
Canavan disease	Aspartoacylase	2
Hemophilia A	Factor VIII	2
Hemophilia B	Factor IX	2
Chronic granulomatous disease	Gp91 phox	2
ALS	CNTF	1
Familial hypercholesterolemia	LDL-R	1
Hunter disease	ldurinate-2-sulfatase	1
Leukocyte adherence deficiency	CD 18	1
Muscular dystrophy	Sarcoglycan, dystrophin, utrophin	1
Fanconi anemia	Group A gene	1
Purine nucleoside phosphorylase deficiency	PNP	1
Ornithin transcarbamylase deficiency	OTC	1

[1] From Ref. 48.

TABLE 7.1-3. Disease Targets for Gene Therapy: Multigenic Diseases[1]

Cancer	**Vascular disease**
Gynecological: breast, ovary, cervix	Peripheral arterial disease
Nervous system: glioblastoma, leptomeningeal carcinomatosis, glioma, astrocytoma, neuroblastoma	Coronary heart disease
	Venous ulcers
	Vascular complications of diabetes
Gastrointestinal: colon, colorectal, liver mestastases, post-hepatitis liver cancer	
Genito urinary: prostate, renal	**Other diseases**
Skin: melanoma	Inflammatory bowel disease
Head and neck	Rheumatoid arthritis
Lung: adenocarcinoma, small cell, non-small cell	Chronic renal disease
Mesothelioma	Carpal tunnel syndrome
Hematological: leukemia, lymphoma, multiple	Alzheimer's disease
Myeloma	Fractures
Sarcoma	Diabetic neuropathy
Germ cell tumors	Parkinson's disease
	Erectile dysfunction
Infectious	Superficial corneal opacity
HIV/AIDS	Retinitis pigmentosa
Tetanus	Glaucoma
CMV infection	
Adenovirus infection	

[1] From Ref. 1.

The first trials have been designed to establish feasibility and safety, to demonstrate the expression of therapeutic protein(s) *in vivo* by the genes transferred, and in some cases, to show therapeutic benefit.

As of January 31, 2004, there were 918 trials in 24 countries on record [1]. The U.S. accounts for two thirds of these trials. Cancer is by far the most common disease indication, followed by inherited monogenic diseases and cardiovascular diseases. Viral vectors have been the most frequently used vehicles for transferring genes into human cells, with retroviruses and adenoviruses representing the vast majority. Over 100 distinct genes have been transferred.

7.1.3 FROM BENCH TO BEDSIDE: THE DEVELOPMENT OF AD5FGF-4 TO TREAT PATIENTS WITH RECURRENT ANGINA

A brief summary of the preclinical and early clinical development and manufacturing of the Ad5FGF-4 gene therapy product for the facilitation of angiogenesis in patients with chronic myocardial ischemia (recurrent angina) is provided below for the purpose of illustrating the complex processes involved in the many stages of preclinical and clinical development of an HGT product.

7.1.3.1 Preclinical Efficacy

Specific criteria need to be fulfilled for angiogenic gene therapy to be successful. The gene selected should code for a protein with proven angiogenic activity, the vector should provide high gene-transfer efficiency, the delivery technique should target the ischemic tissue, and the procedure should be safe, in both the short and the long term [50]. In addition, appropriate current Good Manufacturing Practices (cGMP) need to be established (for details, see Section 7.1.3.3). Preclinical and initial clinical studies indicate that angiogenic gene transfer with Ad5FGF-4, delivered by a single intracoronary injection, may meet these criteria [16, 50–55].

Proof-of-Concept Study. Preclinical investigation of Ad5FGF-4 involved demonstration of myocardial angiogenesis in a porcine model of stress-induced myocardial ischemia [51]. In this experimental model, an ameroid constrictor is placed around the proximal left circumflex coronary artery, leading to gradual closure of the artery over the following weeks. The subsequent development of collateral vessels allows normal myocardial function and blood perfusion at rest, but blood flow is insufficient to prevent ischemia during periods of increased oxygen demand. In the proof-of-concept studies, stress-induced (atrial pacing) left ventricular function and blood flow changes were evaluated by two-dimensional echocardiography approximately 35 days after ameroid placement. Ad5FGF-4 (10^{11} viral particle [v.p.] per animal) ($n = 6$) was then administered by intracoronary injection. Ventricular function and blood flow were reassessed 14 days later, and the animals were killed to quantify the presence of adenoviral DNA and FGF-4 mRNA and protein expression in the myocardium.

Polymerase chain reaction (PCR) and reverse-transcription–PCR (RT–PCR) analysis demonstrated the presence of Ad5 DNA and FGF-4 mRNA, respectively, in the injected pig hearts [51]. Immunoblotting showed that pigs treated with

Ad5FGF-4 expressed FGF-4 protein in heart tissue but not in other organs, such as the liver and eye. Contractile function, assessed as the degree of wall thickening of the ischemic region during atrial pacing, had improved significantly 2 weeks after FGF-4 gene transfer compared with preinjection (Figure 7.1-7A). This functional

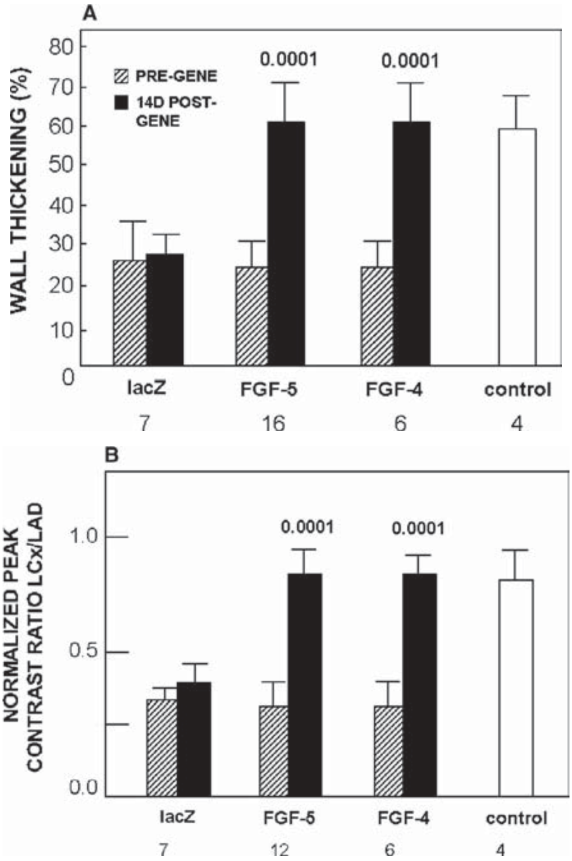

Figure 7.1-7. Proof-of-principle pig studies for angiogenic gene therapy after intracoronary delivery of Ad5FGF-4. (A) Regional contractile function. Basal wall thickening in the ischemic region of the ameroid-equipped pig heart was normal, but atrial pacing (200 bpm) was associated with reduced wall thickening. At 2 weeks after intracoronary Ad5FGF-4 gene transfer (10^{12} v.p.), there was a 2.3-fold increase in wall thickening in the ischemic region during pacing ($p < 0.0001$); similar to results observed after Ad5FGF-5 gene transfer. Pigs receiving Ad5LacZ showed a similar degree of pacing-induced deficit in the ischemic region before and 2 weeks after gene transfer. (B) Regional myocardial blood flow. Before gene transfer, animals showed a deficit in blood flow in the ischemic region during pacing. At 2 weeks after Ad5FGF-4 gene transfer, the animals showed improved flow in the ischemic region ($p < 0.0001$); this was similar to results observed after Ad5FGF-5 gene transfer. Pigs receiving Ad5LacZ showed a similar degree of pacing-induced deficit in the ischemic region before and 2 weeks after gene transfer. Columns represent mean values for number of experiments shown below the columns; error bars denote 1 SD. (Reproduced with permission from Mary Ann Liebert, Inc.)

improvement was associated with a normalization of regional blood flow during atrial pacing (Figure 7.1-7B) [51]. Thus, this study provided experimental evidence that a single intracoronary injection of Ad5FGF-4 ameliorates deficits in myocardial blood flow and function in the setting of chronic myocardial ischemia in pigs.

Follow-up studies in the same pig model showed that the effect of single Ad5FGF-4 injection lasted at least for 3 months, and that the effect was dose dependent [51].

7.1.3.2 Toxicology and Biodistribution

A Good Laboratory Practices (GLP) toxicology and biodistribution study was performed to determine the potential adverse effects of Ad5FGF-4 in healthy pigs after either intracoronary or left ventricular (systemic) administration (10^{12} v.p. left ventricular, 10^{10}–10^{12} v.p. intracoronary). Systemic biodistribution of the product was also assessed.

This study found no significant test article-related toxicologic effects [51]. PCR analysis for adenoviral DNA and RT–PCR analysis for the transgene (FGF-4) mRNA were performed to assess vector biodistribution. Adenoviral DNA was detected in 27 of 110 organs examined from animals injected intracoronary with 10^{12} v.p. Ad5FGF-4. Adenoviral DNA was detected in the lung, liver, spleen, and testis. Detectable adenoviral DNA typically decreased over time in most organs. The presence of viral DNA in the testis was observed at 5 days but not at 28 or 84 days. In no case in which adenoviral DNA was present in extracardiac sites was transgene expression detectable at the mRNA level after RT–PCR analysis [51]. These results (along with cGMP; see Section 7.1.3.3) supported the submission of an investigational new drug (IND) application in 1998.

7.1.3.3 cGMP Manufacturing and Characterization of the Gene Therapy Vector

This section summarizes the various activities required in the course of cGMP manufacturing and testing of the Ad5FGF-4 product for the initiation and advancement of its clinical development and reaching a "well characterized product" status with the Regulatory Authorities.

Vector Construction. Construction of the recombinant replication incompetent (E1/2 deleted) adenovirus serotype 5 (Ad5) expressing the human FGF-4 cDNA required three components: the FGF-4 transgene, a plasmid shuttle vector to carry the transgene as well as 5′ Ad5 sequences, and a second plasmid carrying the bulk of the Ad5 genome.

The full-length cDNA for human FGF-4 (the "transgene") was isolated from a cDNA library, which was constructed from mRNA of Kaposi's sarcoma DNA transformed NIH3T3 cells [56]. The cDNA that encodes the FGF-4 peptide is approximately 1.2 kB in size, and the FGF-4 protein has 206 amino acids, including a 33-amino-acid signal peptide at the N-terminus.

Plasmid pACCMVplpASR(-) (the "shuttle vector") contains the heterologous CMV promoter, a polylinker, and SV40 polyadenylation sequences flanked by

partial human Ad5 sequences [57]. The FGF-4 cDNA was subcloned, as an Eco R1 fragment, into this adenovirus shuttle vector at its single Eco R1 site.

Plasmid pJM17 (the "adenovirus plasmid") contains the required Ad5 sequences except that the E1 region is disrupted by the insertion of pBR322 sequences [58]. A unique feature of this plasmid is the presence of some nonviral sequences in the E3 region [59] that become relevant for the viral vector identity testing.

To generate the Ad5FGF-4 viral vector, plasmids pACSR/FGF-4 and pJM17 were co-transfected into HEK 293 cells using a calcium phosphate method. The cells were overlaid with nutrient agarose. Homologous recombination between the vectors created E1-deleted, FGF-4 gene-containing vector genomes capable of replication in HEK 293 cells.

Master Virus Bank. Six clones were isolated from one round of virus plaque purification and were screened for protein expression. One clone was selected, amplified on HEK 293 cells, purified by cesium chloride (CsCl) ultracentrifugation, and used for preparation of a Master Virus Bank (MVB). A purified Ad5FGF-4 virus seed was propagated through three consecutive rounds of plaque purification. A final plaque was then expanded and purified by anion exchange chromatography, sterilized by filtration, and stored at −70°C. This virus stock was checked for sterility and absence of measurable replication competent adenovirus (RCA). An MVB was then created by one additional cycle of propagation in serum-free suspension culture of HEK 293 cells, and this virus was purified, aliquoted, and frozen. The MVB was tested and confirmed to be free of RCA as well as adventitious agents. The MVB was stored at −70°C.

Master Cell Bank and Manufacturer's Working Cell Bank. A scalable manufacturing process to meet clinical, as well as commercial, needs for recombinant adenovirus vector would only be attractive if it could be performed without using bovine serum in the culture medium. For these reasons, attachment and serum-dependent HEK 293 cells were first adapted to suspension culture by direct transfer into shake flasks in a modified William's essential medium containing 2% fetal bovine serum (Hyclone, Gamma irradiated). The cultures were passaged continually for over 6 weeks in the same environment until the cells exhibited a consistent growth pattern of less than 48 hours of doubling time and greater than 90% viability. These suspension-adapted cells were subsequently adapted to serum-free medium (modified IS293, Irvine Scientific) by gradual weaning. Cells from this bank were thawed and expanded and then used to generate a Master Cell Bank (MCB). Culture identification as human cells, growth on soft agarose to assess potential tumorigenicity, and screening for adventitious agents were also performed (according to current cell-line testing guidelines). Starting from the MCB, a Manufacturer's Working Cell Bank (MWCB) was prepared and then similarly tested before routine use.

Manufacture of the Bulk Drug Substance. The Ad5FGF-4 vector was manufactured under cGMP in a state-of-the-art, validated facility, following Biosafety Level 2 (BL2) practices. For the preparation of the Ad5FGF-4 drug substance, cells from the MWCB and virus from the MVB were employed. The virus was propagated in suspension cultures of HEK 293 cells using serum-free medium and the virus

progeny was purified using a combination of anion exchange chromatography (AIEX) and ultra-filtration (UF). The purified bulk drug substance was stored at –70°C.

Drug Substance (Virus) Purification. Medium components and extracellular (nonviral) contaminants were largely removed from adenoviral infected HEK 293 cells using three successive physiological buffer solution (PBS) washes and centrifugation of the cells at the time of harvest. The harvested cells were then frozen in a solution of PBS with 2% sucrose and stored at –70°C, until purification. The virus purification process was initiated with two additional cycles of freeze and thaw steps. After the final thaw, the ruptured cell suspension was centrifuged to remove cell debris. Virus purification was established with a protocol based on traditional protein purification techniques: column chromatography and ultra-filtration. Separation from nucleic acid contaminants was achieved by combining strategic peak collection and utilization of a tangential flow ultra-filtration step with a 100-kDa molecular-weight cutoff pore size membrane. Both of these purification procedures are readily and linearily scaled up and thus can support the large-scale production of Ad5FGF-4 for both clinical testings and commercial use.

Manufacture Scale-Up. The adenovirus harvest process consisted of three general steps: concentration, lysis, and clarification. In the small-scale process, the intact adenovirus-infected cells in culture medium were aliquoted and batch centrifuged to achieve a 30-fold concentration, and the supernatant was manually removed and replaced with a smaller volume of the freeze buffer. Although sufficing for harvest volumes of no more than 10 L, such a manual process would prove to be inadequate on a larger manufacturing scale.

A successful harvest method was identified using continuous centrifugation in a Westfalia CSC-6 disk-stack device with a hydroheratic feed system (HHFS). Scale-up of the adenovirus harvest process using a continuous centrifuge with HHFS has been shown to efficiently separate and concentrate an infected cell pellet while allowing the relatively easy exchange of growth medium for freezing buffer without open, manual manipulation. This patented process step combined separation of the cell pellet from culture medium, medium/buffer exchange, cell concentration, and then cell lysis in a single-unit operation step. The resulting lysate could be clarified and the virus purified.

Analytical Techniques and Release Specifications of Bulk Virus Lots. The crude viral harvest was tested for adventitious agents as needed to comply with current regulatory guidelines. Purified virus was tested to confirm the absence of RCAs, residual host cell proteins and DNA, and endotoxin, and to quantify total and infectious vector particles and, thus, the infectivity ratio. Bulk virus lots were released after meeting specifications, which included <1 endotoxin unit/mL and infectivity ratios of >2% (infectious titer/total viral particles).

Chromatographic Assays for the Quantitation of Intact Viral Particles. One main challenge in the development of the adenovirus purification process is the quantitation of intact viral particles in crude samples. Nonaggregated, purified viral samples were easily quantified by the reverse phase (RP)–high-performance liquid chro-

matography (HPLC) method [60]. The RP–HPLC assay quantitates the individual structural proteins with UV absorbance at 214 nm as the basis for the measurement of the adenovirus concentration. Unfortunately this assay could not be used to calculate the yields of the purification steps because it could not reliably quantitate crude samples. To solve this problem, an anion exchange (AIEX)–HPLC procedure was developed using a trimethyl anion exchange (TMAE) resin. The TMAE–HPLC was suitable for the analysis of all in-process samples ranging from clarified cell harvest to the final formulated, purified recombinant adenovirus product.

Endpoint Dilution (EPD) Assay for Infectivity. To determine infectivity, an endpoint dilution assay was developed [61]. The precision of this assay has a standard deviation of 0.2 when viral titers are expressed in $\log_{10}$.

Replication Competent Adenoviruses (RCA). Recombination between the viral E1 gene carried by HEK 293 cells and the E1 deleted recombinant adenovirus can and does occur at low frequency to generate RCAs, essentially wild-type Ad5 lacking the FGF-4 transgene. A highly sensitive assay involving viral amplification and cytopathic effect (CPE) readout has been described [62]. The limit of detection of this assay was one RCA in 3.2×10^{12} virus particles. Virus banks and bulk Ad5FGF-4 virus batches testing positive for RCA were not used in clinical studies.

Host Cell Protein Detection by ELISA. Typically biotechnology products have been produced in cell lines not of human origin. In such cases, residual host cell proteins (HCPs) are perceived as a safety concern to the patient. In the case of Ad5FGF-4 produced in HEK 293 cells, it is expected that the patient may respond to viral proteins with an immune response, but it is less clear that human HCPs will be immunogenic or pose a serious safety concern. One approach to detection of such HCP is by enzyme-linked immunosorbent assay (ELISA) using a polyclonal antibody reagent such as the HEK 293 HCP detection kit offered by Cygnus Technologies (Renchesler, MD). This ELISA was used to show a consistent, high HCP titer in crude cell lysates and to show that the diethyl-aminoethyl (DEAE) chromatography step is sufficient and reproducible to reduce HCPs to below the level of quantitation (20 ng/mL).

Residual DNA. Two methods were used to quantitate residual host cell (HEK 293) DNA in Ad5FGF-4 preparations. The first, using membrane hybridization of an oligonucleotide probe followed by chemiluminescent detection, was based on a procedure described by Walsh et al. [63]. Extracted samples were blotted onto a positively charged nylon membrane using a slot blot apparatus, the blot was then hybridized with a biotinylated oligonucleotide probe specific to the primate alpha-satellite sequence D17Z1, and the bound probe was detected with a streptavidin–alkaline phosphatase conjugate, followed by a chemiluminescent alkaline phosphatase substrate. The second method used TaqMan PCR quantitation of *Alu* repeat sequences in virus samples extracted using the Qiagen QIAAmp Viral RNA Mini Kit. In-process sample testing showed that the two methods gave similar results, both demonstrating a greater than 3 log reduction in the level of host cell DNA by the purification process, with final purified material containing less than 0.5-ng/mL DNA.

Product Identity Tests by PCR. The adenoviral backbone of the Ad5FGF-4 genome is derived from *dl*309, an Ad5 mutant, commonly used for the construction of E1-deleted adenoviral vectors. This mutant has a short stretch of foreign DNA inserted in place of a portion of the E3 region [59]. PCR confirmation of the type of adenovirus backbone (*dl*309 or wild-type Ad5 E3 region) served as a test for product identity and purity. It was possible to confirm transgene orientation as well as differentiate the product digest pattern from those obtained from either wt Ad5, RCA, or vectors containing different transgenes.

Product Potency Tests. Two assays were developed that measure the potency of the FGF-4 protein. In the first case, a "one-step" growth promotion assay is conducted on normal, human retinal pigment epithelial cells (ARPE-19). The assay measures metabolic activity (Alamar blue dye metabolism) after infection of ARPE-19 cells with a serial dilution of the drug substance (Ad5FGF-4). The increase in metabolic activity correlated with FGF-4 protein production (determined by an FGF-4 ELISA), increased *de novo* DNA synthesis (measured by BrdU incorporation), and an increase in cell number.

The second assay measured the production of FGF-4 protein produced in and secreted by A549 cells after infection with different doses of Ad5FGF-4. An FGF-4 specific ELISA (R&D Systems) allowed quantitation of FGF-4 protein present in the cell culture medium. The FGF-4 produced was confirmed as biologically active by stimulating the growth of ARPE-19 cells (see above).

DNA Sequencing of the Entire Viral Vector. The complete DNA sequence of the Ad5FGF-4 genome was determined using double-stranded DNA sequencing of Ad5FGF-4 DNA extracted from an MVB expansion. A total of 166 oligonucleotide primers were used to obtain overlapping readings from both strands of DNA. The observed sequence was compared with that predicted for Ad5FGF-4 by insertion of the FGF-4 transgene sequence into the wild-type Ad5 sequence [64], (Genbank Accession Number M73260, originally deposited as NC001406), into which the *dl*309 specific mutations had been incorporated [59]. The observed sequence matched the predicted 5′ 4.9 kB of vector sequence including the FGF-4 transgene. The sequence data distal to the transgene (3' end) confirmed that the Ad5FGF-4 backbone was derived from the Ad5 mutant *d*/309.

Genome Analysis. As a further safety precaution, and as a specific regulatory request, the DNA sequence of the FGF-4 transgene was analyzed for other possible open reading frames (ORFs) that might encode unexpected foreign proteins upon infection of target cells with the recombinant adenovirus. This analysis also included any reading frames that crossed the transgene/virus junctions and might therefore involve viral sequences. The genome analysis confirmed that only FGF-4 protein is made from the transgene carried in Ad5FGF-4.

The cGMP manufacturing and analytical process (outlined above) and the facility where it took place (Berlex Biosciences, Richmond, CA) have been approved by both the U.S. Food and Drug Administration (FDA) and the European Regulatory Agencies. Based on the test data, the FDA qualified Ad5FGF-4 as a "well characterized product."

7.1.3.4 Clinical Studies

There are several goals of Ad5FGF-4 angiogenic gene therapy for patients with chronic myocardial ischemia. It should promote new collateral vessel formation in the heart. In turn, this should increase perfusion of ischemic regions, leading to improved myocardial oxygen delivery and left ventricular function. From the patient's perspective, the ultimate goal of treatment should be to reduce or ameliorate symptoms of angina, increase exercise capacity, improve quality of life, and decrease the long-term risk of acute coronary events (such as acute myocardial infarction).

The clinical development program was initiated in 1998 to determine whether the improvement in cardiac perfusion and function (without any product-related adverse effects) detected in pigs translates into a clinical therapeutic benefit in patients with chronic stable angina. Four clinical studies [Angiogenic Gene Therapy (AGENT) phase 1/2 trial, AGENT 2 phase 2 trial, and AGENT 3 and 4 phase 2B/3 trials] have been initiated, and some (AGENT and AGENT-2) have been completed to date.

The Phase 1/2 AGENT Trial. The Angiogenic Gene Therapy Trial (AGENT) was the first ever randomized, double-blind, placebo-controlled (12 sites) U.S. clinical trial of angiogenic gene therapy for myocardial ischemia. The objectives of the AGENT trial were to evaluate the safety and anti-ischemic effects of five ascending doses of Ad5FGF-4 (3.2×10^8 to 3.2×10^{10} v.p.), randomizing in a ratio of 1:2 (placebo:active) in patients with chronic stable exertional angina, who had recurring angina despite optimal medical treatment and were not in need of immediate surgical revascularization.

A total of 79 patients with chronic stable angina were enrolled. Patients could exercise for ≥3 minutes in an exercise treadmill test (ETT) using the modified Balke protocol. The adenovirus vector was infused over 90 seconds through subselective catheters into all major patent coronary arteries and grafts, 40% into the right coronary distribution and 60% into the left coronary distribution. Repeat treadmill exercise tests were performed at 4 and 12 weeks posttreatment.

The increase from baseline in treadmill exercise duration at weeks 4 and 12 was greater among patients receiving 10^{10} v.p. Ad5FGF-4 than among those receiving placebo (the difference at week 4 was statistically significant) (Figure 7.1-8) [52]. Analysis of the subgroup of patients with a baseline ETT time of <10 minutes showed the gene therapy produced a statistically significant increase in exercise capacity compared with placebo at 12 weeks (27% vs. 12%; $p = 0.01$).

The Phase 2 AGENT-2 Trial. AGENT 2 was designed to assess whether Ad5FGF-4 improved myocardial perfusion in patients with stable angina. It was also designed to further evaluate safety. Based on the results of the AGENT trial, a dose of 10^{10} v.p. was selected. The primary endpoint was the change in stress-related (adenosine-induced) reversible perfusion defect size (RPDS) as assessed by single-photon emission computed tomography (SPECT), 8 weeks after treatment [52].

A total of 52 patients underwent double-blind randomization (35 to Ad5FGF-4, 17 to placebo). Total perfusion defect size (PDS) at baseline was 32% and RPDS was 20%.

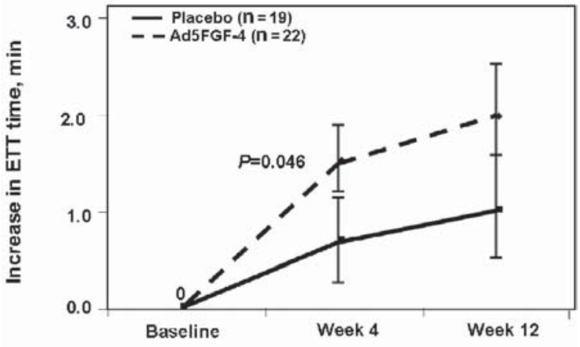

Figure 7.1-8. AGENT Trial ETT Results. Mean (± SEM) change in total exercise treadmill test (ETT) time for patients at 4 and 12 weeks after intracoronary infusion of 10^{10} v.p. of Ad5FGF4 (n = 22) or placebo (n = 19).

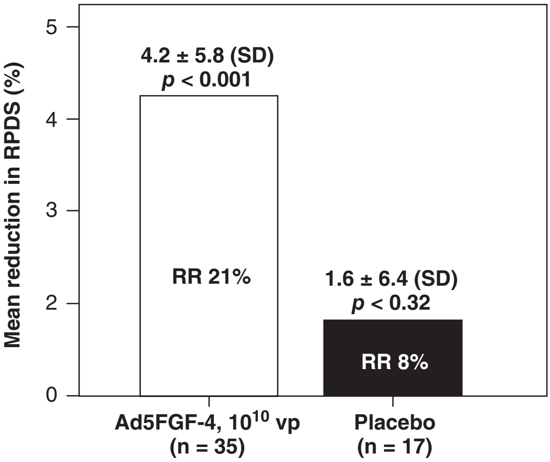

Figure 7.1-9. AGENT-2 Trial Perfusion Results. Mean change in reversible perfusion defect size (RPDS) compared with baseline for all active (n = 35) and placebo (n = 17) patients at 4 and 8 weeks after intracoronary infusion of Ad5FGF-4 (10^{10} v.p.) or placebo. RR = relative reduction in RPDS compared with baseline. (Reproduced with permission from Elsevier.)

The mean reduction in RPDS from baseline at 8 weeks posttreatment in the Ad5FGF-4 group was 4.2 ± 5.6% ($p < 0.001$), a 21% decrease from baseline, versus a reduction in the placebo group of only 1.6 ± 5.4% ($p = 0.32$), corresponding to a decrease of 8% from baseline (Figure 7.1-9). Similar results were observed for the change in total PDS from baseline at 8 weeks posttreatment: Ad5FGF-4 decreased total PDS by a mean of 4.6 ± 5.6% ($p < 0.001$) compared with a reduction of 2.4 ± 6.5% with placebo (p = NS).

More of the patients who received the active product than those who received placebo reported complete resolution of angina (30% vs. 13%) and no nitroglycerin use (43% vs. 17%) at 8 weeks. In addition, the incidence of worsening/unstable angina and revascularation by coronary artery bypass grafting or angioplasty at 12

months was considerably lower in the Ad5FGF-4 group (6% and 6%, respectively) compared with those in the placebo group (24% and 16%, respectively).

Safety in AGENT and AGENT 2 Trials. In the AGENT and AGENT-2 trials combined, a total of 131 patients (95 on Ad5FGF-4 and 36 on placebo) were treated and followed for 12 months. Overall, Ad5FGF-4 was well tolerated. There was no rise in cardiac enzymes, electrocardiographic change, or clinical evidence of myocarditis associated with the treatment [52, 53].

Vector distribution after intracoronary administration was examined in the AGENT trial [52]. Adenovirus could be detected by endpoint dilution infectivity assay in the pulmonary artery during intracoronary infusion and in peripheral venous blood 1 hour later. The frequency of positive samples increased with increasing doses of Ad5FGF-4 (Figure 7.1-10). Virus was not detected in the urine collected over 6 hours after treatment. Neutralizing antibody titer to Ad5 increased in most patients, but no FGF-4 protein was detected in the circulation at any time. Semen samples (n = 8) were tested by PCR (8 weeks posttreatment) and found to be negative for Ad5FGF-4 DNA. Ad5FGF-4-related adverse effects included dose-related transient fever (n = 8[8%]) and transient increase in liver enzymes (n = 3 [3%]).

Overall, the safety profile was reassuring and consistent with safety data in other cardiovascular adenoviral gene therapy trials [65, 66]. There was no evidence of myocarditis, retinal neovascularization, or angioma formation.

The positive trend toward efficacy and the safety observed in these two trials were in good agreement with the preclinical safety and efficacy data obtained in pigs, and they provided the basis to progress the clinical development to larger, multinational phase 2b/3 trials (AGENT-3 and AGENT-4), the results of which will be reported in the future.

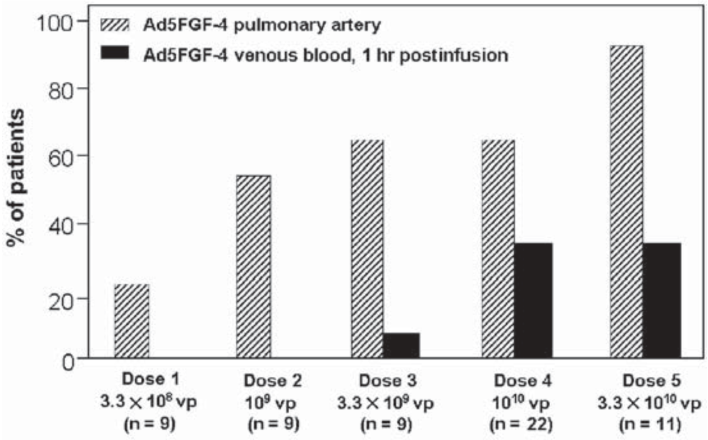

Figure 7.1-10. AGENT Trial Virus Distribution. Detection of adenovirus in the pulmonary artery during intrcoronary infusion and in venous blood at 1 hour after infusion in patients treated with increasing doses of Ad5FGF-4 in the AGENT trial (n = 60). 7.1.3.5 Lessons Learned from Past Failures

The remarkable clinical safety observed in most cardiovascular gene therapy trials to date [52, 53, 65, 66] is of no coincidence. Lessons learned from past failures at the manufacturing, preclinical efficacy and safety, and clinical development levels were all taken into account in the development of Ad5FGF-4.

Failures were due primarily to two factors: safety issues and lack of clinical efficacy.

The tragic death of Jesse Gelsinger at the University of Pennsylvania treated with a very high dose (>10 e13 vp) of a first-generation adenoviral vector raised the issue of dose and innate immune response. We learned that side effects of Ad5 are dose dependent, which follow a so-called "elbow" shape (i.e., no effect up to a certain dose and severe effects at the next dose). Therefore we have tested the dose-response relationship of efficacy, biodistribution, side effects, and toxic effects very thoroughly in our preclinical models, and we chose the doses of10e9 and 10e10 vp (more than three orders of magnitude lower than the dose used in the "Gelsinger" case).

Another gene therapy clinical trial that led to serious side effects was the SCID trial in France, where several of the children treated developed leukemia. These later were attributed to retrovirus integration at a site in the genome, which led to significant clonal expansion of the treated lymphocytes. Therefore, the choice of vector could be of great importance. In our product candidate, we intentionally avoided the use of integrating vectors (e.g., retrovirus, lentivirus, and AAV). As relatively short-term and transient gene expression is sufficient for therapeutic angiogenesis, we did not need to use these integrating vectors.

Both the "Gelsinger" case and the "SCID Trial" intensified regulatory scrutiny, which served the field very well. Small (mostly physician sponsored) trials using poorly characterized material are not allowed anymore. Both the FDA and the European Regulatory Agencies require well-controlled cGMP Manufacturing to be in place before clinical testing can start.

The recent failure of Hemofilia B trials due to lack of efficacy raised other important issues. All animal tests using the AAV.fIX product showed positive results from mouse to subhuman primates. The lack of efficacy in humans is now attributed (at least in part) to a memory T-cell mediated immune response against the AAV vector, which is absent in animals. However, no human-specific immune response to Ad5 vectors has been identified to date.

7.1.4 CONCLUSIONS

The progress of gene therapy in the past 17 years has been slower than was expected, which is due to several factors. Gene therapy is a pioneering new therapeutic modality based on complex biological systems occurring at the leading edge of biomedical knowledge. Incomplete knowledge of the genes involved in the pathomechanism of diseases constitutes a limit to generate clinically effective gene therapies, especially in complex diseases with multiple interacting genetic and environmental factors. Stringent and time-consuming safety studies are needed as is the establishment of new regulatory frameworks essential to control the applications of gene therapy and ensure safety to the patient and the population at large.

High costs are involved in the R&D of gene therapy and complex issues of intellectual property and commercial rights need to be resolved.

Despite the early high exceptions and the subsequent setbacks, one has to recognize that this new therapeutic modality is still in its infancy. It will neither deliver medical "miracles" (as its early proponents predicted) nor will it "disappear" because of a few disappointing setbacks (as some of its recent antagonists predict). As with all new technologies, gene therapy has to run its course in its current "development phase" before it reaches "maturation," when its full potential will be exploited.

7.2.1 NONVIRAL CODING NUCLEIC ACIDS: DEFINITION AND CHARACTERISTICS IN RELATION TO POTENTIAL THERAPEUTIC USE

7.2.1.1 Historical Overview

Extracted from the nucleus of human cells in the kitchen of Tübingen's castle (Germany), Nuclein is an heterogeneous product that was introduced in 1868 by Friedrich Miescher (1844–1895). Miescher's pupil, Richard Altmann (1852–1900),

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.
Copyright © 2007 John Wiley & Sons, Inc.

further fractionated Nuclein and isolated in 1889 the substance that he named "nucleic acids." These molecules were characterized by Albrecht Kossel (1853–1927, winner of the Nobel Prize for Medicine in 1910). Kossel used chemical hydrolysis of nucleic acids to identify their basic components: the nucleotides. Five nucleotides are found in the Nuclein: two purines [adenylic acid (A) and guanylic acid (G)] and three pyrimidines [cytidylic acid (C), uridylic acid (U), and thymidylic acid (T)]. In 1910, Kossel could also distinguish between two families of nucleic acids present in Nuclein: one is degraded at high pH and contains A, C, G, and U; one is resistant and contains A, C, G, and T (Figure 7.2-1). The precise chemical structure of the nucleotides was deciphered by a student of Kossel: Phoebus Levene (1869–1940) together with Walter Abraham Jacob (1883–1967) in 1929. These researchers found that nucleotides consist of a nitrogen base (Adenine, Guanine, Cytosine, Thymine, or Uracile), a sugar (pentose), and a phosphate group. They also found that nucleotides are linked linearly in the order of phosphate-sugar thanks to phosphodiester bonds. This way, they generate a polymer with a phosphodiester backbone. The pentose in the high-pH-sensitive nucleic acid is a ribose, whereas in the high-pH-resistant nucleic acid, it is a 2′-deoxyribose. Based on this chemical difference are the names of the two nucleic acids: RNA for

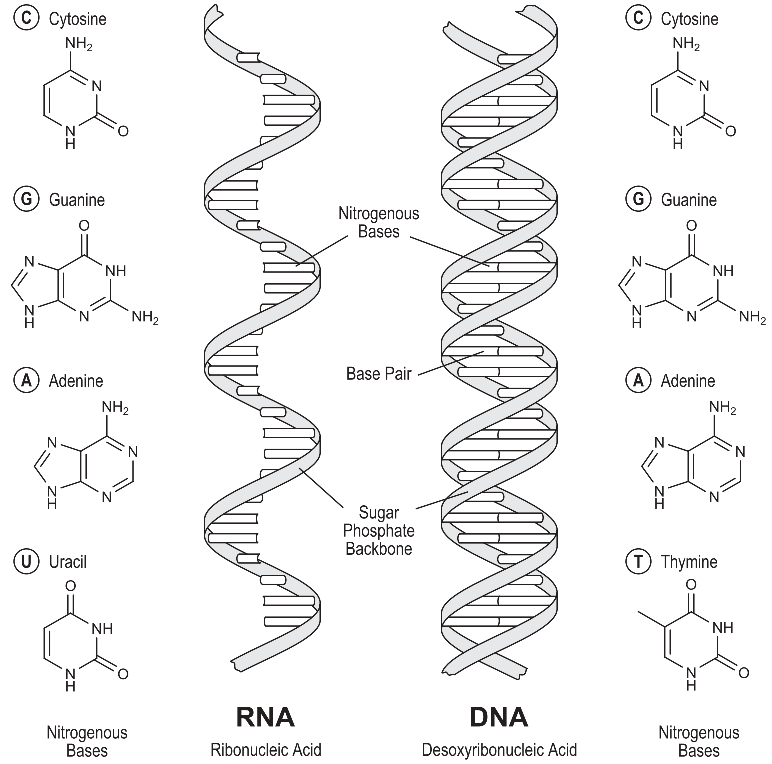

Figure 7.2-1. Structure of DNA and RNA molecules. The structure of the four nucleotides that compose RNA (on the left) or DNA (on the right) is shown. The representation of linear RNA and DNA molecules is shown in the middle. Actually, RNA makes a secondary structure through intra-strand base pairing (not shown).

the ribo-nucleic acid and DNA for the deoxyribo-nucleic acid. Although the Nuclein contains RNA and DNA, the cytosole of cells was shown by Tornbjörn Caspersson (1911–1998) and Jean Brachet (1909–1988) to contain only RNA. In 1953, Jim Watson (1928–), Francis Crick (1916–2004), and Maurice Wilkins (1917–), who received the Nobel Prize in 1962 for their resolution of the structure of DNA, demonstrated that, thanks to specific hydrogen bonds between their base moieties, nucleotides are complementary: A pairs with T or U using two hydrogen bonds and G pairs with C using three hydrogen bonds. Helped by the x-ray photograph of DNA (called photograph 51) obtained by Rosalind Franklin (1920–1958), they proposed that DNA is a molecule with two antiparallel strands shaped in a regular helix of a 2 nm diameter and 3.4 nm step (10 nucleotides for one turn) with its phosphodiester backbone on the outside and the bases on the inside of the helix (Figure 7.2-1). One year earlier, in 1952, Alfred Hershey (1908–1997, Nobel Prize winner in 1969) and Martha Chase (1927–2003) demonstrated using T2 phages that DNA is the genetic material in bacteria. There results confirmed the conclusions of Oswald Theodore Avery (1877–1955) who showed in 1943 that the "transforming principle" that can modify *Pneumococcus*'s phenotype from "smooth" to "rough" is DNA. By deduction and because of the location and behavior of DNA in eukaryotic cells, it was admitted, before being experimentally demonstrated, that DNA is the genetic material in higher organisms as well.

Meanwhile, the characterization of the cytosolic RNA-rich granules called ribosomes and identified by Albert Claude (1898–1983, Nobel Prize in 1974) indicated that RNA is involved in protein synthesis [1, 2]. Such a function of RNA was first hypothesized by Torbjoern Caspersson (1910–1997) and Jean Brachet (1909–1998) at the end of the 1930s and was then based on the relation between the RNA content of cells and their activity (proliferation). Ribosomes contain ribosomic RNA (rRNA) and are the site of protein production. The key intermediate between nucleic acids and proteins is the hybrid aminoacyl-RNA molecule called transfer RNA (tRNA) identified in 1958 [3]. It consists in a family of at least 20 members in any organism. A tRNA is a short (between 75 and 85 nucleotides) RNA molecule linked at its 3′ end to one amino-acid [4, 5]. Finally, the identification of an unstable RNA called messenger (mRNA) [6, 7] which is a copy of genes to be translated into proteins completed the basic description of the fundamental protein machinery. It is summarized in Crick's central dogma of molecular biology (Figure 7.2-2): DNA contained in the nucleus is transcribed into (messenger) RNA, which is translated into proteins [8]. Since the formulation of this central dogma, the molecular mechanisms involved in these processes have been characterized in detail. Of interest, we now know that the transient nature of all RNA molecules compared with DNA is not due to the chemical structure difference (in cells, pH are neutral or acidic: DNA and RNA are practically equally stable at the chemical level) but due to the abundance inside and outside the cells of potent and stable ribonucleases (RNases). We have also learned that RNA has more functions than initially postulated: It can replace DNA as genome in viruses and eventually (i.e., in retroviruses) be reverse transcribed into DNA. Moreover, several types of RNA molecules with various biological activities (structure, enzyme activities, containment of gene information) are involved in each step of gene expression (see Section 7.2.1.3). Nowadays, thanks to the molecular biology methods, we can also introduce designed foreign DNA and RNA molecules into cells (Figure 7.2-2). As proposed by Crick

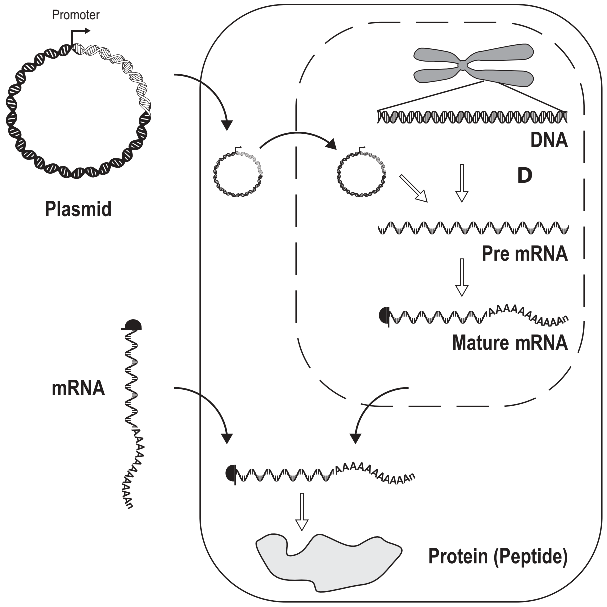

Figure 7.2-2. Central Dogma. The genes located on the chromosomes are transcribed into mRNA, which is exported from the nucleus to the cytosole where it is translated. Thanks to molecular biology techniques, it is possible to bring exogenous genetic information. Foreign DNA molecules must cross two membranes: the cytoplasmic and the nuclear envelopes, whereas mRNA must cross only the cytoplamic membrane to be active.

et al. in 1961, through a genetic code based on three letters (three consecutive bases: a codon), the nucleic acid information copied from the DNA genome into mRNA is translated in proteins. Each possible codon ($4^3 = 64$ possibilities) corresponds to one precise amino acid. This genetic code is universal: It is conserved between all living organisms. As there are only 20 amino acids, most of them are encoded by more than one codon. Some codons are favored (more frequently found in highly expressed genes) in a species-specific manner. For example, alanine, which is encoded by four codons would be preferably encoded by GCA in *Bacillus subtilis*, by GCC in *Homo sapiens*, by GCG in *Escherichia coli*, and GCT in *Saccharomyces cerevisiae*. The correspondence between codons and amino acids, i.e., the fundamental translation process, is performed by specialized enzymes called aminoacyl tRNA synthetases. There are at least 20 different aminoacyl tRNA synthetases in any organism. Each is responsible for loading one amino acid on the adequate tRNA(s). By transferring a specific amino acid on a specific tRNA, which has the adequate anticodon (complementary to the codon in the mRNA), aminoacyl tRNA synthetase convert genetic information (nucleotides) into protein information (amino acids).

7.2.1.2 DNA: The Stable Genetic Information Store

In eukaryotic cells, DNA molecules are located in the nucleus. During the interphase (between two cell divisions) of the cell cycle, DNA molecules are packed by histones into an heterogenic structure called the chromatin. Through intense con-

densation of the chromatin, each DNA molecule can be visualised as a chromosome during mitosis or meiosis. A human cell contains 23 pairs of DNA molecules that consist altogether ca. 3.15×10^9 bases. These molecules stretched would represent altogether a ca. 2-m-long chain. They have a stable nucleotide sequence that is eventually modified only at the ends (the telomeres). At this location, an inducible ribo–nucleo–protein complex that contains a reverse transcriptase (telomerase) uses a matrix RNA molecule to elongate the DNA molecules with a repetitive sequence motif. In proliferating cells not expressing the telomerase, the telomeres shorten at each division due to incomplete replication of DNA molecules at their extremities. Below a certain size of the telomeres (the Hayflick limit), the cell undergoes senescence and starts a self-destruction program (apoptosis). Thus the shortening of telomeres at each replication cycle is a method to "date" a cell: to know how many times it divided. For cells that need to proliferate (germ and stem cells, for example), the telomerase complex is induced and maintains or extends the telomeres' length, keeping the cell "young." Aside from the telomeres, the sequence of the chromosomic DNA molecules is unmodified in healthy cells. However, genomic DNA molecules have a dynamic structure in constant reorganization and modification: Methylations of residues, condensation into a closed chromatin configuration, opening into an accessible chromatin configuration, or changes of the double-helix structure (A, B or Z) can affect the availability of the DNA sequences for gene expression. Several important conserved sequences define a functional DNA stretch. Many of them have a role that is not yet characterized. Only ca. 2% of the human genome is functionally identified as being genes. These entities are characterized by a promoter that is the starting point of mRNA transcription. Promoters are recognized by the RNA polymerase II (the RNA polymerase responsible for the production of mRNA in eukaryotes). They have a minimal core sequence of a few nucleotides [usually a "TATA(A/T)A (A/T)" sequence called a TATA box or Hogness box], 19 to 27 bases upstream of the initiation site of the mRNA. The TATA box is usually surrounded by G- and C-rich sequences. Its efficacy largely depends on upstream proximal control sequences. The so-called "CAAT Box" (consensus GG(C/T)CAATCT) and "GC box" (consensus GGGCGG) enhance the activity of the promoter, i.e., its utilization by the RNA polymerase II. Distal upstream and downstream sequences called "Enhancers" also impact the activity of the promoter. An efficacious promoter in eukaryotic cells requires ca. 100 bases upstream from the TATA box. Highly specialized promoters such as "Locus Control Regions" that also affect the local chromatin structure and keep it in an opened configuration can increase the efficacy of transcription. Downstream of the promoter is the transcribed sequence that is segmented between exons (sequences that will be present in the cytosolic mRNA) and introns (sequences that will be spliced-out from the neo-transcribed mRNA in the nucleus). Transcription of mRNA stops at a transcription stop signal, which is usually a U-repeat. Before it leaves the nucleus, the immature mRNA is further processed as described bellow.

7.2.1.3 RNA: The MultiFunction Molecule

As opposed to DNA that has a well-determined unique function that is to stably store the genetic information, RNA is a pluri- (or even omni-)potent molecule.

RNA molecules can have all functions of leaving: storage of genetic information, enzymatic activity, and construction of defined three-dimensional structures. RNA is the only biomolecule that has all of these activities. Thus, it was proposed as the primordial macromolecule that, on its own, started the concept of life 4.2 billion years ago [9].

Structure-related Functions (rRNA, tRNA, aptamers). Because of its single-stranded nature, RNA refolds according to the most thermodynamically favored base-pairing. This way, it generates stem loops which position each other into complex three-dimensional structures. It is still hard to predict the dominant structures that will adopt a precise RNA sequence, but several algorithms can help in predicting them (see www.bioinfo.rpi.edu/applications/mfold/rna/form1.cgi).

The sequence-dictated three-dimensional conformation of an RNA molecule is essential in the functionality of several RNA types: The ribosomic RNAs fold into structures that scaffold the ribosomes, and the tRNAs fold into defined structures that allow their recognition by both amino-acyl tRNA synthetase and ribosomes. In both cases, some nucleotide sequences that remain single stranded are involved in the enzymatic processes performed by the molecules. Thus, the sequence of an RNA dictates its structure and allows it to perform its function. Both are strictly connected. One single mutation in a rRNA or a tRNA may completely change the favored three-dimensional structure of the molecule and totally impair the RNA's function(s).

The scaffolding characteristic of RNA molecules is used in drugs under the generic name of aptamers. Selected for their capacity to interact precisely with a target structure similarly to the antibody–antigen interaction, aptamers can specifically bind to any molecule or complex of interest. The first pharmaceutical aptamer is Macugen™ (Eyetech Pharmaceuticals, Inc., and Pfizer, Inc.). It recognizes and neutralizes specifically the vascular endothelial growth factor, thus inhibiting pathologic blood vessel growth. It is used as treatment against age-related acute macular degeneration.

Regulation of Protein Expression-related Functions (antisense, siRNA, miRNA). Small RNA molecules of ca. 20 nucleotides in length can remain linear with all their bases available to pair with a complementary sequence present on another RNA molecule. Such "antisense" RNA oligonucleotides can this way impair the function (block translation) of mRNA. Another type of short RNA molecules of ca. 20 nucleotides in length is double stranded and has two bases overhangs. It is called small inhibitory RNA (siRNA) when naturally produced in the cytosole out of foreign double-stranded RNA molecules or micro-RNA (miRNA) when encoded in the DNA genome. Through its recognition by a proteic complex called RISK, one strand is discarded (the sense strand) and the other strand (the antisense) is used as a guide to direct RISK to a complementary sequence in a mRNA and induce a cleavage on this target molecule. Thus, siRNA or miRNA are a catalytic version of antisense RNA: one molecule can inhibit (induce the degradation of) many mRNA. Some miRNAs can also modify the DNA sequence in the promoter region by inducing methylations. This way, they dictate the level of packaging into the chromatin and the expression of a gene. For more information on small RNA molecules as regulators of gene expression and their use as therapeutics, refer to Chapter 7.6.

Enzymatic Functions (ribozymes). Through a fixed three-dimensional structure and the availability of certain nonpaired residues, RNA molecules can fold into enzymes called ribozymes. The evidence of such an enzymatic capacity of RNA was discovered by Altmann [10] and Cech [11]. It was acknowledged with a Nobel Prize (Chemistry, 1989). Initially, this enzymatic activity was restricted to the capacity of ribozymes to recognize and cleave or religate in an autonomous way a target RNA (mRNA) sequence. Later, other enzymatic capacities of ribozymes were evidenced: Selected ribozymes can catalyse the synthesis of nucleotides [12] or the creation of amide bonds [13].

Coding Functions (mRNA). The pre-messenger RNA produced by transcription of the genomic DNA is processed before leaving the nucleus: Splicing of introns is made by spliceosomes that are ribo–proteic complexes. Within these structures, the RNA provides the sequence specificity of the spliceosome's activity. An exon does not have any sequence recognized by the spliceosome. It is the intron, and its borders that are recognized and excised. Evolutionarily, introns may derive from movable genetic elements called transposons. Thus, theoretically, introns can be introduced naturally (through evolution) or experimentally (thanks to molecular biology methods) within any coding sequence. They present the advantage that they enhance the efficacy of gene expression, probably through the facilitation of mRNA export to the cytosole. Moreover, thanks to regulated alternative splicing mechanisms, some specific exons may be spliced out with flanking introns. Such alternatively spliced mRNAs encode proteins with missing domain(s) and thus with different function(s). Meanwhile, the deregulation of the splicing mechanisms in dysfunctional cells, such as tumor cells, may allow introns to remain in the mature mRNA. Then, a protein with an extra domain and eventually truncated (if the intron contains a stop codon in the frame of translation) is generated. Aside from being spliced, the immature mRNA is also capped at its 5′ end (the addition of a methylated guanine followed by three phosphates bonds) and poly-adenylated at its 3′ end (the addition of several hundreds of adenine residues). The spliced, capped, poly-adenylated mRNA is exported to the cytoplasm through nuclear pores. In the cytosole, several elongation initiation factors recognize the Cap structure, whereas the poly-A binding protein binds to the 3′ poly A tail. These proteins allow the ribosomes to bind to the mRNA and start to scan from the 5′ end the nucleotide sequence until it finds a start codon (ATG) in a "Kozak" surrounding (A/GNNNAUGG). At this location, the first amino acid, always a Methionine, is brought by a tRNA that has the 5′ CAU 3′ anticodon. Then, the ribosome translocates toward the 3′ end to the next codon where an adequate tRNA will bring the second amino acid encoded by the gene. The process continues toward the 3′ end of the mRNA and stops when the ribosome meets a UGA, UAA, or UAG "termination" codon. The neosynthesized protein and the ribosomes are then released. Several ribosomes are sitting on one mRNA. According to its stability and efficacy of translation, one mRNA can produce many proteins. Ultimately, the mRNA is degraded by intracellular RNases. This catabolic process is highly regulated: Several sequences in the mRNA, and especially at its ends, before and after the coding sequence (UnTranslated Regions: UTR), have primary and secondary structures that are recognized by specific proteins in the cytosole. Those proteins may induce or, on the contrary, prevent the detection and degradation of the mRNA by the intracellular RNases, which are in general exonucleases [10].

This means that they degrade the mRNA starting by the 5′ or 3′ ends. Both ends are protected in the mature mRNA: the Cap on the 5′ and the poly-A tail covered by the poly-A binding proteins on the 3′. Specific and regulated mechanisms of decapping and deadenylation will render the mRNA accessible to the exonucleases. Accelerated degradation (shortening mRNA half-life) can be induced by the presence of AU-rich sequences called AUREs in the 3′ UTR, or by the presence of a specific restriction site. This latter possibility is illustrated by the regulation of iron metabolism: An iron-induced endoribonuclease recognizes a sequence present in the mRNA coding for the transferrin receptor (TfR) that is responsible for iron-loaded transferin uptake. The presence of high iron stocks in the cell induces the endonuclease, which cleaves the TfR-encoding mRNA. Thus, it prevents TfR expression and further iron uptake. Inhibition of mRNA degradation (increasing mRNA half-life) involves other untranslated sequences as illustrated with the very stable globin mRNAs: They contain in their 3′ UTR, pyrimidine-rich sequences that are recognized by a ubiquitous protein complex called the alpha-complex. It stabilizes the poly-A binding proteins associated with the poly-A tail and secures the integrity of the 3′ end of the mRNA, thus increasing the half-life of the whole RNA molecule. Depending on the presence of stabilization and destabilization sequences in its UTRs, its length, structure, and efficacy of translation, the intracellular mRNA can have a half-life varying from minutes to weeks [11]. Outside the cells, naked mRNA are degraded within seconds because of the abundant, ubiquitous, stable, and processive extracellular RNases [14]. The presence of such an efficacious machinery to degrade extracellular RNA may have been developed as a protection against viruses, especially those with RNA genomes. It may also control the secretion and recapture of RNA by neighboring cells, which is hypothesized to represent a way for cells to communicate [15].

7.2.1.4 Recognition of Nucleic Acids by Immune Cells

In eukaryotic cells, DNA is strictly in the nucleus and in energy-producing sub-compartments (mitochondria and chloroplast), whereas RNA is strictly in those same compartments plus the cytosole. In healthy situations there is no nucleic acid in the endoplasmic reticulum, golgi apparatus, endosomes or lysosomes, and associated vesicles. The immune system developed the tools to scrutinize for the presence of nucleic acids in those compartments because it would be associated with a pathogenic situation such as the presence of an infectious agent. A family of receptors similar to immunity-related receptors from flies called Tolls receptors is dedicated to the detection of such "danger signals." This family of Toll-like receptors (TLRs) contains 11 known members. Four of them were shown to recognize nucleic acids: TLR3 is specific for double-stranded RNA (dsRNA), TLR7 and TLR8 recognize single-stranded RNA (ssRNA), and TLR9 recognizes an unmethylated DNA pattern ("CpG motif") that is found specifically in the genome of microorganisms such as bacteria (Figure 7.2-3). These four receptors are located in the lumen of cytoplasmic vesicles (mainly endosomes) in immune cells like B cells, NK cells, granulocytes, macrophages, or dendritic cells (DCs). TLR3, 7, and 8 detect the infection by viruses such as influenza (dsRNA genome) or HIV (ssRNA genome), whereas TLR9 signals the presence of bacteria in the endosomes. Upon engagement of TLRs, immune cells are activated. They trigger an adaptive (involving T

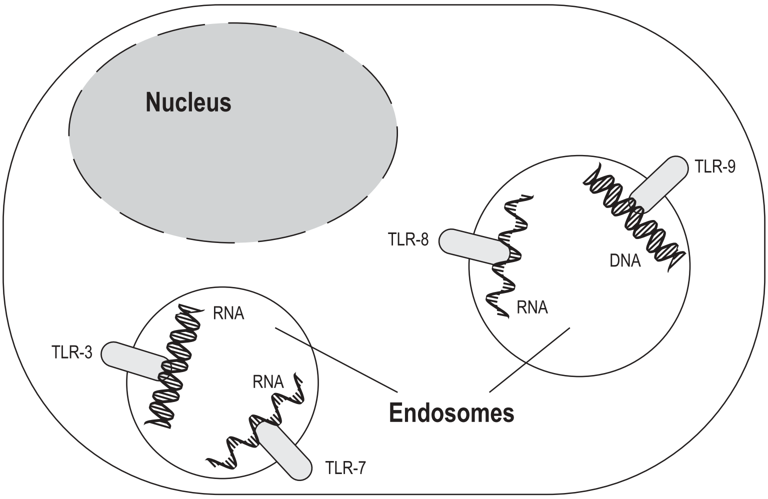

Figure 7.2-3. Recognition of nucleic acids by TLR. TLR 3, −7, −8, and −9 are located in the endosomes and recognize dsRNA (TLR3), stabilized ssRNA (TLR7 and TLR8), and bacteria DNA (TLR9).

and B lymhocytes) immune response specific for the antigens associated with or encoded by the foreign nucleic acid(s). This natural immune detection of exogenous nucleic acids is an advantage for the utilization of these molecules in vaccines but a disadvantage for the utilization of nucleic acids in gene therapy.

7.2.1.5 Production of Plasmid DNA and Messenger RNA

Plasmid DNA. Plasmid DNA (pDNA) are small (from 2 to 15 kb) circular DNA molecules that contain a bacterial origin of replication. They can proliferate within a bacteria and represent up to 1% of the microorganims's mass. They are manipulated to code for a protein that neutralizes an antibiotic. Moreover, they can contain any desired sequence, such as for example a promoter, a gene from bacterial or non-bacterial origin, and a poly-adenylation signal. Plasmids are purified from bacteria grown in the presence of the antibiotic that they can neutralize. This guarantees that the bacteria will conserve and amplify their plasmids during fermentation. Frequently, the antibiotic is ampicillin, which is deactivated by the protein β-lactamase encoded by many standard plasmid vectors. The bacteria are pelleted, usually by centrifugation, and cells are lysed, usually thanks to sodium dodecyl sulfate (SDS) and sodium hydroxide. After neutralization with potassium acetate, most proteins and the genomic DNA precipitate while the plasmids remain in the aqueous phase. Several methods exist to purify pDNA from these solutions, but the most commonly used is anionic exchange chromatography (see, for example, the protocole by Qiagen at www.qiagen.com). Protocols are available to eliminate most lipopolysaccharides coming from the bacteria and that may affect the functionality of the pDNA for therapeutic utilizations. However, standard purification methods will provide the pDNA with three topologies: Most is supercoiled circular DNA, but some is in the form of a relaxed circle (one strand has at least one nick) or linear (both strands were broken at the same place). The

supercoiled plasmid is the form that should be used for research and therapy because, based on *in vivo* transcription studies, it is the most active form [16, 17]. Although the nicked pDNA molecules are most often not strongly affecting the functionality of the plasmid *in vitro* or *in vivo*, it is custom to use pDNA with a low amount of these topologies for preclinical and clinical utilizations. At laboratory scale, the purification of the supercoiled pDNA can be obtained using caesium chloride gradients. For larger scale and clinical trials, specialized companies offer the production of high-quality pDNA for research and therapy [Good Manufacturing Practice (GMP) certification; see, for example, plasmid factory at www.plasmidfactory.com]. One liter of bacteria culture can yield up to 30 mg of pDNA.

Messenger RNA. Messenger RNA are produced from purified pDNA using bacterial RNA polymerases in a reaction called "*in vitro* transcription." The pDNA used for *in vitro* transcription must contain a specific promoter recognized by the bacteriophage RNA polymerases T3, T7, or SP6 in front of the coding sequence of interest. It is linearized using a unique restriction site that must be at the end of the sequence to be transcribed. Then, the linearized plasmid is mixed with the RNA polymerase and the four nucleotides plus, in standard reactions, an excess of Cap analog (m7G(5′)ppp(5′)G) compared with GTP. Usually the Cap analog is at ca. 6 mM in the reaction; ATP, UTP, and CTP are at 4 mM; and GTP is at 1.5 mM in the final reaction. The RNA polymerase synthesizes more than 100 mRNA molecules from one pDNA template. After the synthesis of the mRNA, 1 hour at 37°C, the DNA is destroyed by a DNase and the mRNA is recovered by precipitation, usually with lithium chloride. Afterward, the mRNA is resuspended in the adequate solution.

7.2.1.6 Packaging of Nucleic Acids for Therapy

Although some cells in skin, muscle, brain, and so on can spontaneously take up exogenous injected naked pDNA or mRNA [18], this process is relatively inefficient and can consequently be used only when a local expression of a protein is desired, i.e., for vaccination. Even if physical methods exist to enhance the uptake of naked nuclei acids (electroporation or hydrodynamic delivery; see Section 7.2.2.2), increasing the efficacy of transfection *in vivo* is best reached using encapsulation of the nucleic acids. Two methods are used: cationic polymers or liposomes.

Polymeric Particles. Cationic polymers can spontaneously associate with the anionic nucleic acids. Such complexes can keep a positively charged surface that allows an interaction with the negatively charged cell surfaces. Commonly used cationic polymers for the production of micro- or nanoparticles include chitosan, protamine, poly-L-lysine (PLL), poly-ethylenimine (PEI), and polyamidoamine dendrimers [19]. Usually, a simple mixing of the cationic polymers and the nucleic acid, eventually with high-speed homogenization, is enough to obtain particles. Thus, production is very easy and upscalable. However, some of these cationic polymers, such as PEI or PLL, are toxic or have secondary effects (for example, chitosan induces hypocholesterolemia). Moreover, particles generated by simple

mixing of nucleic acids and cationic polymers may be very heterogenous in size and physical properties, making them hard to qualify for pharmaceutical use. A more controlled method to produce particles is based on poly(lactide co-glycolide) (PLG). It is a biodegradable and biocompatible molecule used for several biomedical products including sutures. As it is a negatively charged molecule, it needs to be mixed with cationic polymers such as those listed above or chemical products [cetyltrimethylammonium bromide (CTAB), dimethyl dioctadecyl ammonium bromide (DDA), or 1,2-dioleoyl-1,3-trimethylammoniopropane (DOTAP), for example]. Optimally, a mixture of several reagents allows the production of homogenous particles with a defined size (from ca. 100 nm up to μm) and surface charge (zeta potential). When using PLG, protocols based on the solvent evaporation process are used [20]. Cationic particles can be manufactured and then coated with the nucleic acid or produced in the presence of the nucleic acid. In the first case, the genetic material is on the outside of the particles, and in the second in case, it is inside. Because the production of the PLG particles involves high shear, organic/aqueous interface, high temperature, and freeze-drying, the nucleic acid may be denatured or degraded during the process. Thus, for a production that is reliable, reproducible, and easy to upscale in GMP conditions, the coating of nucleic acids on the surface of premade cationic PLG particles is preferred. In both cases, the nucleic acid associated to the particles is protected from the activity of nucleases and can be applied by injection (the particles are phagocytosed by cells) or, for vaccination, by gene-gun [21]. The release of the nucleic acid is largely determined by the nature of the polymers used for the preparation of the particles. *In vitro*, the particles may readily release quickly a significant amount of nucleic acid in the injection solution. For example, PLG/CTAB microparticles released ca. 35% of their loaded pDNA within 1 day [20]. For this reason, particles should be stored lyophilized and injected quickly after reconstitution in the injection's buffer. *In vivo*, the biodegradability of the polymers and the site/method of delivery will dictate the release of the genetic information. For some particles, the release may be performed slowly, over several days [20]. Polymers with specific degradation patterns (for example, in endosomes: at low pH) can be engineered to increase the efficacy of delivery and regulate the time frame in which nucleic acids are available for expression within the cell. Some layer-per-layer production processes allow the production of particles with several layers of nucleic acids separated by layers of polymers (see www.capsulution.de). The choice of the polymer(s) will dictate the degradation profile of the particles and thus the release of the several layers of nucleic acids. Theoretically, such a strategy allows the slow release of nucleic acids within cells over a long time.

Liposomes. Liposomes are vesicles that consist of an aqueous compartment enclosed in a phospholipids bilayer. As they lack proteinaceous components, liposomes are not immunogenic. A broad variety of cationic liposomes containing eventually modified lipids have been used to deliver pDNA and mRNA for therapeutic utilizations. These formulations are usually based on a cationic lipid such as 1,2-dioleol-3-trimethylammonium propane (DOTAP) and a fusogenic lipid such as 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine (DOPE) [22, 23]. Despite their ease of production and efficacy *in vitro* for transfecting cultured cells, cationic liposomes face toxicity issues *in vivo* [24, 25]. Meanwhile, their heterogeneous size

and instability are drawbacks for a pharmaceutical production and qualification. Moreover, cationic liposomes are often inactivated in the presence of serum. As possible improvements of cationic liposomes, immunoliposomes, which are liposomes coated with an antibody, are developed. Thanks to their targeting, they are more efficacious than classic liposomes and can consequently be administered at a lower dosage. This way, the immunoliposomes are less toxic. Another variation of liposomes are called stealth liposomes. They consist in poly(ethylene glycol) (PEG)-coated liposomes. PEG prevents adsorption of the liposomes by endothelial cells after intravenous delivery. Thus, stealth liposomes are remaining in the circulation and are distributed more homogenously through the body than classic liposomes.

7.2.2 PLASMID DNA AND MESSENGER RNA FOR THERAPY

Plasmid DNA (pDNA) and messenger RNA (mRNA) are attractive tools for therapy because they are simple molecules that are easy to produce, store, detect, and manipulate using molecular biology techniques. They can be used to quickly turn into a drug any genetic information. Alternatives to pDNA and mRNA are virus- or bacteria-derived vehicles that can contain the genetic information to be expressed as a drug. The drawbacks of these methods are as follows:

1. Safety issues: The modified infectious agents may revert to a wild-type phenotype or may recombine with wild-type viruses to produce new sorts of pathogens.
2. Specificity: Not only the gene of interest is injected into a patient but also the proteins and eventually parts of the genetic information of the pathogen. The function of these proteins may interfere with the function of the transgene (in vaccination, for example, some pathogen-specific mechanisms may interfere with the priming of the immune response against the transgene), and moreover, an immune response against the vehicle (virus or bacteria) may be dominant. Not only could this hide the response against the relevant antigen for vaccination, but it could also prevent the repeated or chronic delivery of the drug for gene therapy.

Plasmid DNA and mRNA, which are both nonviral coding nucleic acid vehicles, are minimal genetic vectors: in their human host, they express only the therapeutic protein of interest. The two main utilizations of pDNA and mRNA for therapy are as follows:

1. Vaccination using simply the gene sequences of pathogens (viruses, bacteria, parasites, or tumors).
2. Genetic complementation after the gene responsible for a genetic disease is characterized.

Vaccination is by far the most exploited feature of nonviral coding nucleic acids. This is due to

1. The fact that a local, transient expression of a foreign protein is enough to trigger an immune response.
2. The natural capacity of pDNA and mRNA to stimulate the immune system through TLR.

As the production of nucleic acids is barely affected by their sequence, generic production facilities and methods were developed to produce GMP-certified pDNA or mRNA. Several specialized bioindustries throughout the world can supply within a few weeks any nucleic acid to be used in therapy. This feature is unique because all other polymeric biomolecules used in therapy (synthetic peptides, recombinant proteins, or viruses) face more or less severe production and storage issues that are changing depending on their sequence. Thus, pDNA and mRNA seem to be the most versatile and simplest biomolecules to be used as active pharmaceutical ingredients in new drugs. Both nucleic acids were used in clinical trials and are known to be safe. Efficacy was reported, but pDNA- and mRNA-based drugs should be optimized before such treatments are available on the market.

7.2.2.1 Design and Optimization of pDNA and mRNA Vectors

Coding Sequence. As mentioned in Section 7.2.1, most amino acids are encoded by several codons, some of them being more favorable because they correspond to more abundant tRNA. Unfavorable codons or “rare” codons (as opposed to frequent, i.e., favorable codons) force the ribosome to pause during translation, and this may result in the premature ending of translation that generates abortive proteins. In any case, unfavorable codons decrease the efficacy of translation of full-length proteins. This phenomenon is particularly pronounced when the vaccine nucleic acid is a copy of a gene from a non-mammalian organism: Genes from bacteria or parasites have a codon usage very different from mammals. Moreover, some human virus genes and some endogenous human genes have an unfavorable codon usage that may be part of the mechanisms of regulation of their specific expression. For example, the HIV GAG gene has a “bad” codon usage that will limit the efficacy of gag production. This is actually important in the regulation of the virus replication’s cycle. Thus, for human genes and more importantly for nonhuman genes, a codon optimization should preferably be performed in the coding part of therapeutic nucleic acids. The design of the gene is performed starting from the protein sequence to be expressed. Through algorithms that are based on the precise human codon usage a coding sequence will be proposed that should be ideally translated by the human cell machinery. The corresponding gene is synthesized by assembly of synthetic oligonucleotides. This process has another advantage, which is to generate a totally synthetic gene that can be very well documented and consequently easily introduced in a GMP manufacturing process (see Section 7.2.2.4).

Noncoding Sequences. The nucleic acid vector can be optimized in the noncoding (untranslated) parts of the mRNA. Mainly, as mentioned in Section 7.2.1, the AURES destabilizing sequences should be deleted because they would destabilize the mRNA and limit the expression of the antigen. In general, only the coding sequence of the gene of interest should be used for constructing the therapeutic

vector; any sequence upstream of the ATG and downstream of the stop codon should be avoided. Meanwhile, stabilization thanks to 3′ UTR [26] in the form, for example, of the ca. 180 bases or ca. 80 bases UTR from the β- or α-globin genes, respectively, can be added after the coding sequence of interest (after the stop codon). Both of these sequences are recognized by the ubiquitous α-complex, which stabilizes the mRNA and enhances its translation rate. They are routinely used in the pDNA and mRNA vectors used for therapy [27–30].

Specific Optimization of pDNA Vectors. The promoter used for the expression (transcription) of the transgene offers the possibility to control the level, site, and eventually time of expression of the transgenic protein. Concerning the level of expression, strong ubiquitous promoters helped by enhancers will be adequate when a high and broad expression of the transgene is needed. However, if an expression of the transgene is expected in specific cell types, investigators can use the large panel of restricted promoters that are active thanks to cell-type-specific transcription factors. This way, the expression of the transgene can be restricted to the liver (albumin promoter, for example), lymphocytes (immunoglobulin promoter or CD2 locus control region, for example), antigen presenting cells (fascin promoter for example), and so on. The drawback of these promoters is that they may lead to a relatively weak transcription activity compared with ubiquitous promoters. The control of time of expression is a critical parameter for all pDNA-based approaches because a long-term expression may have serious negative effects on the efficacy of the treatment (immune tolerance instead of immune activation, for example) or unaccept-able side effects (overexpression of growth factors or other proteins with physiological activity that are used in gene therapy). A way to finely tune the expression of a transgene is to use an inducible promoter such as the Tet-On or Tet-Off promoters [30a]. Their activity depends on the Tet-On or Tet-Off transcription factors that must be constitutively encoded by the therapeutic pDNA construct. The Tet-On and Tet-Off proteins should be expressed thanks to ubiquitous promoters. The presence of tetracyclin or its analog Doxicyclin, which can just be added in the drinking water, will activate (Tet-On) or deactivate (Tet-Off) the transcription capacity of the Tet protein. Accordingly, it will turn ON (Tet-On) or OFF (Tet-Off) the transcription of the transgene of interest. The drawback of these systems is that they are "leaky," thus always giving a basal expression of the transgene even in conditions where it should be silenced (in the presence of Doxicyclin for Tet-off and in its absence for Tet-On).

The other functional parts of the plasmid such as the transcription termination signal, the bacterial origin of replication, and the antibiotic used for production of the plasmid do not impact the efficacy of the pDNA as a therapeutic vector. However, the antibiotic-resistance gene expressed by the plasmid when it is in a bacteria (the gene is expressed thanks to bacteria-specific controlling sequences) is relevant for the regulatory aspects (see Section 7.2.2.4). Moreover, the overall sequence of the plasmid is active at the level of immune stimulation: The more the plasmid contains unmethylated CpG immnostimulating motifs, the more it may induce signaling through TLR9 in human immune cells, and consequently, the stronger may be the priming of the immune response. Thus, for vaccination approaches, pDNA vectors should be enriched in CpG motifs, whereas for gene therapy approaches, pDNA should be depleted of such sequences.

Specific Optimization of mRNA Vectors. As mentioned, a 3′ globin (α or β) UTR at the end of the mRNA provides higher intracellular stability to the mRNA, which is of advantage whether the mRNA is the vaccine vector or a product of the vaccine vector (with pDNA vaccines as mentioned in the above paragraph). Aside from this, specific modifications of the mRNA vector are the poly-A tail and the 5′ Cap structure. Concerning the poly A tail, it should be of a minimum of 30 residues and preferably exceed 100 residues [31]. To generate the poly-A tail, there are two methods: Either it is encoded in the plasmid DNA that is used as a matrix for *in vitro* transcription or it is added by a specific polymerase (Poly(A) polymerase) at the end of the mRNA transcripts. In the first case, a A-tail can be of a maximum of ca. 120 As because more residues would titrate the adenosine triphosphate in the transcription reaction and limit its output. The other method is to submit the *in vitro* transcribed mRNA to the activity of the Poly(A) polymerase, which is a commercially available enzyme that polymerizes A residues at the 3′ end of a ribonucleic acid, in a matrix-independent manner. The enzyme can add several hundred A residues at the 3′ end of the mRNA molecules. This method is preferred to produce efficacious and stable mRNA for research purposes. However, the production of such poly-adenylated mRNA in GMP conditions is limited by the fact that the poly-adenylation process is not totally controlled and may generate heterogeneous molecules with more or less long A tails. This could make endproduct controlling, characterization of a batch, and batch-to-batch reproducibility more difficult than when the poly-A tail is encoded in the plasmid and is consequently clearly defined in length.

As mentioned in Section 7.2.1, at the 5′ end of mRNA molecules to be translated by eukaryotic cells, there is the characteristic Cap structure. It consists of a 7-methylated guanine residue linked through three phosphates to the first residue of the mRNA. A noncapped mRNA is not translated in eukaryotic cells. Not only is this structure essential for recognition of the mRNA by the translation machinery (the cap is recognized by the initiation factor 4: eIF4), but it also protects the 5′ end of the mRNA against exonucleases. Similarly to what was described for the poly-A tail, either the Cap structure is incorporated during the transcription process or it is added afterward on the *in vitro* transcribed mRNA.

In the first case, a fourfold excess of synthetic Cap analog (m7G(5′)ppp(5′)G) versus GTP in the transcription mixture guarantees that ca. 80% of the produced molecules will start with a Cap instead of a canonical G residue (the T7, T3, or SP6 promoters are made in a way that they will start transcription with a G residue). The drawback of this method is that the GTP content in the transcription reaction must be lowered compared with the other residues and thus becomes the limiting factor for the transcription. It significantly reduces the amount of recovered mRNA compared with an *in vitro* transcription reaction without Cap and with an identical concentration of all four residues. However, this method to produce capped mRNA is efficacious, fast, and reliable. Some modifications of the Cap analog can improve the efficacy of the mRNA vector: The standard synthetic Cap is a di-guanine molecule with one of its G methylated and three phosphates in-between the nucleotides. It can be incorporated at the start of the mRNA in two orientations: the methylated G being at the 5′ end or the non-methylted G at the 5′ end. Only the former situation will give a functional mRNA. Thus, statistically half of the capped mRNA molecules are nonfunctional. Strategies to avoid this phenomenon include

the anti-reverse Cap structure (ARCA) [32]. It consists in a Cap analog in which the sugar carrying the methylated guanine is modified in its 3′ position (OCH_3). Thus, the dinucleotide can be used as the start nucleotide by the RNA polymerase only in the functional orientation where the 3′OH of the non-methylated based is used to extend the mRNA. ARCA Cap enhances the functionality of *in vitro* transcribed mRNA vectors. However, ARCA Cap is relatively difficult to synthesize and consequently more costly than the standard Cap analog.

The second method for capping mRNA takes advantage of the activity of the vaccinia virus capping enzyme, also known as guanylyltransferase. This enzyme is commercially available. In the presence of GTP and S-adenosyl methionine (SAM), it can add a natural Cap structure (7-methylguanosine) to the 5′ triphosphate of a RNA molecule. As it is an enzymatic reaction, it can bring a correct Cap to all mRNA molecules, and thus, it is optimal compared with *in vitro* transcription in the presence of standard Cap but similar theoretically to *in vitro* transcription in the presence of ARCA Cap.

Because of the lack of a reliable quantitative assay to control for the presence of the Cap structure, aside from a functional assay of the mRNA expression (transfection of the mRNA in cells and detection of the translated protein), the enzymatic capping of mRNA is rarely used to produce mRNA for research or therapy. The utilization of the synthetic Cap (nonmodified analog or ARCA) in the *in vitro* transcription reaction is the standard method to produce capped mRNA.

Aside from the 5′ and 3′ ends, some internal modifications of the mRNA such as a phosphorothiate backbone or 2′ modifications of residues can be brought into the mRNA as long as the modified residues are substrate for the RNA polymerases routinely used for *in vitro* transcription (T7, T3, or SP6 RNA polymerases) and do not interfere with the translation process. It seems that only a few modifications such as phosphorothioate nucleotides and 2′ amino residues can be used [14]. However, they lower the efficacy of transcription and translation while they do not noticeably increase the stability of the mRNA toward RNases. Some more work may allow the identifications of modifications that may allow the efficacious production of mRNA, which resists extracellular RNases and remains well translatable by the ribosome. Such mRNA would be optimized compared with native mRNA for therapeutic uses.

7.2.2.2 Vaccination

Introduction. Upon entry of a pathogen (virus, bacteria, or parasite) or upon pathologic genetic modifications of a cell of the body (tumors), pathogen associated molecular patterns (PAMPs) or “danger signals” such as dsRNA or stabilized ssRNA (virus), CpG DNA or flagelin (bacteria), uric acid, or heat shock proteins (tumors), for example, are recognized by immune receptors such as TLR receptors or scavenger receptors. These activating receptors are expressed by cells of the innate immunity such as macrophages and DCs that are professional antigen presenting cells (APCs). Some PAMPs also stimulate B cells, NK cells, or NKT cells. Professional APCs loaded with a pathogen’s derived material and stimulated by the associated PAMP migrate from the site of detection of the danger signal to the draining secondary lymphoid organs such as lymph nodes and activate antigen-specific T and B lymphocytes through their clonotypic receptors: T-cell receptor

(TCR) for the former and surface immunoglobulin for the latter. There are approximately 5×10^9 T cells (ca. 70% are CD4 positive helper cells and ca. 30% are CD8 positive cytotoxic cells called CTLs) and 2×10^9 B cells in an adult human body. Generally, only a few hundred naïve lymphocytes specific for a precise antigen are available (frequency ca. 10^{-7}) [33]. Upon an encounter with the antigen-loaded activated APC, specific lymphocytes are triggered and proliferate. A lymphocyte clone may expand so much that it reaches a frequency of 10^{-2} [34]. Activated lymphocytes become armed effector cells. Armed B lymphocytes secrete the clonotypic immunoglobulin that sprays through the body, recognize its antigen, and inactivate it or target it to destruction by effector mechanisms of the innate immunity. Armed CD4-positive T lymphocytes secrete cytokines (mainly interferon-γ for Th1 cells and Il-4 for Th2 cells) that are necessary for immune cells' activity and they stimulate APCs. Armed CD8-positive T lymphocytes migrate to the site of antigen expression and kill cells expressing it. Upon disappearance of the antigen (complete elimination of the pathogen), armed effector cells disappear (contraction of the immune response) and some memory cells remain for the individual's whole life. Not only does this memory cell allow a higher number of specific lymphocytes to be present in the body at an eventual second appearance of the antigen than at the time of the primary encounter, but also memory lymphocytes have the peculiarity to react very quickly and efficiently (higher affinity of the antibodies for example). Thus, in the case of reappearance of the antigen, the neutralization of the pathogen (infectious agent or tumor cells) will be much faster than at the time of first priming. Prophylactic vaccination mimics a first contact between the immune system and a pathogen. It guaranties that, should the pathogen be present in the body, its recognition and elimination will be efficient and fast, preventing acute or chronic (persistent) disease. Therapeutic vaccination or immunotherapy aims at boosting the more or less preexisting immune response (triggered naturally by the already present pathogen), sustaining its strength (stimulating the proliferation of specific lymphocytes) and broadness (stimulating a larger spectrum of lymphocytes specific for the pathogen) to enhance its efficacy. As shown for several pathogens such as for example, Hepatitis B Virus (HBV), Human Immunodeficiency Virus (HIV), or tumor, a strong immune response against the pathogen is associated with a better control of the disease. High morbidity and mortality is often due to a weak immune response against those pathogens. Thus, immunotherapy aims at enhancing the natural capacity of the immune system to help control the pathogens. Another type of vaccination is used to shift or tolerize a preexisting pathologic immune response: in allergies or autoimmune diseases. Those immunotherapeutic regimen allow the manipulation of a preexisting immune response to render it armless.

Nucleic Acids for Vaccination. In all cases where the antigen of interest is a protein, nucleic acids can be used as a method to vaccinate. An adequate pDNA or mRNA vector can be produced *in vitro* (see above Section 7.2.2.1), formulated for the delivery (see Section 7.2.1.6) and eventually co-injected with an adjuvant in the form of a danger signal or cytokine. The local expression of the foreign nucleic acid-encoded protein associated with the local activation of innate immunity will trigger a T- and B-lymphocyte-mediated antigen-specific immune response that can protect against a challenge with the pathogen (infectious agent or tumor cell)

that expresses this protein. It can also modify an existing pathologic immune response (autoimmunity, allergy) to render it armless. Both pDNA- and mRNA-based vaccines were reported to be capable of inducing humoral and cellular immunity (review by Liu and Ulmer for pDNA [35] and Pascolo for mRNA [36]). The particularly advantageous feature of this vaccination technique is that because antigens are made by the cells of the body, their epitopes are presented on major histocompatibility complex (MHC) I molecules and a CTL response is generated. Other vaccine methods based on proteins or inactivated infectious agents do not usually efficiently induce CTL. These cells are particularly relevant for antivirus, anti-intracellular pathogen and antitumor immunity. Thus, nucleic-acid based vaccines are theoretically very attractive modalities in the context of these pathogens.

It is usually accepted, although not firmly demonstrated, that the stronger is the transgene's expression (the highest is the amount of produced antigen), the better is the triggering of the immune response. Thus, enhancing the injected nucleic acid's translation (see 7.2.2.1) is a common method for improving the efficacy of nucleic acid-based vaccination. Improving the efficacy of the processing and presentation of the coded antigen was also reported to strongly impact the vaccine's potential (see below). However, of foremost importance is probably the site of delivery, the formulation, and the used adjuvant, which have a very strong and documented impact on the efficacy of the pDNA- or mRNA-based vaccines.

Optimization of the Antigen Processing and T-cell Priming. When the antigen encoded by the nucleic acid is to be recognized by T lymphocytes, its derived peptide epitopes must be efficaciously presented by MHC class I or class II molecules. Although any cytosolic, membrane or secreted protein can be used to produce MHC I and MHC II associated epitopes, several methods to enhance this presentation were described.

For augmenting the presentation by MHC I molecules, a sequence coding for ubiquitin can be inserted at the beginning of the gene. The produced protein will be cleaved after the ubiquitin, thus exposing a non-methionine N-terminal residue [37]. Should this residue be a "destabilizing" one, the protein is quickly degraded by the proteasome and its derived epitope efficiently presented on MHC I proteins. Another method to enhance MHC I epitope presentation is to insert a sequence coding for Herpes Simplex Virus (HSV) VP22 protein or heat schock protein 60 or calreticulin at the beginning of the gene [38–40]. HSV VP22, HSP60, and calreticulin moieties have the particularity to enhance MHCI-antigen presentation of the conjugated protein.

For augmenting the presentation by MHC II molecules, the engineering of genes encoding Invariant chain (Ii) [41] or lysosome-associated membrane protein-1 (LAMP-1) [42] fused to the antigen is recommended. Both Ii and LAMP-1 can direct the foreign nucleic acid-encoded protein to the cellular compartments where the degradation of antigens and the loading of MHC II molecules take place.

Shipping the antigen to the extracelullar compartment and at the same time targeting it to APC is another method to enhance T-cell priming: Whatever cell expresses the foreign nucleic acid, the antigen will be released and captured by APCs. To this end, the antigen can be fused for example to CD40L, Flt-3L, or CTLA4 [43–45] because these molecules bind to APC-specific surface proteins.

These strategies enhanced the efficacy of pDNA-based vaccines but may have the theoretical drawback of triggering an immune response against the self-protein used as fusion. Such an immune response would lead to autoimmune disorders targeting the immune system.

Finally, for enhancing the priming of the T cell, especially when the immune system may be tolerant (self-proteins used in anticancer vaccination), the addition of a "foreign" sequence to the antigen such as for example the Pan DR Epitope (PADRE: AKFVAAWTLKAAA) [46] or the utilization of a xenogenic antigen (the sequence of the antigen in species other than human) that has a ca. 90% homology to the nominal antigen are shown to increase the vaccine potential of nucleic acids [47, 48].

Specific Functional Optimization of pDNA Vectors for Vaccination. For a good expression of the vaccine transgene, a strong promoter must be used. Investigators can chose between (1) ubiquitous promoters such as the commonly used promoter of the early genes of CMV, eventually enhanced using additional regulatory elements (Operators [49]); and (2) cell-type specific promoters such as those that can promote transcription only in APCs (promoter exclusively used by dermal dendritic cells such as the fascin gene [50], for example) or locus control regions [12]. In the first case, independently of the site of injection and of the cell type that take up the pDNA, there will be a local expression of the protein, and through direct presentation (when the plasmid was taken by APC) or cross-presentation (when the plasmid was taken up by a somatic cell and the produced protein phagocytosed by neighboring APCs), specific lymphocytes are activated. In the latter case, expression of the antigen is limited to APCs. This has several advantages: As APCs are terminally differentiated cells, they cannot persist or proliferate; thus, long-term uncontrolled expression of the transgene and risks of transformation (when the transgene is an oncogene to be used in antitumor vaccination) are excluded. The induction of immune tolerance due to long-term expression of the antigen by somatic cells is also excluded. Moreover, the delivery of vaccine plasmids that have an expression restricted to APCs was reported to enhance the efficacy of vaccination compared with ubiquitously expressed plasmids [13].

Should the plasmid contain no CpG motifs, the introduction of some of these sequences outside of the functional sequences (i.e., origin of replication, antibiotic resistance, and relevant gene expression cassette) would be needed to render the plasmid functional for vaccination purposes.

Delivery of Nonviral Coding Nucleic Acids for Vaccination

Injection of Naked Nucleic Acids. Although *in vitro* cultured cells do not usually take up naked nucleic acids (pDNA or mRNA) spontaneously, skin cells and muscle cells do in vivo. As published in the milestone article by Wolff et al. [18] and presented in Figure 7.2-4, the direct injection of pDNA or mRNA resuspended in an isotonic buffer results in the local uptake of the nucleic acid that can be visualized by the expression of the encoded protein (luciferase, EGFP, CAT, or β-galactosidase are easily detectable markers) or by the induction of an immune response directed against the encoded protein. This is true whether the injection is made intramuscular, intradermal, or subcutaneous (review by Wolff and Budker

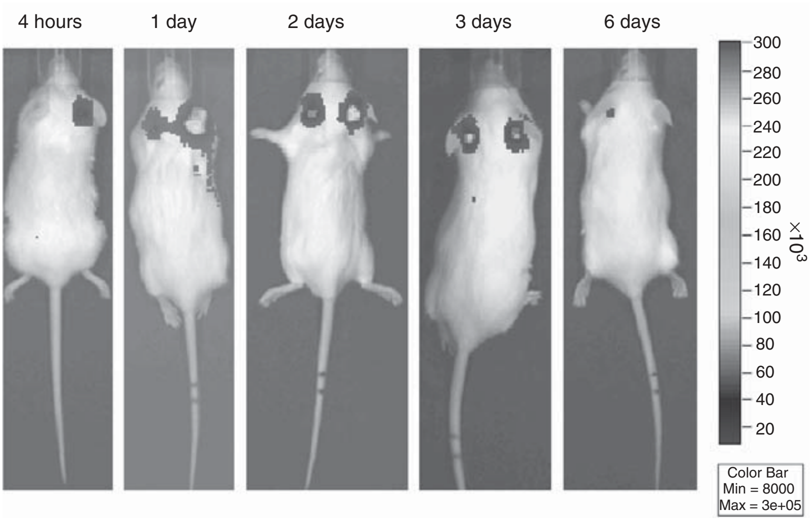

Figure 7.2-4. Expression of luciferase *in vivo* after injection of nonviral coding nucleic acids. Mice were injected in the ear pina with 10 µg of naked mRNA (right ear "R") or 10 µg of naked pDNA (left ear "D") coding luciferase. At the indicated time points, mice received a systemic injection of luciferin and were monitored by an *in vivo* imaging system for luciferase-mediated light emission. The injection of mRNA quickly results in strong luciferase expression at the site of application and totally vanishes after a few days. Plasmid DNA gives an expression at the site of injection that peaks later than the one obtained with mRNA injections, and that remains for a long time (up to weeks, depending on the injections).

[50]). To get an immune response, standard injections in mice consist of 50 to 200 µg of nucleic acids. A great optimization is obtained by direct intra-lymph-node injections, which proved in preclinical models to be much more efficacious than other routes, i.e., giving similar immunity than a 100-fold higher dose injected intramuscularly or intradermally [51]. Such a method was evaluated in clinical trials and found to be a feasible and safe approach [52].

The mechanisms and molecules necessary for the spontaneous uptake of exogenous nucleic acids are not fully characterized. However, it is probable that both pDNA and mRNA are phagocytosed, eventually in a receptor-mediated way (the reporter gene expression, after pDNA or mRNA injection, is a saturating process that can be competed with irrelevant nucleic acids), and travel through endosomes before they can reach, in an unknown way, the cytosole and, for pDNA, subsquently the nucleus (Figure 7.2-2). As pDNA and mRNA vectors contain intrinsic danger signals (nonmethylated CpG sequences recognized by TLR9 for the former and any nonmodified ribonucleic acids recognized by TLR7 and TLR8 for the latter) that are detected in the endosomes of cells that have phagocytosed the exogenous nucleic acid (Figure 7.2-3), the expression of the encoded protein parallels a local activation of the immune system. This results in the development of a B-cell- and T-cell-mediated immune response specific for the protein encoded by the injected nucleic acid. After the antigen is not expressed any longer, the triggered immune response becomes a memory response that provides an advantage to the treated

individual, should he be re-exposed to the nominal antigen expressed by a pathogen.

An *in vivo* electroporation method was developed and tested in order to enhance the penetration of injected naked nuclei acids in cells at the site of delivery (for review, see Prud'homme et al. [53]). After the injection of the nucleic acid, a short electric pulse is given through the injected tissue thanks to electrodes connected to a programmed generator. This method allows a strong enhancement of the uptake of the injected pDNA. So far, however, it has not been successful in enhancing the uptake of injected mRNA (unpublished personal observation). For pDNA vaccination, *in vivo* electroporation is becoming a standard method to enhance the efficacy of vaccination in mice and it is being tested in a phase I trial in humans (see www.clinicaltrials.com).

Delivery of Vaccine Nucleic Acids Using Particles or Cells. One problem when using injections of naked nucleic acids for vaccination is that a big amount of vector is needed to vaccinate mice and *a fortiori* humans. This is partly due to the quick degradation of the extracellular vector (half-life within seconds for the mRNA [14] and eventually minutes for pDNA [54]) and its relatively poor uptake by cells. Only a few thousand plasmids are expressed at the site of injection [55]. For vaccination, three strategies were developed that can protect the nucleic acid and/or deliver it efficiently to its functional site (cytosol for mRNA and nucleus for pDNA): Gene Gun, *in vitro* transfection of professional APCs before adoptive transfer, and finally encapsulation in particles or liposomes.

GENE-GUN. The gene-gun technology is based on a ballistic delivery. The nucleic acid is precipitated on micrometric gold particles that are resuspended in a buffer and quickly injected into an horizontal tubing of 4 mm in diameter and 75 cm in length. The particles are left there to sediment. Thereafter, the buffer is slowly discarded and the tube is turned 180° along its axis in a way that the initial bead's bed is on the "roof" and disperses slowly through gravity on the inside of the tubing, covering it homogeneously. After it is dried in the inside, the tube is chopped into the size of cartridge (ca. 1.25-cm-long tubes). The cartridges are placed in the cartridge holder of a gun that is connected to pressured helium. Upon firing, the gas goes through the cartridge and propels the beads with high speed. Should the gun be a few centimeters from the skin, the beads penetrate the *stratum corneum* and stop in the dermis. They release the nucleic acid in the hit cells or cells' nuclei. Within these cells are dermis DCs and Langerhans cells. They are activated probably through signaling by TLR9 (pDNA vaccines [56]) or TLR7 and TLR8 (mRNA vaccines [57]) and migrate to the draining lymph node where they can activate antigen-specific lymphocytes.

ADOPTIVE TRANSFER OF *IN VITRO* TRANSFECTED APCS. As the key event in vaccination is the presentation of the antigen and its derived epitopes by professional APCs, researchers investigated the possibility of generating a pure APC population out of blood cells and of modifying these cells with exogenous nucleic acids before re-implanting them in the body. Because the transfection of pDNA in APCs such as DCs is inefficient and, when successful, induces apoptosis, the methods of genetic modification of APCs were principally developed using mRNA vectors. As APC,

the monocyte-derived dendritic cells are most often used. They are easily produced, even in GMP conditions, starting from blood monocytes that are extracted from total blood either using their characteristic to stick quickly on plastic surfaces or by sorting (magnetic beads or FACS) with monoclonal antibodies specific for monocytes such as CD14. The monocytes are cultivated 1 week with GM–CSF and interleukine-4 to generate immature DCs. These cells can be easily transfected with mRNA using simple co-incubation or, for a more efficient, more controlled uptake, electroporation. Eventually, the cells are rendered mature by the addition of one or several danger signals and further cultivated 1 or 2 days. Then the cells are re-injected into the patient. Although the method was shown to work in animals and in humans (see Section 7.2.2.1), the optimal danger signal(s) and site of injection are still to be precisely defined. For the maturation, a cocktail containing IL-1β, IL-6, TNF-α, and PGE2 may be optimal to generate mature DCs that can migrate to the lymph nodes draining the site of adoptive transfer without dying too early from overstimulation [58]. Using this type of cocktail, DCs injected subcutaneous or intradermally are expected to go to the secondary lymphoid organs and prime antigen-specific lymphocytes. Alternatively, the direct intra-lymph-node injection of mature transfected DCs may be the best method to guarantee that most *in vitro* generated APCs are at their site of activity after adoptive re-implantation. The utilization of this method in many human clinical trials is ongoing throughout the world, and optimized protocols will soon be deducted from these studies.

PARTICLES. Both pDNA and mRNA vectors entrapped in particles or coated on particles were shown to be potent vaccines. In all cases, the particle strategy allowed a drastic reduction of the amount of the nucleic acid needed to get a significant immunity. For mRNA vectors, Martinon et al. [59] were the first to report that influenza nucleoprotein coding mRNA entrapped in liposomes can induce an immune response against influenza virus in mice. It was then shown that minimal amounts of mRNA (down to 1 μg of encapsulated mRNA injected intradermal or intravenous) are enough to prime an antigen-specific immune response [60]. This technology has not yet been transferred to human clinical trial. Encapsulated pDNA, however, were shown earlier to be potent vaccine formulations. Plasmid DNA entrapped [61] or coated [20] on cationic microparticles or enclosed in liposomes [62] are more potent than naked pDNA as vaccines. Using either intramuscular or intravenous routes of delivery, doses as low as 1 μg of encapsulated pDNA were shown to prime humoral and cellular immune responses in mice. Using these formulations, oral [61, 63, 64], intranasal [65], or other mucosal delivery routes (intrarectal [66], for example) can be used to stimulate mucosal and systemic immunity in animals (mice or macaques).

Adjuvants. Although nucleic acids have the intrinsic capacity to signal “danger” through TLR7, 8, or 9, extra-immunostimulation can enhance or polarize the immune response. It can be achieved by injection of cytokines or nucleic-acid-coding cytokines together with the vaccine. The cytokine GM–CSF is one of the most studied adjuvants in the context of nucleic acid vaccinations. It was shown to enhance and to polarize toward Th1 immune responses after pDNA [67] or mRNA [68] applications. The optimal timing of application of such an adjuvant is not clearly established. Theoretically, the local delivery of GM–CSF should attract

immature DCs that would render the site more reactive to a consecutive nucleic acid injection. However, practically, in mice it looks like the injection of GM–CSF should at best follow the injection of pDNA or mRNA. The optimal timing of GM–CSF injections in humans would need to be deducted from clinical trials especially designed to decipher this matter. Inflammatory cytokines such as IL-12 are also foreseen as promising adjuvants to be used in combination with nucleic acid vaccines.

Preclinical Results and Clinical Applications. Both pDNA- and mRNA-based vaccinations were demonstrated to be efficacious in animal models as prophylactic or therapeutic immunotherapies against tumors, infectious diseases, and allergy. Two pDNA-based vaccines are commercialized for veterinary use: an anti-equine fever and an anti-infectious hematopoietic necrosis virus (IHNV) for farm-raised salmons. In humans, several formulations of nucleic acid vaccines are tested in clinical trials (see the actualized list of trials at www.clinicaltrials.gov). Although pDNA-based vaccine trials were reported in the context of antitumor, antivirus (HIV, influenza virus, HBV) and antiparasite (*Plasmodium falciparum*) approaches, mRNA-based vaccines were up to now tested only as immunotherapies against cancer (review by Liu and Ulmer for pDNA [35] and Pascolo for mRNA [36]).

Anti-infectious Diseases Vaccines (HIV, Plasmodium falciparum, influenza virus, HBV, Mycobacterium tuberculosis). Theoretically, any infectious agent can be recognized by the immune system, and thus, vaccination is of interest to prevent acute infection or reduce chronic replication. Preclinical results have shown at least in mice that for all economically or socially relevant pathogens, pDNA-based vaccination is a robust method to prevent or treat the infections. Several trials in the human population are ongoing (see www.clinicaltrials.com) and address the safety of pDNA vaccines designed to trigger immunity against HIV, *Plasmodium falciparum*, influenza virus, HBV, *Mycobacterium tuberculosis*, severe acute respiratory syndrome (SARS) virus, West Nile Virus, or Ebola virus. Most are phase I trials and thus address only the safety and dose. The following paragraphs describe the results obtained for several of these test vaccines.

AIDS. The Acquired Immunodeficiency Syndrome (AIDS) is the fourth cause of death in the world (an estimated 3.5 million people die from AIDS every year). An estimated 40.3 million persons are living with HIV, and 5 million people per year become infected. An affordable and efficacious anti-AIDS vaccine is urgently needed (review by Girard et al. [69]). Due to the potency of pDNA vaccines to induce CTL in mice and the known efficacy of these cells to control HIV replication in humans, the first trials using direct injection of nucleic acids were performed in HIV-infected individuals in the mid-1990s. Follow-up trials were performed in uninfected volunteers. These studies showed that anti-HIV pDNA vaccines are feasible and safe [70]. The induced immune responses were less strong than expected based on preclinical studies. However, CTL responses could be recorded after injection of naked pDNA [70]. Interestingly, in infected patients, the pDNA vaccines could induce new anti-HIV immune specificities, not triggered by the infection itself. Thus, in the context of immunotherapy, pDNA vaccination has indeed the potential to boost the preexisting immunity but also to broaden it by

inducing new virus-specific CTL and antibodies. Up to now, no clinical efficacy of pDNA vaccines against HIV could be demonstrated. However, strategies using pDNA as a prime followed by recombinant viruses or proteins as boost are being evaluated as vaccine protocols in high-risk populations [71, 72].

MALARIA. *Plasmodium falciparum* (*P. falciparum*) is the most pathogenic parasite causative of malaria. Yearly, 300–400 millions clinical cases of *P. falciparum* infections are reported, among which 2–3 million are deadly. Moreover, an increase of the incidence of the disease has been observed due to the emergence of drug-resistant parasites and of insecticide-resistant mosquitos. For these reasons, a protective and cost-effective vaccine against *P. falciparum* is needed. *P. falciparum*, being an intracellular parasite, its control requests the recognition by CTL. Thus again, nucleic acid-based immunotherapies are theoretically adapted for the development of a preventive or therapeutic vaccine against malaria. The same year as the report of anti-HIV pDNA-based vaccines was published so was the result of the first anti-malaria pDNA-based vaccine [73]. In this and follow-up studies, the induction by the pDNA vaccine of CTL against *P. falciparum* epitopes was documented. However, no antibody response was induced. The codon usage of *P. falciparum* is very inadequate for mammal cells. Thus, the pDNA vaccines based on native *P. falciparum* genes may have been relatively inefficiently translated *in vivo*. This may account for the generation of CTL, which are recognizing fragments of the protein but fail to generate antibodies that require the production of the full-length foreign protein. To conclude, although the documented induction of anti-malaria T cells by pDNA applications [74, 75] is an encouraging progress toward the development of an antimalaria vaccine, a randomized placebo-controlled phase III trial is required to see whether pDNA-induced anti-*P. falciparum* immunity results in the reduction of the burden of infection, morbidity, and mortality within populations living in endemic areas.

HEPATITIS B. The hepatitis B virus (HBV), which may have infected more than one third of the population, is responsible for approximately 1 to 2 million deaths every year. After infection, most people clear the virus through an efficient immune response. However, the virus persists in ca. 10% of the people and eventually leads to liver diseases such as hepatocellular cancer. Although the anti-HBV vaccine based on the recombinant surface antigen is efficient and safe, 5% to 10% of healthy immunocompetent subjects do not respond to it [75]. For those people and the ca. 350 million carriers, an alternative vaccine that would trigger a B-cell but also a T-cell response is of great interest. Indeed, a potent T-cell response of the Th1 type is believed to lead to the control of HBV. Several prophylactic and therapeutic trials are ongoing. One of the most successful methods to trigger immunity against HBV using pDNA is based on the utilization of the gene-gun: A trial showed that ballistic delivery of pDNA coding HBS could induce CD4 and CD8 T cells as well as protective levels of antibodies in all treated hepatitis-naïve volunteers [76]. Moreover, no or low responders to the standard vaccine were found to respond to the pDNA applied with the gene-gun (12 out of 16 patients responded [77]). Each dose of the vaccine contained no more than 4 µg of plasmid. Subjects received between one and three doses, with a two-month interval in-between applications. Thus pDNA-based vaccination is a safe, feasible, cost-effective, and pro-

mising prophylactic and therapeutic approach against HBV. The results of phase II and III trials are needed to prove clinical efficacy and allow commercialization of this vaccine.

TUBERCULOSIS. *Mycobacterium tuberculosis* is the etiologic agent of tuberculosis. The disease is due to the immune response against the pathogen more than to the pathogen itself. Immunotherapy using the whole inactivated pathogen or BCG may enhance rather than decrease the disease. Nucleic acid vaccination offers the possibility to perform immunotherapy with the immunogenic parts of the pathogen that are associated with a protective immune response rather than with a pathologic immune response. Heat Shock Protein (HSP) 65 is a dominant mycobacterial antigen. Vaccination with HSP65-encoding pDNA in mice was superior to infection in priming protective T cells [78]. In this model, the same method was found to be efficacious in a therapeutic setting [79]. However, these results were not confirmed by another laboratory, where vaccination of mice with pDNA encoding mycobacterium HSP65 enhanced the pathology. These contradictive results may be due to the ratio of Th1 versus Th2 cells primed by the vaccine, which may be linked with the purity of the nucleic acid (the presence of endotoxin, which orientate the response toward Th2), the site of injection (intradermal delivery orientates the response toward Th2), or the level of immunological naivety of mice that depends on the clean conditions in which they are kept. As an improvement of the approach, a combination between efficacious anti-mycobacterium chemotherapy and pDNA vaccination may allow a sustained immune control of the pathogen [80]. This regimen may be used in infected patients suffering from tuberculosis. However, the risk of increasing rather than decreasing the pathologies associated with *Mycobacterium tuberculosis* using pDNA vaccination is a drawback that limits the testing of this immunotherapy.

Antitumor Vaccines. Many, if not all, tumor cells express characterized specific antigens (self-proteins or virus-encoded proteins) that make them recognizable and controllable by the immune system, especially by T cells. The capacity of immune-stimulation approaches, among them, nucleic acid-based vaccines, to control tumors was clearly proven in many animal models. For this reason, nucleic acid vaccines coding tumor antigens such as virus-encoded oncogenes (for example, HPV 16 E7), self-proteins (prostate antigens for prostate cancer, clonotypic antibodies for B-cell leukemia, melanocyte-specific proteins for melanoma, or shared tumor antigens such as testis-antigens for many tumor types, for example) or mutated oncogenes (p53 or cRas, for example) were tested as immunotherapy in cancer patients [81]. Prophylactic vaccination against cancer is validated in mice [82] but not yet transferred to healthy, tumor-prone individuals identified thanks to family history and detection through genotyping using known tumor-predisposition markers.

PLASMID DNA-BASED ANTI-TUMOR VACCINES. One of the first reports of an antitumor pDNA-vaccine phase I trial used a dual expression plasmid coding HBS and carcino embryonic antigen (CEA), a protein overexpressed on many epithelial cancers. The plasmid was repetitively injected intramuscularly. Per injection, up to 2 mg was applied. Some patients developed a good immune response toward HBS, but there was only a very limited response toward CEA. No objective clinical

response was recorded. Similar results were obtained in another phase I trial using a pDNA coding gp100 (an enzyme involved in melanine synthesis and expressed in most melanoma [83]) whether the DNA was injected intramuscularly or intradermally. As a superior vaccination strategy that may allow breaking tolerance, the intranodal delivery of pDNA coding tyrosinase (like gp100, it is a protein expressed in melanocytes and melanoma) was tested in melanoma patients [52]. Patients received up to 800 μg of pDNA every 2 weeks for four cycles. The treatment was feasible and safe. Nearly half of the patients (11 of 26) showed the triggering of an immune response against tyrosinase. Overall survival in this small cohort was found to be higher than expected. Meanwhile the utilization of an adjuvant in the form of recombinant cytokines (IL-2 and GM-CSF) applied subctaneously was tested in a phase I trial involving prostate tumor patients [84]. The pDNA (up to 900 μg per injection, five cycles) was given intramuscularly and intradermally. Cellular and humoral immune responses targeted to PSA could be detected in two of three patients injected with the highest dose. Biochemical regression was recorded in these two immunologically responding patients. Finally, as an immunotherapy strategy targeting the idiotype of B-cell lymphoma, pDNA expressing patient-specific clonotype were delivered with a needleless device (Biojector). Patients received monthly injections of up to 1800 μg of pDNA [85]. Here again, an immune response (B or T cell) could be triggered against the tumor-specific antigen (the antibody's idiotype) in most patients (7 out of 12).

Viral oncogenes are a privileged target for antitumor immunotherapies: Being foreign molecules, they are usually efficaciously recognized by the immune system and can be used as prophylactic antitumor vaccination targets. Human Papilloma Virus-16 (HPV-16) encodes two oncogens: E6 and E7. PLG-encapsulated pDNA coding for a few HLA-A2 epitopes of HPV-16 E7 administered intramuscularly could induce an immune response against HPV-16 in most treated patients suffering from HPV-16 associated anal dysplasia [86] or cervical intraepithelial neoplasia [87]. Clinical responses (histological responses) were observed in some patients (3 out of 12 in the study by Klencke et al.; 5 out of 15 in the study by Sheets et al.). Thus, pDNA-based vaccinations against HPV can be envisioned as a possible prophylactic and therapeutic antitumor immunotherapy regimen. This technology may become a standard anti-HPV therapy in the relatively near future.

MESSENGER RNA-BASED ANTITUMOR VACCINES. The only published results where mRNA vectors were used to vaccinate cancer patients are based on the utilization of mRNA-transfected DCs as described above. This popular method first described in 1996 [88] was validated in several preclinical mouse models and used to vaccinate prostate or renal cancer patients with different mRNA preparations (review by Gilboa [89]). In most patients, an increased T-cell immune response against the antigen(s) encoded by the mRNA(s) could be observed. Thus, mRNA-based vaccines using *in vitro* transfection of autologous DCs is a feasible and efficacious approach to stimulate a T-cell immune response against tumor antigen. Phase II and III trials are needed to show the clinical efficacy of mRNA-transfected DCs as anticancer immunotherapy. However, the need for a large amount of blood to prepare a few vaccine doses, the costly and variegating production of DC in GMP-conditions, as well as the logistic issues restrict the utilization of this technology. As an alternative, direct injections of naked or protamine-encapsulated mRNA

was shown to be efficacious for priming cellular and humoral immune responses in mice [27, 90]. It is being evaluated in human as anticancer immunotherapy (ongoing phase I/II studies).

CONCLUSION ON ANTITUMOR VACCINES BASED ON PDNA OR MRNA. Most published results show limited efficacy of nucleic acid-based vaccines as anticancer immunotherapies, highlighting the need for improving these strategies. However, the possibility of triggering an immune response against self-tumor antigens with pDNA or mRNA vaccines sustains the hope that once the correct antigens and optimized immunization methods will be identified, antitumor vaccinations would be a way to get regression or at least stabilization of tumor diseases in many patients. The fundamental knowledge of immune-tolerance and control of autoimmunity will help to find the protocols that will allow nucleic-acid based vaccines to become potent antitumor therapies. Of particular and new interest is the role of regulatory T cells (Treg) that can suppress immunity and are usually increased in number in the blood of tumor patients. Antitumor vaccination may enhance the activity of suppressive cells rather than the one of effector antitumor cells, thus leading to a failure of the therapeutic approach [91]. Controlling, i.e., reducing, the activity of Treg and of other immunomodulatory cells or molecules may be crucial for the success of anticancer immunotherapies. Methods such as chemotherapies, which are lymphoablative or specific inhibition of gene expression using siRNA (anti-TGF-β or IL-10, for example), may allow a transient reduction of natural immunosuppression that could be used for intensive vaccination protocols. Such combinations are being evaluated in clinical trials.

Anti-allergy Vaccines. Allergic diseases affect approximately one third of the population, and for unclear reasons, prevalence of these diseases is increasing. Through the triggering of Th2 type of T helper cells, environmental antigens induce the release of Il-4, Il-5, and Il-13 activate basophil, eosinophil, mast cells, and IgE, which eventually induce the development of inflammatory allergic diseases such as asthma, eczema, hay fever, and rhinitis. The desensitization of a patient can be obtained through repeated injections of increasing doses (starting at very low doses) of the nominal allergen over the course of several years. However, this protocol has been reported to have inconsistent efficacy and in rare cases very strong toxicity [92]. As vaccination with pDNA was reported to induce a Th1 response and inhibit the Th2 response, it was anticipated that pDNA vaccines could have a potential for the prevention and cure of allergic diseases. Indeed, it was demonstrated in animal models that the injection of pDNA coding for an allergen (β-galactsidase in experimental models or relevant allergen such as house dust mite Derp5, latex Hevb5, peanut Arah2, honeybee venom phospholipase A2, pollen allergen Cryj1, or Betv) can be a prophylactic or therapeutic treatment against allergies [93]. However, a clear control of the Th2 response, eventually using the co-injection of the vaccine with nucleic acids coding Il-12 or IL-15 as enhancers of the Th1 response, is needed before pDNA desensitization protocols can be planned for testing in the human population.

Conclusion on Vaccination Using Nonviral Coding Nucleic Acids. Both pDNA and mRNA vectors can induce antigen-specific humoral and cellular immunity of

the Th1 and/or Th2 types. When using direct intramuscular injections of naked plasmid, a minimum of 800 μg of pDNA seems to be necessary to get a detectable immune response. Optimization of the vectors as described in Section 7.2.2.1 is a standard way to increase the efficacy of the nucleic acid-based vaccines and should be used for any clinical trials. The choice of the relevant pathogen-derived antigen, especially in the case of antitumor immunotherapies, is critical: This antigen should be well immunogenic and recognized by T and/or antibodies on pathogenic cells (infected and malignant) or by antibodies on infectious agents. The delivery method should be cost-efficient, praticable, and result in the induction of a strong immune response. Although the efficient intra-lymph-node delivery method may be adequate for therapy of a limited number of patients with advanced nontreatable diseases (tumor patients, for example), the gene-gun delivery sounds like the most favorable delivery method for easy, painless, efficacious, and cost-effective nucleic-acid-based vaccination of large populations. The utilization of a nontoxic adjuvant is always relevant, and at the moment, GM–CSF, which is the most frequently used cytokine in the context of nucleic acid vaccination trials, looks like a fairly good candidate. Meanwhile the control of Tregs is fundamental to trigger efficient immunity, especially in anticancer immunotherapies. The choice of the vehicle (pDNA or mRNA) needs to be addressed in clinical trials where both vectors are compared. Although mRNA looks safer due to its transient nature, pDNA may be more efficacious and require less injections for reaching protective immunity (high antibody titers and high T-cell frequencies). On another hand, long-term persistence of antigen expression when using pDNA may interfere with the development of memory T cells [94] and thus render a prophylactic vaccine inefficient. The induction of memory cells by mRNA- and pDNA-based vaccines needs to be evaluated and compared in human populations, especially when prophylactic vaccination is envisioned. Thus, it could be stated that the prevention of diseases or the treatment of chronic non-life-threatening diseases (i.e, allergy) may be most adequately addressed by mRNA vectors, whereas the treatment of late-stage patients (AIDS or tumor patients, for example) may be at the moment best addressed with pDNA vectors.

7.2.2.3 Gene Therapy

Introduction. Known mutated genes that are the cause of recessive genetic diseases are, for example, adenosine deaminase in severe combined immunodeficiency disease (SCID), cystic fibrosis transmembrane conductance regulator gene (CFTR) in cystic fibrosis, hypoxanthine-guanine phosphoribosyl transferase in Lesch-Nyhan disease, glucocerebrosidase enzyme in Gacher disease, dystrophin in Duchenne muscular dystrophy, and factors XIII and XI for some hemophilia. In these cases, using foreign recombinant nucleic acids, it is possible to bring the protein that is missing or deficient. This technology is called gene complementation. The challenge of nucleic-acid-based gene therapies is to bring in all defined target cells an amount of nucleic acid that would provide a functional quantity of the encoded protein without over- or under-expression by some cells and without stimulating immunity or inducing apoptosis. General optimizations of gene expression as described for vaccination with pDNA and mRNA vectors in Section 7.2.2.1 should be performed to obtain the highest possible expression, thus efficacy, from the nuclei-acid-based

drugs. At the same time, the vectors should be designed to have low immunogenicity, for example, by eliminating CpG sequences in pDNA vehicles. Using pDNA vectors, the utilization of promoters that specifically drive gene expression in the adequate tissue or cell type is a method to lower side effects such as expression of the exogenous vector in irrelevant organs or cells. Although delivery of naked nucleic acid is evidenced *in vivo* and can be used for some approaches, the efficacious systemic delivery of nucleic acids needed for gene therapy is best obtained thanks to encapsulation [19]. Both methods are presented below. None of them has been used in human clinical trials. Up to now, gene therapy approaches tested in humans are based on virus-derived constructs that can efficiently penetrate cells and integrate in the nucleus. However, because of safety issues, pDNA and eventually mRNA (not used in preclinical models up to now) may appear again as favorable vehicles for gene complementation.

Naked pDNA for Gene Therapy. As published by Wolff et al. in 1990, the injection of naked pDNA in the mouse skeletal muscle results in local transgene expression [18]. Since then, other species such as rats, cats, or monkeys and other sites such as skin, liver, brain, urological organs (assisted by *in vivo* electroporation), thyroid, and tumors were shown to be permissive to the local uptake of injected naked pDNA [95]. However, the local transgene expression obtained by direct injection of naked pDNA into an organ is usually too low to be used in the context of genetic disease, even when the missing function is contained in a soluble protein secreted in the bloodstream (for example, coagulation factors in hemophilia). It was estimated that after injection of naked pDNA, only a few thousand plasmids are functionally retained within cells of the injected tissue [56]. To treat a genetic disease, a physiological expression of the therapeutic molecule by all cells that need the missing function or a functional level of the protein in the body fluids is required. For this reason, gene therapy approaches based on naked pDNA use a systemic delivery method such as intravenous or, at best when organs other than lungs are targeted, intra-arterial injections. Indeed, the intravascular injection of naked pDNA surprisingly results in the expression of the encoded protein, especially in the liver [50]. As it is the case for intramuscular and intraskin injections, the intravascular injection of naked pDNA was initially a (negative) control of experiments designed to test the potency of transfection reagents. To reach a good expression level in mouse hepatocytes, the pDNA should be injected in a relatively large volume and short delivery time ("hydrodynamic" delivery) through the tail vein, the portal vein, the hepatic vein, or the bile duct. One injection can transfect about 1% of the hepatocytes throughout the entire mouse liver. This method can be used to produce *in situ* liver-specific proteins and soluble proteins such as coagulation factors XIII and XI that are missing in hemophilic patients. The production of critical proteins such as growth hormones with this technology is theoretically possible but would be hazardous because the amount of protein produced and the duration of the expression are not controlled.

Although naked siRNA can be delivered using the same procedure, naked mRNA would not be suitable because it is degraded within seconds in the serum [14].

Using hydrodynamic injection in a muscle's artery or vein, the expression of naked pDNA can also be obtained in the muscle. However, for a high expression,

the blood flow through the targeted vessel must be stopped surgically during the injection [96, 97]. Expression of the naked pDNA can also be obtained in the cardiac myocytes after injection in the left ventricular wall.

These preclinical observations made in mice, rats, and monkeys allow us to foresee the utilization of naked pDNA as a treatment of muscle diseases such as Duchenne muscular dystrophy, peripheral limb ischemia, and cardiac ischemia. However, the methods described above for animals (hydrodynamic injection, transient stop of blood flow through a muscle) are difficult to transpose to the human situation. Instead of an hydrodynamic delivery, human may benefit from the utilization of a vasodilator before pDNA injection. This treatment could increase the permeability of discontinuous endothelium such as those in liver, spleen, and bone marrow and induce permeability through continuous endothelium such as those in the brain. This way, plasmid DNA may go through the vascular wall and reach the target cells of the organs. As mentioned, the utilization of pDNA for gene therapy in humans has not yet been evaluated in clinical trials. Virus-based gene complementation is still observed as the most feasible method although safety issues are raised. Encapsulated pDNA is possibly an improved version of naked pDNA for gene therapy and has better safety features than virus-based delivery systems.

Encapsulated pDNA for Gene Therapy. Both cationic liposomes and polymeric particles were used to deliver efficiently pDNA in animal models for gene therapy approaches. Although in these preclinical assays the expression of the transgene vanished after few days, the uncontrolled long-term expression as well as a possible overexpression after repeated delivery of encapsulated pDNA are safety issues that must be addressed before these methods are evaluated in clinical trials. However, thanks to the recent knowledge on gene regulation (utilization of inducible promoters such as Tet On and Tet Off promoters), immune activation (CpG motifs), immune modulation (Tregs for immunosuppression, for example), we can anticipate new generations of safe (controllable and nonimmunogenic) encapsulated plasmid constructs that will be the basis of future drugs designed to treat genetic diseases.

Preclinical Results Obtained with Liposome Formulations. One of the most frequent genetic diseases with high morbidity and mortality for which the deficient gene has been identified is cystic fibrosis. It is due to mutations in the CFTR, which is a transporter of chloride anions. This deficiency is recessive: Bringing the correct gene in the cells can correct it. As cystic fibrosis affects the lung, local gene therapy approaches where the genetic vehicle is delivered through airways is foreseen as an efficacious and safe method. As early as 1992, liposomes encapsulating pDNA coding for CFTR were found to be capable of bringing this protein function to airway epithelium of the lung after intratrachea instillation in mice [98]. Optimization of the delivery can be obtained by modifying the liposome formulation [99]. This promising method was not evaluated in patients.

Meanwhile, the intravenous delivery of lipid-entrapped pDNA was shown to efficaciously lead to gene expression, especially in liver, lung, and kidneys [100]. The addition of targeting molecules can efficiently target the vesicles to specific cells. For example, the utilization of galactosyl-cholesterol or mannosylated-

cholesterol in the liposome formulation allows efficient delivery of the pDNA to the liver in mice [101, 102].

To conclude, cationic liposome formulations were shown in animal models to be efficient, safe, and versatile delivery vehicles for pDNA molecules. The engineering of liposomes coated with targeting molecules is one method to enhance the efficacy and specificity of these vehicles. Clinical trials in humans are needed to demonstrate the feasibility, safety, and efficacy of these approaches.

Preclinical Results Obtained with Particles. Poly-L-lysine and poly-L-Ornithine were used to generate particles that can entrap pDNA. The cationic polymers can be coupled to a targeting molecule such as galactose or mannose for enhanced delivery to the liver after intravenous or intraportal injections in mice [102–104]. Expression in other organs than the liver (for example, kidneys) is observed; however, expression in the liver using these particles is dominant. Such particles are found to be more efficient and to persist for a longer time in the circulation than liposomes. Hepatic expression of the pDNA delivered by poly-L-Lysine particles can be found several months after delivery [105]. These promising formulations were not evaluated in humans.

Conclusion on Gene Therapy Using Nonviral Coding Nucleic Acids. As opposed to vaccination strategies, the local delivery of naked pDNA in an organ is not foreseen as a possible gene therapy approach because the protein expression is too low. However, the systemic delivery through the blood circulation of naked or entrapped pDNA was found to result in strong expression of the transgene, mainly in the liver. The utilization of hepatocyte-specific promoters in the pDNA would allow us to turn these methods into liver-specific expression systems. They may be used to produce soluble proteins such as coagulation factors XIII and XI or erythropoietin in patients suffering from genetic deficiencies for these molecules. Encapsulated pDNA expressed by hepatocytes could also theoretically be used for the sustained production of therapeutic monoclonal antibodies (the anti-Her-2/neu antibody: Herceptin, for example) by the body's own cells in tumor patients. Aside from that, some methods (hydrodynamic delivery, occlusion of veins, particles) can allow delivery of pDNA in the muscle as a possible treatment for myopathies. Finally, inoculation through the airways can result in gene expression in the lung and could be used as a treatment against cystic fibrosis. Thus, although they are not yet tested in humans, the gene therapy approaches based on simple pDNA coding for a therapeutic protein are very exciting and promising approaches that offer a broad range of applications. However, several issues have to be addressed:

1. The natural immunogenicity of the pDNA. Even without any known CpG sequence in the plasmid, repeated applications may still induce the activation of the immune system. This immune response could neutralize the produced transgenic protein and result in the specific killing of cells expressing it. As a remedy, the utilization of immunosuppressive drugs concomitantly with the application of pDNA-based gene therapies should probably be envisioned.
2. The uncontrolled persistence and expression of the transgene prevents its utilization for the production of active molecules such as growth factors. Repeated applications may result in some patients in the accumulation of

pDNA and overexpression of the transgene. This would have negative effects on the producing organs (necrosis) and pathogenic systemic effect due to the protein's own activity. The utilization of inducible promoters and a careful monitoring of the patients before each application of the pDNA would be needed to perform safe clinical trials.

Cationic liposomes that were frequently used and validated in several laboratories and animal models may be the first approaches used for gene therapy using pDNA in humans. Meanwhile, the utilization of encapsulated mRNA appears theoretically as a method to circumvent all limitations of pDNA-based approaches for gene therapy. Encapsulated mRNA were not yet reported as gene therapy tools but because they are transient molecules, readily expressed in the cytosole, and if nonstabilized, barely activate immunity (TLR7 and TLR8), they can be foreseen as safe (transient), efficient (expressed in the cytosole), and nonimmunogenic (not stabilized) genetic information vehicles to be used in gene therapy.

7.2.2.4 Pharmaceutical Production and Regulations

7.2.2.4.1 Plasmid DNA. Several companies in the United States and Europe offer the contract manufacture of documented pDNA for preclinical use and of GMP-certified pDNA for clinical utilisations (see, for example, the Plasmid Factory at www.plasmidfactory.com). It is regulatory practice that ampicilin is not used in GMP production in order to avoid cross-contaminations and concerns with penicillin-allergies. Instead, plasmids containing a kanamycin-resistance gene are frequently used. At best, the starting material is a pDNA containing a synthetic gene constructed by assembly of oligonucleotides. This way, the history of the pDNA can be clearly reported in the production's file. The whole manufacturing process is free of bovine-derived products. The plasmid of interest is tested in different *E. coli* strains and several culture media to find out the best conditions for producing the highest amount and best quality plasmid. The final product should meet regulatory guidelines such as those of the FDA: http://www.fda.gov/cberg/gdlns/plasdnavac.htm. It should appear as a clear and colorless solution by visual inspection. The final controls must meet the following criteria:

1. Identity: Sequencing should show 100% identity with the expected sequence. Electrophoresis or chromatography studies should be used to show that the pDNA is predominantly supercoiled. The restriction enzyme digest pattern analyzed by gel electrophoresis can be included. Susceptibility to DNase can also be used as a proof of molecular identity.
2. Content: Quantification should be performed by absorbance at 260 nm. Osmolarity and pH should also be measured using standard methods.
3. Purity: Residual proteins, chromosomal bacteria DNA, RNA, and endotoxin must be below specified limits. Sterility must be controlled by standard microbiological assays.

Moreover, some tests can be performed to check counter-ions (should be NaCl, thanks to precipitation of the pDNA with alcohol plus NaCl), residual solvents (if they are used during the production), and potency (functional assay using, for

example, transfection of cells and verification of the expression of the protein of interest or testing of the immune response after injection in an animal model).

Production of pDNA using up to 100-m^3 scale fermentation is performed by specialized industries [106]. Batches of more than 1 kg of pDNA can be produced. As functional doses for vaccination in humans were of ca. 800 µg (intramuscular injection) or 4 µg (gene-gun), 1 kg of pDNA is enough for 1,250,000 or 250,000,000 doses, respectively. This is largely enough for pDNA-based therapies to be commercialized worldwide as treatments against infectious diseases, cancer, or genetic diseases.

Preclinical toxicology studies should address the standard systemic and local reactogenicity, histopathology, and toxicity (acute and chronic dosage) in rodent and nonrodent animals. Also, as pDNA-based therapies are classified as gene therapy approaches, additional strict safety issues must be addressed before starting a clinical trial (for a review, see Ref. 35). The potency of the pDNA to integrate in the genome of the injected animal must be tested using assays that can detect one integrated pDNA in more than 150,000 nuclei. The potential of the pDNA preparation to induce anti-DNA antibodies (the etiologic agents of systemic lupus erythematosus) must be evaluated. The biodistribution and persistence of the pDNA must also be measured: Tissues and body fluids are analyzed at different time points for the presence of the pDNA using PCR methods. Of particular relevance is the study of pDNA in germ cells because such an event could theoretically generate transgenic descendants.

These toxicology studies were performed many times using many different pDNA batches. Close to no integration of pDNA in genomes, no induction of pathogenic anti-DNA antibodies, and a clearance of injected pDNA within days were reported. However, long-term (months) antigen expression in mice using intramuscular injections of a pDNA that may replicate in mammalian cells was found [107]. In this case, the cellular response triggered by the vaccine was weak and may in part account for the persistence of the foreign nucleic acid. The antigen coded by the vaccine in this preclinical study (Hepatitis Surface Antigen) associated with specific antibodies formed circulating immune complexes that caused pathologic lesions in liver and kidney. Thus, special care should be devoted to the design of the plasmid to guarantee that it cannot replicate in mammalian cells. Meanwhile, the regulatory authorities acknowledged the fact that since the first report of trials in humans using injections of up to 800 µg of nonviral coding pDNA (1998), no adverse events have ever been registered. Thus, especially for phase I trials, the toxicology studies can now be facilitated in agreement with the relevant authorities. For vaccination, gene-gun offers the extra-safety advantages that very low doses are used and that the pDNA is delivered exclusively in the dermis, avoiding systemic distribution and potential side effects while guaranteeing the elimination of most of the injected product through natural skin regeneration.

7.2.2.4.2 Messenger RNA. Two companies offer contract manufacture of mRNA at laboratory and clinical grade (GMP-certified): Asuragen, a spin-off of Ambion, in the United States and CureVac in Europe. Here again, the whole manufacturing process is free of bovine-derived products. There are no official guidelines for the production of mRNA; however, it can be proposed that the final product should be checked by the standard quality controls. It should appear as a clear and

colorless solution by visual inspection. The following criteria would have to be met by the results of the final controls:

1. Identity: Sequencing of the plasmid used for *in vitro* transcription should show 100% identity with the expected sequence. At best, reverse transcription and sequencing of the final mRNA could be performed. It should also show 100% identity with the expected sequence. Susceptibility to RNase could additionally be used as a proof of molecular identity.
2. Content: Quantification should be performed by absorbance at 260 nm. Osmolarity and pH should also be measured using standard methods.
3. Purity: Residual proteins, chromosomal bacteria DNA, plasmid DNA, bacteria RNA, aberrant mRNA transcripts (smaller or larger by-products of the transcription) and endotoxin shoud be below specified limits. Sterility must be controlled by standard microbiological assays.

As is the case for pDNA, some physical tests can be performed to check counterions, residual solvents (if they are used during the production), and potency (functional assay using, for example, transfection of cells and verification of the expression of the protein of interest or testing of the immune response after injection in an animal model).

Preclinical toxicology studies should address the standard systemic and local reactogenicity, histopathology, and toxicity (acute and chronic dosage) in rodent and nonrodent animals. Since the FDA and some European authorities decided to classify mRNA-based therapies as no-gene therapy (for nonreplicative mRNA as depicted in this chapter), the implementation of clinical trials does not require additional specific toxicology testing.

7.2.3 CONCLUSIONS AND PERSPECTIVES

Since the initial publication by Wolff et al. showing that the injection of pDNA or mRNA simply coding for a protein can result in gene expression *in vivo*, many studies have been performed in animal models and humans showing that this method is safe and can elicit the expected results, which is the expression of the protein. Because pDNA and stabilized mRNA have the natural capacity to activate the immune system through the triggering of TLR, pDNA- and mRNA-based therapeutic utilizations are mostly tested in the field of vaccination. However, since gene therapies based on viruses have shown severe toxicity features in recent human trials, some pDNA or mRNA formulations may now be intensely developed as safer alternatives. Of special interest is the yet unexplored use of (encapsulated) mRNA for gene therapy. As this transient nucleic acid cannot persist or accumulate and would not generate unwanted long-term side effects even after repeated injections, it may seem as the optimal active pharmaceutical ingredient for gene therapies. Meanwhile, vaccination strategies based on nonviral coding nucleic acids are very advanced in terms of time to commercialization. The injection of naked pDNA and the adoptive transfert of APCs transfected with mRNA were demonstrated in many human clinical trials to be feasible and safe and to result in the development of the expected antigen-specific immunity. Optimal formulation, dosage, frequency of application, and adjuvant still need to be clearly defined.

Improvements of the methods include the optimization of the gene sequence, the optimization of the antigen processing, the enhancement of uptake using for example electrical methods, or the use of particles for formulating the vaccines. Concerning the last point, three types of particles were evaluated: liposomes, cationic degradable polymers, and coated gold particles delivered by gene-gun. This latter technology seems to be at the moment the most efficacious, versatile, cost-efficient method for vaccination with nucleic acids. Moreover, it is painless for the patient and very reproducible because the operator cannot influence the delivery (as opposed to injections, especially intradermal injections). The company Powdermed (www.powdermed.com) is developing and implementing the utilization of gene-gun-based therapies to deliver pDNA as vaccines against infectious diseases and cancer. Meanwhile, for autologuous vaccination, which may be needed for example with the mutating and patient-specific HIV virus, vaccination with adoptively transferred mRNA-transfected DCs as developed by Argos pharmaceuticals (www.argospharmaceuticals.com) may be of high potency. The choice between pDNA and mRNA for clinical utilizations is a matter of cost and efficacy. Although there was an intense development and optimization of pDNA-based vaccines, accompanied by the implementation of industrial production facilities, mRNA was until recently, relatively unexplored. However, as summarized in Table 7.2-1, mRNA offers many advantages over pDNA in the context of therapeutic utilizations. Being active in the cytosole, mRNA does not need to cross the very selective nuclear envelope to be expressed. Being transient, mRNA can allow the controlled production in terms of quantity and time frame of the protein of interest. Moreover, as it is a single-stranded molecule, mRNA does not have the discrete topologies that have pDNA and that could affect its clinical efficacy. This feature allows mRNA to have theoretically a higher functional batch-to-batch reproducibility. At the level of efficacy for vaccination, pDNA is assumed currently to be superior to mRNA; however, the direct comparison of optimal formulations of pDNA and mRNA using gene-gun delivery, for example, as a consistent and reliable method, still needs to be performed. Meanwhile the unique possibility that offers mRNA to transfect, without inducing death, DCs *in vitro*, is a guarantee of vaccine efficacy using a minimum amount of nucleic acid. Thus, although pDNA-based vaccination approaches are very advanced and may soon be commercialized, it can be

TABLE 7.2-1.

Parameter	pDNA	mRNA
Delivery to the functional site	Hard (Nucleus)	Easy (Cytosole)
Control of level of expression	Hard	Easy
Control of duration of expression	Hard (Days to months)	Easy (Hours to few days)
Large-scale GMP production	Easy	Easy
Conservation	Easy	Easy
Batch-to-batch reproducibility	Low (Three topologies)	High
Regulatory issues	Severe (Gene therapy)	Easy
Immunogenicity (vaccines)	High	Low
Usage for gene therapy	Efficacious	Not tested

envisioned that due to their safety features, mRNA-based approaches will be the second generation of nucleic-acid-based vaccination strategies.

Several companies active in the field of nucleic-acid-based vaccines will probably manage to get their product(s) and methods brought to the market for disease-specific utilizations. Prevention and treatments of hepatitis B, AIDS, influenza, and some cancer are the most advanced. Thus, in the near future, drugs containing pDNA or mRNA as an active pharmaceutical ingredient should be available in pharmacies and help in treating or preventing pandemic infections (HIV, influenza virus, *plasmodium falciparum*, etc.) as well diseases with unmet medical needs such as certain types of cancers. The continuous optimization of these methods ensures that the future pDNA- or mRNA-based drugs will get more and more efficacious and will be used for a large area of therapeutic applications.

7.3.1 INTRODUCTION

The ability to control the gene expression of a desired cellular population via the delivery of nucleic acids has inspired applications in clinical and basic science. In the past, nonviral gene delivery referred to the delivery of plasmid DNA (pDNA) whereby the expression of a target protein, which could restore normal biological function or aid during wound healing, would be increased. More recently, however, the term *gene delivery* has expanded to include the delivery of small interfering RNA (siRNA) and oligonucleotides (ON), which can be used to decrease or

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

downregulate the expression of a target protein. Ongoing clinical trials using gene delivery as a therapeutic agent include cancer [1], cystic fibrosis [2–4], adenosine deaminase deficiency [5], and infectious diseases such as acquired immunodeficiency syndrome (AIDS) [6].

Gene delivery employs both viral and nonviral vectors to deliver nucleic acids. Although viral delivery strategies are in general more efficient than their nonviral counterparts, an increasing concern about immune responses to viral vectors *in vivo*, which could pose additional risks for patients undergoing gene therapy [7], has motivated the development of nonviral delivery vectors that aim to synthetically mimic biologically produced viruses. Nonviral delivery vectors have to be engineered to be able to package plasmid DNA to form particles that can (1) travel through biological fluids without losing activity, (2) target appropriate cells, (3) be internalized by the targeted cell population, and (4) finally trafficked to the intracellular site of action (e.g., nucleus and/or cytosol; Figure 7.3-1). Furthermore, the ideal delivery system would achieve the above-mentioned points while being nonimmunogenic and nontoxic. Although there have been numerous approaches to the engineering of delivery vectors, this chapter will focus mainly on nonviral delivery vectors that show promising approaches to overcome the delivery limitations mentioned above or that have been tested *in vivo*.

Strategies to administer nonviral delivery vectors *in vivo* can be divided into two main approaches: systemic delivery or direct injection of DNA nanoparticles and the implantation of a matrix that releases "naked" DNA or DNA nanoparticles. Systemic delivery aims at engineering delivery vectors that can be delivered noninvasively through a bodily fluid such as intravenously, transdermally, and orally, while targeting an appropriate tissue (e.g., tumor) or organ (e.g., lung). Local delivery, on the other hand, aims at bypassing the tissue-targeting step by delivering the nonviral vectors directly (or nearby) to the site of action, typically with the use of a polymeric matrix. The polymeric matrix can be designed to slowly release the

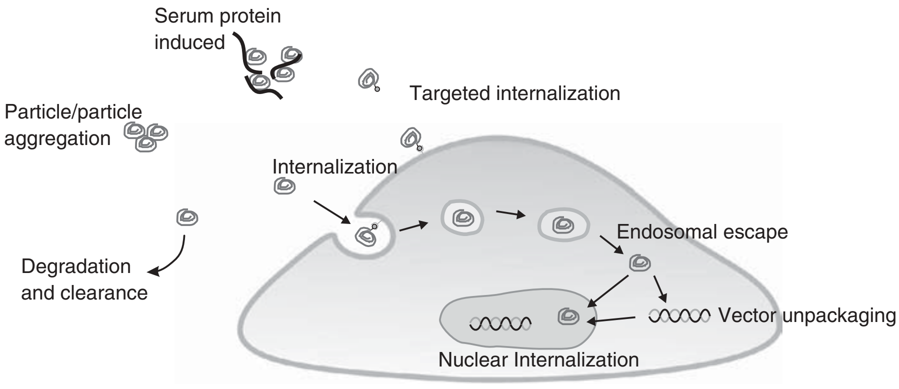

Figure 7.3-1. Limitations of nonviral gene delivery formulations are shown. Limitations can be divided into extracellular limitations, such as (1) interaction with serum components, (2) particle–particle interaction, (3) clearance from target site, and (4) targeting, and intracellular limitations, such as (1) internalization, (2) endosomal escape, (3) vector unpackaging, and (4) nuclear internalization.

DNA nanoparticles to the local environment where cells can internalize them or can be designed so that it can be infiltrated with local cells that can take up the DNA nanoparticles residing inside the matrix.

Design parameters for targeted cellular internalization and intracellular trafficking are similar for systemic and local delivery approaches; however, the design of the vector physical properties such as surface coating and particle size must be tailored to the method of application. This chapter will be divided into sections with Section 7.3.2 discussing systemic and direct injection formulations (Tables 7.3-1–7.3-4), Section 7.3.3 discussing matrix-based delivery formulations (Tables 7.3-2–7.3-5), and Section 7.3.4 discussing limitations with nonviral nucleic acid delivery and current solutions (Tables 7.3-4 and 7.3-7).

7.3.2 SYSTEMIC AND DIRECT INJECTION DELIVERY

In vivo production and secretion of therapeutic proteins by DNA delivery can be achieved through either systemic or local administration, each providing a unique opportunity for gene therapy. Systemic delivery allows noninvasive access to many target cells and tissue that are not accessible by direct administration. The most common approach involves the complexation of naked DNA with cationic lipids (lipoplexes) or cationic polymers (polyplexes) that package the DNA into nanosized aggregates. The major factors limiting the *in vivo* effectiveness for systemically delivered lipoplexes and polyplexes is colloidal instability and ineffective targeting. For intravenous administration, complexes are rapidly eliminated from the blood stream (<30 minutes) and found mostly in the liver and to a lesser extent in organs with fine capillary beds like skin, muscle, and intestine [8]. The interaction of biomolecules from the physiological fluid with the complexes induces aggregation and dissociation of the complexes, which limits bioavailability and internalization [9, 10]. The association of serum components (albumin, heparin, lipoprotein, or specific opsonins) with polyplexes and lipoplexes, which can target the complex for clearance by macrophages and is affected by the surface charge density and surface morphology of complexes [11]. Cationic formulations (i.e., lipoplexes and polyplexes) can provide an enhanced stability against degradation and may allow for a more efficient interaction with the negatively charged endothelial cell; however, noncationic or less cationic formulations may be required to avoid accumulation in the reticuloendothelial system. Variations in the charge ratio may be used as part of a passive targeting strategy. For lipoplexes delivered intravenously, different formulations (e.g., charge ratio) can be used to target the lung, liver, blood cells, or tumors [12, 13].

To avoid the difficulties of crossing the endothelium and nonspecific uptake by the liver, DNA can be delivered directly to the target tissue by injection of polyplexes, lipoplexes, or microspheres with encapsulated DNA. Injection of lipoplexes and polyplexes into the desired tissue can be used to achieve *in vivo* gene transfer. However, transfection depends on the physico-chemical properties of the complexes and the rate of clearance from the tissue, which varies from tissue to tissue and depends on factors such as the lymph supply. Nevertheless, polyplexes have been found to be sufficiently small and stable so as to diffuse throughout the brain ventricular spaces after a local injection injection [14].

7.3.2.1 Formulations

Unprotected plasmid DNA (naked DNA) is unstable under *in vivo* conditions, due to rapid degradation by serum nucleases [10, 15, 16]. Therefore, carriers or vectors are necessary to protect DNA or RNA from degradation to facilitate uptake into specific cells, and to transfer the DNA or RNA their target location (e.g., nucleus or cytosol). Delivery vectors for systemic delivery are designed to increase gene transfer function by enhancing the stability of DNA, the efficiency of cellular uptake and intracellular trafficking, and the biodistribution of DNA. In this section, the formulations that have been developed to deliver nucleic acids such as plasmid DNA (pDNA), oligonucleotide (ON), or small interfering RNA (siRNA) will be reviewed. Tables 7.3-1 and 7.3-2 summarize the most widely used cationic polymer and cationic lipid formulations.

Cationic Polymers. Cationic polymers have been used since the late 1980s [20] as formulations for nucleic acid delivery. Cationic polymers contain high densities of primary, secondary, or tertiary amines, some of which are protonated at neutral pH. This high density of positive charges allows the cationic polymers to form stable condensed structures with pDNA, termed polyplexes, which are capable of entering the cell. Furthermore, polyplexes protect the DNA from nucleases found in serum and other extracellular environments. Table 7.3-1 shows the structure of frequently used cationic polymers, which have been used *in vivo* to deliver therapeutic genes, although many novel polymers are being developed, including polyallylamine [29], peptoids [30], poly(dimethyl aminoethyl methacrylate) [31, 32], poly(trime-thyl aminoethyl methacrylate) [33], poly(β-amino ester) [34, 35], and poly(phosphoester) [36–38]. Cationic polymers vary widely in molecular architecture, ranging from linear to highly branched molecules, which influences their complexation with nucleic acids as well as their transfection efficiency. In addition to providing positive charges for DNA complexation, the primary amines also serve as functional groups to chemically modify the polymers with ligands and peptides that can enhance one or more of the steps in the transfection process (Section 7.3.4, Tables 7.3-3, 7.3-4). Furthermore, tertiary and some secondary amines are typically neutral at physiological pH and have been found to aid in intracellular trafficking by facilitating the release of the polyplexes from the endosome though endosomal buffering (Section 7.3.4.2). The use of cationic polymers and lipids to deliver therapeutically relevant genes and their therapeutic outcome is summarized in Tables 7.3-5, 7.3-6, and 7.3-7 for formulations delivered systemically or via a matrix-based delivery approach.

Interaction of Cationic Polymers with DNA. Cationic polymers form aggregates with DNA, termed polyplexes, via electrostatic interactions, which protect the nucleic acid from degradation [121]. During the complexation of DNA with cationic polymers, the extended structure of DNA is changed to a more condensed configuration forming aggregates in the nanometer size range. Polyplexes typically give rise to particles with spherical, globular, or rod-like structures, which are 20 to 200 nm in diameter [122, 123] but can reach up to 1000 nm. Evidence that electrostatic interactions mediate the complexation of cationic polymers include Fourier transform infrared resonance (FTIR) data showing a reduction of the asymmetric

phosphate stretching vibration of plasmid DNA after complexation with polyethyleneimine (PEI) [124]. Furthermore, microcalorimetric measurements have shown that complex formation between the graft copolymer poly(ethylene oxide)-PEI and a poly(dTA) result from the formation of ion pairs between ionized amino groups of PEI segments of the copolymer and the phosphate groups of DNA [125]. An increase in salt concentration generally results in a decrease binding affinity between the cationic polymer and the DNA probably due to a charge shielding effect at the higher salt concentrations [125–127].

The complexation and condensation behavior depend on the polymer's physical properties, including molecular weight, density of charges, whether it is linear or branched, and the ratio of polymer to DNA [10, 15, 127]. The molecular weight of the cationic polymer influences both the condensation behavior as well as the complex size. In general, for most cationic polymers, an increase in molecular weight results in a decrease of complex size until a condensation limit is achieved. For example, for PEI, it has been found that molecular weights higher than 25 kDa showed no further increase of complex size, whereas molecular weights of 2 kDa or lower result in a decreased ability to complex DNA to form small complexes

[128]. The stability and size of the polyplexes formed between cationic polymers and DNA have also been correlated to primary amine content [10, 129]. Low branched PEI (low density of primary amines) requires higher N/P rations to complete condensation compared with highly branched derivatives (high density of primary amines) [130]. Last, complex size tends to decrease with an increasing polymer-to-DNA ratio [10, 121, 131].

Polyplexes as Cellular Transfection Agents. In addition to reducing the size of DNA and protecting the DNA from degradation by serum nucleases, binding of polycations to DNA typically results in polyplexes having a net positive charge. This positive charge has been found to be essential for efficient transfection [14, 17, 130]. It is thought that the positively charged polyplexes electrostatically interact with the negatively charged proteoglycans of the cell membrane [132], resulting in nonspecific adsorptive endocytosis (Figure 7.3-1). The polyplexes, which are now trapped inside the endosomes, need to escape before endosome–lysosome fusion occurs, which would result in polyplex degradation inside the lysosomes (Section 7.3.4.2). Cationic polymers such as PEI have the advantage over other cationic polymers [e.g., poly(amino acids)] in that they do not require an endosomal lysotropic agent to be added to achieve efficient transfection [17, 18]. Once released from the endosome the polyplexes need to transport the DNA to the nucleus where it can be transcribed or siRNA or ON to the cytosol, where they can mediate gene downregulation. The transition from the cytosol to the nucleus is not well understood, and it depends on the physical properties of the polymer and the cell cycle and degree of mitotic activity of the cells. To aid the transition from the cytosol to the nucleus cationic polymers have been modified with nuclear localization sequences typically derived from viruses (Section 7.3.4.2). Full unpackaging or decomplexation of the siRNA and ON in the cytosol is critical for their action. Strategies to enhance decomplexation involve the introduction of environmentally sensitive bonds [44], reducing the affinity of the cationic polymer for the DNA [70–73] and the delivery of enzymes that can degrade the cationic polymer [47] (Table 7.3-4 in Section 7.4.3).

Although positively charged polyplexes promote efficient transfection *in vitro*, they lead to aggregation and low transfection *in vivo* with most polyplexes accumulated in the liver after systemic administration [133]. The aggregation of polyplexes has been attributed to the presence of negatively charged proteins in serum, which can mediate bridging of multiple polyplexes together [8]. Strategies to generate neutral complexes, which do not aggregate or interact with serum components, have been developed and are discussed in Section 7.3.4.1.

Poly(ethylenimine). In recent years, poly(ethylenimine) (Table 7.3-1, PEI) has emerged as a widely used cationic polymer to mediate gene transfer *in vivo* and *in vitro* (for review, see Ref. 10), resulting in two commercially available transfection products ExGene (Fermentas, Inc., Hanover, MD) and jetPEI (Polyplus-transfection, San Marcos, CA). PEI has a protonatable hydrogen every two carbons in its structure, making it the polycation with the highest density of protonable amines [17]. Branched PEI is synthesized using the acid catalyzed ring opening polymerization of aziridine, resulting in a theoretical 1:2:1 ratio of primary to secondary to tertiary amines. However, C-13 nuclear resonance spectroscopy

measurements have shown that the degree of branching is closer to 1 : 1 : 1 for most commercially available PEIs [134], which indicates a higher degree of branching. Linear PEI, on the other hand, is synthesized by ring opening polymerization of 2-ethyl-2-oxazoline followed by acid hydrolysis [135]. Linear and branched PEI can be purchased in a wide variety of molecular weights ranging from less than 1000 Da to 1.6×10^3 kDa; however, the range most typically used for gene delivery is 5 to 25 kDa, mostly due to toxicity caused by higher molecular weight PEIs (Section 7.3.4.2). PEI forms complexes with DNA ranging from 77 to 300 nm in size at N/P ratios ranging from 6 to 10 [10]. High-molecular-weight PEI forms smaller, more stable particles and achieves higher transfection efficiencies than low-molecular-weight PEI; however, it is more toxic [128]. Similarly, highly branched PEI forms smaller particles that are more stable than low-branched PEI and achieves higher transfection efficiencies, but again, it is more toxic than low-branched PEI.

PEI has be used extensively *in vivo* to deliver DNA and siRNA locally to the brain [14, 136] cornea [137], tumors [82, 84], and vasculature [85] and systemically to the lung [80, 83] and tumors [81]. The charge of the DNA/PEI complexes delivered *in vivo* have a profound effect on their organ targeting. Delivery of positively charged complexes in the tail vein in mice resulted in gene transfer primarily in the lungs, whereas surface shielding transferring-PEI–DNA complexes resulted in preferential gene delivery to distantly growing tumors [138]. Tables 7.3-5, 7.3-6 (systemic), and 7.3-7 (matrix) summarize *in vivo* studies involving nonviral vectors and their therapeutic outcome.

Poly(amino acids). Cationic poly(amino acids) (peptide, Table 7.3-1) are some of the most commonly used cationic polymers for gene delivery. Cationic peptides such as polylysine (Table 7.3-1, PLL) are commercially available in a variety of molecular weights. However, commercially available PLLs are highly polydisperse. To synthesize monodisperse peptides, solid phase synthesis is used that involves the immobilization of the growing peptide on a solid support and a series of protecting/deprotecting synthetic steps (e.g., Fmoc chemistry). The sequential addition of each amino acid provides peptides an absolute level of control over the sequence of the growing peptide, which allows for the specific attachment of targeting ligands or other desired modifications anywhere along the molecule.

PLL and its derivatives are the most commonly used cationic peptides for gene delivery, typically used at charge ratios (+/−) ranging from 3 : 1 to 6 : 1. As increasing amounts of PLL are added to DNA, the structure changes from circular to thick, flattened to compact, and finally to toroids and rods at a charge ratio of 6 : 1 [122]. The diameter and cross section of the toroids are approximately 140 nm and 44 nm, respectively [122]. As with other cationic polymers, the ideal length of the PLL represents a balance between two competing effects: effective condensation and cytotoxicity. Relative to low molecular weight, the high-molecular-weight PLL forms tighter, smaller condensates that are more resistant to the effects of salt concentration and sonication [139]. Cell transfection by PLL is typically lower than other cationic polymers that possess a buffering capacity such as poly(ethylene imine) and to cationic lipids. Extensive modifications aiming at improving the transfection efficiency of PLL have been performed, including the partial modification of the PLL side chains with histidine and imidazole groups, to enhance endosomal buffering and escape (Section 7.3.4.2) [65, 140], the addition of PEG to

enhance polyplex stability, the addition of targeting ligands to enhance internalization and targeting, and the addition of covalent bonds within the polyplex to enhance its stability and polyplex unpackaging (Section 7.3.4). Furthermore, peptides containing multiple lysines have been synthesized such as Cys–His–$(Lys)_6$–His–Cys, which enhances endosomal escape, while providing covalent stabilization of the polyplexes via disulfide bonds [44].

PLL and its derivatives have not been as extensively used *in vivo* as other cationic polymers to deliver therapeutically relevant genes; however, they have found some success in systemic delivery to the liver [141] and matrix-based delivery to enhance angiogenesis [120]. Tables 7.3-5, 7.3-6 (systemic), and 7.3-7 (matrix) summarize the *in vivo* studies involving nonviral vectors and their therapeutic outcome.

Cationic Dendrimers. Dendrimers are polymers that branch out from a multifunctional core in a symmetric fashion. After each subsequent monomer addition (a generation), the number of attachment points increases symmetrically generating more branches. Cationic dendrimers have an attractive architecture for gene transfer because their well-defined structure and robust chemistry enables the synthesis of many generations of protonatable amines (for review of dendrimers as gene delivery vectors, see 142). Dendrimers such as poly(amidoamine) dendrimers (PAMAM, Table 7.3-1) and poly(propylenimine) (PPI, Table 7.3-1) have been shown to be capable of mediating gene delivery *in vitro* and *in vivo* [18, 131, 143, 144]. PAMAM is commercially available and is synthesized from either an ammonia or ethylenediamine core by successive addition of methyl acrylate and ethylenediamine [142]. PPI is also commercially available and is synthesized from a butylenediamine core by successive addition of acrylonitrile to a primary amino group followed by hydrogenation of nitrile groups to primary amino groups. The surface charge and diameter of the dendrimers is determined by the number of synthetic steps (i.e., number of generations) [142]. The generation of PAMAM used to complex DNA determines particle size and transfection efficiency. Complexation of DNA with fifth-generation (G5) PAMAM dendrimers produces monodisperse condensates with a radius below 200 nm [18]. At charge ratios (+/−) above or equal to one, no free DNA is observed [18]. Although PAMAM dendrimers of generations 3 (G3) to 10 (G10) can form stable complexes with DNA, the higher generations of dendrimers (G5 to G10) can transfect cells at higher efficiencies [18, 145]. Transfection efficiency of PAMAM is enhanced by partial degradation of the dendrimer structure, forming a less homogeneous structure with a higher density of primary amines [144]. The partially degraded PAMAM dendrimer has resulted in the transfection reagent Superfect. Cationic dendrimers have been used *in vivo* to deliver nucleic acids locally to the cornea [146], tumors [147], heart [148], and lung [145] and systemically to the lung [149], liver [16, 131], spleen [149], and tumors [16]. Tables 7.3-5, 7.3-6 (systemic), and 7.3-7 (matrix) summarize the *in vivo* studies involving nonviral vectors and their therapeutic outcome.

Polysaccharide Containing Polymers. Chitosan (Table 7.3-1) is composed of 2-amino-2-deoxy β-D-glucan and is prepared from naturally occurring chitin via alkaline deacetylation. Unlike other cationic polymers chitosan is nontoxic and biodegradable, making it an ideal candidate for therapeutic applications. Although the density of positive charges of chitosan is lower than for other cationic polymers,

it has been shown to form particles with DNA, which protect the DNA from degradation [21, 150, 151]. Chitosan/DNA complexes have been found to be in the order of 100 nm with a spherical shape [21, 151]. Like other cationic polymers, chitosan has been chemically modified with a variety of ligands or other functionalities to enhance its transfection efficiency [21]. Chitosan has been recently used to deliver DNA mainly intranasally to the lungs for genetic immunization applications. After intranasal administration, DNA/chitosan complexes encoding for RSV antigen could attenuate pulmonary inflammation and reduce viral titer and viral antigen load [86].

Recently dextran grafted with spermine (Table 7.3-1, D-SPM) has been investigated to mediate DNA delivery. D-SPM are synthesized via reductive amination and can form aggregates with plasmid DNA and mediate efficient gene transfer *in vitro* and *in vivo* [22, 152]. Interestingly, the addition of hydrophobic domains, N-oleyl (ODS), to D-SPM (D-SPM–ODS) enhanced the stability of complexes in serum containing media. Furthermore, the addition of ODS groups achieved high transfection in the presence of serum similar to that achieved with linear PEI [153]. These results suggest that the hydrophobic nature of the complexes may be another strategy to improve transfection in the presence of serum. However, the addition of the ODS groups also increased the toxicity of the D-SPM–ODS when compared with D-SPM, but the toxicity was similar to linear PEI and branched PEI [153].

Cyclodextrins (Table 7.3-1, CDs) are cyclic, cup-shaped molecules with a hydrophilic exterior and a hydrophobic interior, which allows them to form inclusion complexes with hydrophobic molecules. Inclusion complexes are bimolecular complexes in which the "host" forms a cavity into which the "guest" molecule binds through noncovalent interactions. CDs are composed of six, seven, or eight glucose units, termed α, β, and γ, respectively; are water soluble; and are U.S. Food and Drug Administration (FDA) approved as solublizing agents for hydrophobic drugs. Davis et al. have investigated cationic molecules containing CDs as gene delivery vectors since 1999 [19]. Cationic CDs could form stable complexes with DNA with sizes in the 100-nm range. More recently CD–PAMAM [149, 154, 155] and CD–PEI [156, 157] have been investigated and were found to efficiently transfect cells and be less toxic than their parent molecules. Furthermore, both CD–PAMAM and CD–PEI have been successfully used *in vivo* [155, 156]. Furthermore, cyclodextrin containing polymers have been recently used to deliver siRNAs to inhibit tumor growth [87]. As mentioned for other cationic polymers, modifications to include targeting functionality are often desirable of a gene delivery formulation. A key advantage of cyclodextrin containing gene delivery formulations is that functionality can be added through inclusion complexes without covalent modifications. Therefore, targeting molecules, which contain a hydrophobic molecule bound to them, can be "tethered" to the polyplex via cyclodextrin. This approach has been used to introduced PEG [158], galactose [158], transferring [88, 159], and insulin [157] to cationic cyclodextrin formulations.

Cationic Lipids. One of the most investigated approaches for condensing nonviral DNA for efficient gene transfer is the use of cationic lipids. Felgner et al. [23] and Bennett et al. for ON [160] used cationic lipids for the first time to deliver DNA and ONs. More recently, siRNA has been delivered to mammalian cells using commercially available lipids [161–163]. The structures of several frequently used

cationic lipids are shown in Table 7.3-2. Although some cationic lipids are used individually to deliver nonviral DNA (e.g., DOTAP), many formulations of cationic lipids also contain a zwitterionic or neutral colipid, such as DOPE (Table 7.3-2) or cholesterol, to enhance transfection. Formulations of cationic lipids have been widely applied for *in vitro* nucleic acid transfection, and more than 30 products are commercially available for this purpose, including Lipofectin (a 1:1 mixture of DOTMA and DOPE), Transfectam, Lipofectase, Lipofect-AMINE, and LipoTaxi [164].

The main components of a cationic lipid are a hydrophilic lipid anchor, a linker group, and a positively charged head group. The lipid anchor is typically either a fatty chain (e.g., derived from oleic or myristic acid) or a cholesterol group, which determines the physical properties of the lipid bilayer, such as flexibility and the rate of lipid exchange [24]. The linker group is an important determinant of the chemical stability, biodegradability, and transfection efficiency of the cationic lipid. Biodegradable lipids are being developed, which can be metabolized by various enzymes (e.g., esterases and peptidases) to minimize toxicity [165, 166]. The linker can also provide sites for the introduction of novel side chains to enhance targeting, uptake, and trafficking. The positively charged head group on the cationic lipid self-assembles with the negatively charged DNA and is a critical determinant of the transfection and cytotoxic properties of liposome formulations. The head groups differ markedly in structure and may be single- or multiple-charged as primary, secondary, tertiary, and/or quaternary amines. The synthesis of novel cationic lipids from libraries of building blocks has provided insight into some structure-activity relationships [167–169]. The hydrophobicity of the lipid moiety has a crucial effect on *in vitro* gene transfer. Multivalent head groups, such as spermine, in a "T-shape" configuration tend to be more effective than their monovalent counterparts at facilitating gene transfer [24, 168, 170]. Generally, increases in the linker length correspond to increases in the gene delivery activity [169]. Continued progress toward a comprehensive relationship among lipid structure, complexation with DNA, and subsequent interaction with the biological environment (e.g., cell membrane and extracellular membrane components) is necessary to facilitate the design of cationic lipids with optimal properties.

Mixing of DNA and cationic lipid results in the collapse of DNA to form a condensed structure (lipoplex), in which nucleic acids are buried within the lipid. The thermodynamic driving force for association of the DNA and lipid is the entropy increase from the release of counter-ions and bound water associated with DNA and the lipid surface [29, 171]. Liposome association with DNA has resulted in tube-like bilayers [28, 172], multilameller complexes [27, 29, 173, 174], as well as structures containing non-bilayer elements [26]. Multilamellar organization, in which DNA is intercalated between cationic lipid bilayers, has been reported for lipolexes resulting from the interaction of DNA with unilameller vesicles of a cationic lipid, such as DOTAP [29] and DODAB [27], respectively, combined with DOPE and cholesterol. Both of these studies used x-ray scattering to show that a periodicity of 6.5 nm occurs in the lamellar structure. The cationic lipid bilayer thickness was 3.9 nm, and the thickness of the water layer was 2.6 nm, which is sufficient to include a hydrated DNA double helix with a total diameter of 2.5 nm. A second periodicity was observed, which was attributed to a DNA–DNA correlation, which ranged from 2.45 nm to 5.71 nm as the concentration of helper lipid was

increased. These lamellar complexes can be converted into hexagonal complexes with DNA confined in inverted lipid micelles by changing the membrane spontaneous curvature or the membrane flexibility [175]. This hexagonal arrangement has demonstrated increased transfection, which is attributed to the relative instability of the complexes due to rapid fusion with anionic vesicles and subsequent DNA release. X-ray diffraction studies and microscopy have illustrated the high degree of variability in lipoplex structure and the need to understand and control the parameters that govern the organization of these structures.

The colloidal properties (e.g., size and stability) of the lipoplexes are principally determined by the cationic lipid/DNA charge ratio and not the composition of the lipid or the helper lipid [176]. The charge ratio (+/−) is typically defined as the number of amines on the cationic lipid relative to the number of phosphate groups on the DNA. A neutral charge ratio (1 : 1 charge ratio for lipid/DNA) is typically avoided because it results in the formation of large aggregates (>1 μm) [176]. Lipoplexes prepared at a positive charge ratio and a negative charge ratio likely represent structures with different lipid and DNA packaging [176]. At a positive charge ratio, large multilamellar vesicles (LMVs, diameter 300–700 nm) transfected cells more efficiently than the small unilameller vesicles (SUVs, diameter 50–200 nm) [24, 177, 178]. These observations were consistent whether the structures were formed as LMVs or as SUVs that aggregated to form LMVs [177]. The order in which DNA and lipid are mixed is critical and significantly affects the lipid and DNA packing [171, 176]. For the addition of DNA to lipid, a gradual increase in size was observed. When adding lipid to DNA, the particle size remains roughly constant until the amount of lipid positive charge exceeds the nucleic acid negative charge, whereupon the particles grow rapidly in size [171].

The net charge on the lipoplex affects its interactions with other components present *in vivo* and *in vitro* (e.g., media, serum, extracellular matrix glycoproteins, and mucosal secretions), which can limit the transfection efficiency. A positive charge ratio, which facilitates interactions with the cell membrane, is frequently used for *in vitro* studies (3 : 1), whereas *in vivo* studies may require the charge ratio to be altered because of interactions with components of the physiological environment [11]. The charge ratio of the complex determines the zeta potential, which ranges from −55 mV to +55 mV as the charge ratio is increased [179]. Multivalent anions present in the serum or media can facilitate fusion of the lipids causing an increase in the size of the particle. Polyanions with adequate anionic charge density (e.g., heparin) release DNA from the complex by binding the cationic lipid [179]. Serum can be a complicating factor for positively charged complexes, possibly causing premature release of the DNA from the complex and enhancing degradation by nucleases. For ON : lipid complexes, the various components of serum (e.g., BSA, lipoproteins, macroglobulin) interact with the complexes and alter the complex diameter, zeta potential, and interfere with cellular uptake and nuclear trafficking [180].

Aggregation of lipoplexes in polyelectrolyte solutions occurs rapidly, which can result in loss of activity in less than 24 hours; thus, strategies are being developed to stabilize the particles and prolong their shelf life. To improve lipoplex stability, PEG–PE has been incorporated into the cationic liposome. PEG containing liposomes are prevented from aggregating and interacting with serum components, which increases their stability [181–183]. Alternatively, new preparation methods

are being developed in which a detergent is present in solution with the cationic lipid and DNA [184]. Removal of the detergent by dialysis allows the formation of uniform complexes. This process yielded a lipid/DNA suspension that was able to transfect tissue culture cells up to 90 days after formation with no loss in activity. Lyophilization, which is a common approach used for many pharmaceuticals, is also being applied to lipoplexes to increase their shelf life. Cryoprotectants (e.g., sucrose and trehalose) are typically added to prevent aggregation and fusion of plasmid/lipid complexes during lyophilization. Complexes lyophilized in the presence of 0.5-M sucrose or trehalose maintained transfection rates and the sizes of rehydrated complexes as compared with nonlyophhilized controls [185].

Cationic polymers such as poly(amino acids) have also been used in combination with liposomes. DNA is initially complexed with polylysine (PLL) at low charge ratios and cationic lipids are subsequently added to completely condense the DNA. Alternatively, the PLL condensed DNA containing a net positive charge can subsequently be complexed with an anionic lipid [168]. Precondensation with polylysine has been shown to reduce serum inhibition and to enhance the transfection efficiency [186, 187].

Catinic polymer formulations have been extensively used to deliver nucleic acids *in vivo* for the treatment of cancer [89–97] and cystic fibrosis [98–102] as an anti-inflammatory agent [103] and to prevent or reduce viral infections [104]. Table 7.3-6 summarizes the use of cationic polymers to deliver nucleic acids *in vivo* and for a therapeutic purpose.

7.3.3 MATRIX-BASED DELIVERY

Matrix-based delivery has been proposed to enhance gene transfer *in vivo* by delaying clearance from the desired tissue, protecting the nucleic acid from degradation, and extending opportunities for internalization. Furthermore, matrix-based delivery can provide sustained delivery to maintain the vector at effective levels within the target tissue. Many of these properties have been observed for controlled release systems that deliver proteins [188]. Gene transfer from tissue engineering matrices may increase the number of cells expressing the transgene along with the extent of transgene expression, while minimizing the quantity of vector used. Additionally, matrix-based delivery may reduce the number of dosages or the required cumulative dose [188]. Matrix-based delivery of nucleic acids can be divided into two delivery approaches: (1) direct encapsulation and release, where naked DNA, polyplexes, or lipoplexes encapsulated into the matrix for later release; and (2) matrix-tethered delivery (also called substrate-mediated or solid phase delivery), where polyplexes or lipoplexes are immobilized to the matrix for release after matrix or tether degradation (Figure 7.3-2). To date most matrix-based delivery approaches involve the encapsulation of naked DNA and its subsequent release to transfect surrounding cells. Polymer encapsulation strategies can shield the vector against degradation, clearance, and an immune response. Drug release from the matrix into the tissue can be designed to occur rapidly, as in a bolus delivery, or over an extended period of time, which may affect the local concentration and cellular internalization. For rapid release, levels would be expected to quickly rise and decline as the DNA is cleared or degraded. For sustained delivery, the

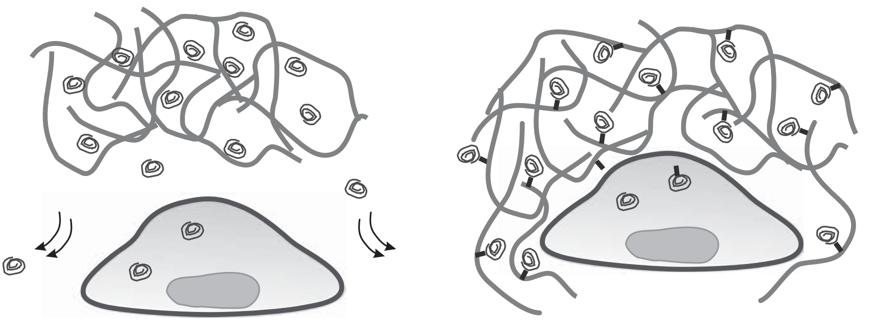

Figure 7.3-2. Matrix-based DNA delivery can be divided into encapsulation and release approaches, where the nucleic acid is encapsulated for later release, and matrix-tethered delivery, where nucleic acid polyplexes or lipoplexes are immobilized directly to a matrix that also supports cell adhesion. These approaches are typically used for applications in tissue engineering where the delivery of nucleic acids is used to augment tissue formation.

concentration may be maintained within an appropriate range by adjusting the release rate (e.g., through the polymer choice). Release of DNA from tissue engineering scaffolds has been observed for times ranging from hours to several weeks [113, 115, 189–191]. Variations in the polymer composition and physical form, which includes properties such as porosity, mass, and size, affects the diffusion of DNA from the vehicle and hence the release rate.

Tethered delivery approaches aim to significantly slow down release kinetics by immobilizing polyplexes or lipoplexes directly to the matrix. Because the polyplexes are immobilized to the matrix, the matrix must also support cell adhesion and infiltration by the surrounding cells rather than function as a nucleic acid reservoir. Internalization of the immobilized polyplexes results after the tether between the polyplex and the matrix is degraded, the matrix is degraded or the affinity of the polyplex for the matrix is reduced due to environmental changes. The release kinetics of the polyplexes in this case depends on the chemistry used for polyplex immobilization and the chemistry of the matrix. Biotynilated polyplexes immobilized to a NeutrAvidin coated substrate was the first example of matrix-tethered delivery [192]. This matrix-tethered delivery strategies resulted in a 100-fold increase of transgene expression compared with bolus delivery, likely due to an increase of the polyplex concentration at the cellular microenvironment. Furthermore, immobilization of polyplexes to the material surface has shown to enhace the stability of the polyplexes in polyelectrolyte solutions, preventing their aggregation [193]. The strength of the tether bond or the number of tethers affects both the density of immobilized polyplexes as well as the transfection efficiency. A high density of tethers results in high surface densities of DNA with low ability to transfect, probably due to the polyplex being too tightly bound to the matrix [192]. More recently, matrix-tethered strategies rely on electrostatic interactions between poly or lipoplexes and the matrix to immobilize the complexes [194, 195].

Matrix-based delivery has been investigated mostly for regenerative medicine applications. Regenerative medicine aims to regenerate tissue by implanting biocompatible and biodegradable scaffolds at sites of injury or disease. The implanted scaffold must provide the mechanical support for the growing tissue and the bio-

active signals needed for proper tissue formation while allowing for cell attachment and growth (for reviews on tissue engineering, see Refs. 196 and 197. Delivery of nucleic acids from tissue engineering scaffolds could be used as the bioactive signals needed to recreate the environments needed for tissue formation allowing for direct manipulation of cellular gene expression patterns. In the following sections, matrix-based nucleic acid delivery will be overviewed with Section 7.3.3.1 focusing on encapsulation and release approaches and Section 7.3.3.2 on matrix-tethered delivery approaches. Table 7.3-7 summarizes *in vivo* studies using matrix-based nucleic acid delivery.

7.3.3.1 Direct Encapsulation and Release

Direct encapsulation and release strategies have been proposed to enhance gene transfer *in vivo* by delaying clearance from the desired tissue, protecting the DNA from degradation and extending the opportunities for internalization (Figure 7.3-2). Furthermore, matrix-based delivery can provide sustained delivery to maintain the vector at effective levels within the target tissue.

Synthetic Polymers. Polymers composed of lactide and glycolide (PLGA) are perhaps the most widely used and recognized biodegradable synthetic polymers because these polymers are FDA approved and are generally considered to be biocompatible. Hydrolytic degradation of the polymer produces lactic acid and glycolic acid, two substances naturally involved in metabolic pathways of the body. The degradation rate can be controlled through the composition of the polymer and molecular weight of the chains. These polymers exhibit relatively even polymer chain scission throughout their bulk after being placed *in vivo*. These properties have led to the use of these materials for drug delivery and as scaffolds for tissue engineering [198]. Drug release from these systems typically occurs by a combination of polymer degradation and drug diffusion from the polymer. Gene delivery from polymeric matrices has been applied to tissue repair and wound healing [106, 113]. These matrices are typically implanted at a specific anatomic location where they serve multiple roles as described previously [139]. Initially, the matrix functions to create and maintain a space *in vivo*. However, the matrix also acts as a scaffold to support cell migration, proliferation, and differentiation of healthy cells from the surrounding tissue. As cells invade the matrix, they encounter DNA that is either released from or entrapped within the matrix.

A gas foaming/particulate leaching process can be employed to fabricate interconnected open pore structures of PLGA for controlled release of DNA [113, 199]. This process employs carbon dioxide to process a mixture of polymer and porogen, in order to fuse adjacent polymer particles into an interconnected structure. The DNA can be lyophilized with the microspheres [113] or encapsulated within the microspheres [200, 201]. Lyophilization of DNA with the microspheres can provide large quantities of incorporated DNA, with relatively rapid release kinetics. Incorporation of DNA into the microspheres provides for a more sustained release relative to the lyophilization method [200], with the release kinetics dependent on the polymer molecular weight and microsphere size [201]. DNA can be incorporated into polymer microspheres using several approaches [201–205]. Subcutaneous implantation of scaffolds results in transfected cells observed within the scaffold

and the tissue immediately adjacent to the scaffold, with protein production sufficient to promote physiological responses [113, 115]. An alternative approach to fabrication of PLG scaffolds for DNA delivery is electrospinning [206]. Electrospinning creates nonwoven, nanofibered membranous structures that release DNA, with maximal release occurring at approximately 2 hours.

Microspheres can also be employed to deliver DNA to tissues. Microspheres loaded with nonviral DNA can be fabricated from nondegradable and degradable polymers in sizes ranging from 0.1 to 100 μm and have been used for applications such as DNA vaccines and systemic protein delivery [198]. One of the main advantages for delivery vehicles of this size is that they can be administered in a minimally invasive manner (e.g., direct injection and oral delivery). The use of biodegradable polymers provides the additional advantage of not having to retrieve the implant after DNA release. Unfortunately, these two qualities (size and degradability) make removal of the devices difficult, should the therapy need to be terminated prematurely. The loading of DNA into the polymer ranges from 0.1- to 10-μg DNA per milligram of polymer using various techniques based on either an emulsion or phase inversion process [204, 207, 208]. A double emulsion process has been used to incorporate aqueous solutions of nonviral DNA, both supercoiled and complexed with poly-L-lysine, into polymer. Incorporation efficiencies ranging from 20% to 80% have been obtained, although the typical incorporation efficiency is approximately 30% [106]. When supercoiled DNA is incorporated using this procedure, the incorporated DNA is structurally intact with 39% of the DNA in the supercoiled conformation. Protecting the DNA by either condensation [207] or using a cryogenic approach [204] can be used to increase the DNA present in the supercoiled form to more than 80%.

DNA polyplexes have been encapsulated and released from polymer microspheres, which may enable these microspheres to be fabricated into matrices using an approach such as the gas-foaming procedure. PLL/DNA complexes have been incorporated into PLG microspheres using a double emulsion process. DNA is incorporated with efficiencies ranging from 30% to 45%, is released over approximately 35 days, and retains its integrity [207, 208]. Alternatively ONs complexed with PEI have been incorporated and released from PLG microspheres. The release profile of the ON/PEI complexes depended on the size, loading, and pore structure of the microspheres. The sustained release of ON/PEI complexes resulted in improved intracellular penetration of the delivered vector as compared with uncomplexed DNA [209, 210]. PLG/DNA scaffolds have successfully been used *in vivo* to enhance matrix deposition [113], angiogenesis [112, 113, 115], and bone formation [114].

Synthetic PEG hydrogels have been extensively investigated as cell transplantation vehicles and as tissue engineering scaffolds. Synthetic hydrogels allow for the complete engineering of the extracellular environment given that they lack direct cellular interactions and have limited protein absorption. Thus, every aspect of the extracellular matrix environment must be engineered, including integrin binding sites, growth factors, and other bioactive signals. DNA delivery from synthetic hydrogels based on PEG have shown that the release rate can be modulated depending on the degree of cross-linking and degradation rate of the hydrogel [211, 212]. Naked DNA encapsulated in photo-cross-linked PEG hydrogels could modulate the release profile of the DNA ranging from linear to a delayed release profile [211].

Naked DNA encoding for transforming growth factor beta-1 encapsulated in thermosensitive hydrogel scaffolds resulted in reepitelization of wounds in diabetic mice if applied at early stages during wound healing.

Natural Polymers. Collagens are the major component of mammalian connective tissue and thus have been widely investigated as a biomaterial for cell growth and drug delivery. At least 14 types of collagen are distributed throughout the body. The most abundant is type I collagen. Type I collagen is found in high concentrations in tendon, skin, bone, and fascia, and thus, these tissues are sources for its isolation. After isolation, typically from bovine or porcine sources, collagen is preserved using techniques such as fixation with aldehydes or other chemical preservatives, gamma-irradiation, or lyophilization [213, 214]. Collagen can be lyophilized to form a spongy product or can be formed into a hydrogel by using its natural ability to self-assemble at neutral pH and body temperature (37°C) or by covalently crosslinking it using aldehydes or carbodiimides [105–107, 215].

Collagen has been used as a matrix for numerous tissue engineering applications, including bone, skin, nerve, and cartilage [216–218]. The collagen serves as a scaffold for the migration of repair cells into the matrix and serves to either retain the DNA within the scaffold [106] or provide gradual release [191]. Collagen-based release may limit vector degradation and can induce transgene expression for up to 40 days [191]. Naked DNA delivery from collagen matrices has been employed to promote tissue formation by transfecting invading fibroblasts. Transfected fibroblasts within DNA-loaded collagen scaffolds, also termed gene-activated matrices (GAMs), subsequently act as bioreactors for localized production of tissue inductive factors. Matrices were prepared by lyophilization of type I collagen and subsequent immersion in a DNA solution. For applications in tissue engineering, collagen/DNA constructs have been implanted into an adult rat femur [105] and a canine bone defect model [106]. Matrices loaded with 1 mg of DNA were capable of transfecting cells *in vivo*, which resulted in protein production for up to 3 weeks postimplant. For the canine model, however, regeneration required 100 mg of plasmid delivered from the matrix for regeneration [106]. Atelocollagen/DNA constructs have also been used for therapeutic applications, including implanted constructs in the muscle to increase platelet number [191], and in the rabbit ear to aid in would healing [110]. Furthermore, atelocollagen/siRNA constructs have been delivered intratumorally to suppress tumor growth [108, 109].

DNA complexed with cationic lipids or cationic polymers can also be incorporated and released from collagen-based matrices, while maintaining their activity. Naked DNA delivery produces substantial transgene expres-sion *in vivo*, but it results in low levels of transgene expression *in vitro*. DNA complexes can transfect cells *in vitro*; thus, the ability to release DNA complexes can extend the applicability of nonviral DNA release matrices to the engineering of tissues *in vitro*. Note, however, that release of DNA complexes may differ significantly from that for naked DNA, due to the different physical properties of complexes relative to naked DNA. Collagen matrices loaded with DNA by pipetting solutions of naked DNA, PEI/DNA complexes, and lipoplexes onto collagen showed different release kinetics [189]. *In vitro* release studies demonstrated that naked DNA was rapidly released, PEI/DNA and lipid complexes were slowly released, and that PEI/DNA complexes with a protective copolymer had intermediate release kinetics. The

PEI/DNA complexes with the protective copolymer gave the highest transfection *in vitro* and *in vivo*, with the highest *in vivo* expression occurring at 4 days and measurable quantities observed at 7 days [189]. PLL/DNA complexes encapsulated in a collagen sponge have been implanted into severed rat optic nerves as a means to promote neuron survival and promote regeneration [111]. The PLL was modified with bFGF to facilitate the internalization and intracellular trafficking. DNA was detected in the retina for up to 3 months. Nerve terminals were observed extending into the collagen, and they seemed appeared capable of transporting the DNA by retrograde transport.

Hydrogels based on agarose, fibrin, hyaluronic acid (HA), and chitosan have been employed independently as biomaterials for fabrication of tissue engineering matrices [219–221] or as materials to regulate DNA delivery. Fibrin matrixes have been extensively used as tissue engineering scaffolds, sealants, and drug delivery matrices. Fibrin sealants have been employed for the delivery of plasmids to promote angiogenesis, with fibrin-based delivery providing similar responses to delivery in PBS solution [119].

Agarose gels have been used to encapsulate PLL/DNA polyplexes and mediate sustained release to transfect smooth muscle cells *in vitro* with an efficiency less than that obtained by freshly formed complexes, but greater than that obtained with naked DNA [222]. Hydrogels based on fibrin and agarose primarily function to limit the release of DNA; however, hydrogels employing chitosan offer the potential to condense the DNA. Chitosan is a positively charged, naturally occurring polysaccharide that can form complexes with DNA. Chitosan/DNA complexes exhibit minimal cytotoxicity, destabilize the lipid bilayer to facilitate internalization [223], and produce high levels of transfection *in vitro* and *in vivo* [42, 224]. Tissue engineering matrices based on these hydrogels, or combinations of these materials, provide a variety of approaches to regulate DNA delivery *in vitro* and *in vivo*. HA-based matrices have not been used extensively for gene delivery, although their potential as tissue engineering scaffold has long been recognized. DNA loaded, cross-linked HA-based delivery systems have been formed in the form of matrices and microspheres. A solution of HA and plasmid DNA was lyophilized to form a spongy material before cross-linking with adipic acid dihydrazide to form a stable three-dimensional matrix. This HA matrix demonstrated the capacity for sustained release of naked DNA, with release likely occurring after degradation of the matrix [225]. The release rate of naked DNA from the matrices, some of which may be associated with HA fragments, could be modulated by the extent of cross-linking in the hydrogel. DNA-loaded hyaluronic acid microspheres have been formed and found to be able to deliver genes both *in vivo* and *in vitro* [226]. The microspheres were formed using a water-in-oil emulsion and covalent cross-linking with adipic acid dihydrazide to stabilize the microspheres. These microspheres could then be implanted to mediate *in vivo* gene delivery or delivered to plated cells. In both cases, the released DNA mediates transgene expression.

HA has also been cross-linked with collagen and used as gene delivery matrices. The procedure used can be similar to that used for collagen gene delivery systems or that used to form HA hydrogels. HA is mixed with collagen and lyophilized to form a spongy material. This material is then cross-linked using carbodiimide chemistry, dehydrothermal treatment, or exposure to ultraviolet light. After cross-linking, the matrices are soaked in a DNA solution [227] to introduce the DNA to

the porous scaffolds. These matrices have been shown to mediate transgene expression *in vivo* and *in vitro* [227].

7.3.3.2 Matrix-Tethered Delivery

Material-tethered delivery combines cationic polymer and cationic lipid formulations with matrix delivery to generate a more efficient delivery strategy by immobilizing the polyplexes or lipoplexes directly to a matrix that also supports cell adhesion and cellular infiltration (Figure 7.3-2). This approach places the nucleic acid directly at the cellular microenvironment, removing the need for diffusion of the complexes to the cell membrane Matrix tethered has not been as extensively used *in vivo* as the direct encapsulation methods described above; however, it has found success mediating DNA delivery from PLGA scaffolds and hyaluronic acid and fibrin hydrogels.

Synthetic Polymers. Matrix-tethered delivery approaches in synthetic polymeric matrices have focused on nonspecific interactions (adsorption) to immobilize the complexes to the matrix. PLGA scaffolds have been coated with a variety of polyplexes such as PAMAM/DNA and PEI/DNA. PAMAM/DNA complexes were dried on a porous PLG scaffold and shown to retain their activity, being able to mediate gene transfer both *in vitro* and *in vivo*, and were found to be a function of DNA concentration and charge ratio [228]. PEI/DNA complexes were absorbed to PLG scaffolds without allowing them to dry on the surface, in contrast to the method described above. It was found that delivery of DNA via matrix-based delivery resulted in similar levels of expression compared with bolus delivery; however, a lower dose of DNA was used. The amount of DNA immobilized was dependent on the time of incubation of the polyplexes with the scaffold, the N/P ratio used, and the initial amount of DNA used [195]. Interestingly, higher amounts of immobilized DNA did not result in higher transgene expression, with 45 ng resulting in more efficient transfection than 600 ng [195].

Natural Polymers. Hyaluronic acid and fibrin were employed independently as biomaterials for fabrication of tissue engineering matrices [221, 229–231] or as materials to mediate gene delivery [232, 233]. HA has been cross-linked with a wide variety of chemistries to form stable hydrogels. DNA/PEI complexes were immobilized to hyaluronic acid hydrogels via biotin–avidin bonds. PEI was modified with biotin groups and subsequently used to complex DNA to form biotynilated polyplexes. The polyplexes were then immobilized to a HA hydrogel, which had been chemically modified to introduce neutravidin, a biotin binding protein. Fibroblasts, which were directly in contact with the polyplex/HA hydrogel, were transfected; however, those directly adjacent to the hydrogel were not, indicating that direct contact of the cell with the tethered polyplexes is essential for transfection [233]. The size of the tethered polyplexes resulted in different transgene expression levels and percent of cells expressing the transgene. Small complexes (~150 nm) resulted in lower levels of transgene expression compared with large complexes (~1000 nm); however, small complexes resulted in ~50% of the cells transfected, which is double that of large complexes. Futhermore, the HA hydrogels used in these studies were topographically patterned with groves and ridges, which

resulted in spatially controlled gene expression along the ridges of the hydrogel surface [232].

Unlike HA, fibrinogen forms a stable hydrogel matrix upon thrombin activation to form a fibrin matrix. Fibrin matrices can be further stabilized by the addition of factor XIIIa, which forms covalent bonds between glutamine and lysine residues. Schense and Hubbell have used factor XIIIa chemistry extensively to bind biologically active peptides [234] and growth factors [235] to fibrin matrices. More recently, Hubbell et al. used the same strategy to immobilize polyplexes to fibrin hydrogels [120, 232]. Two different 21 amino acid peptides were designed to have a DNA binding sequences (Cys–His–(Lys)6–His–Cys) in combination with a transglutaminase substrate site (Asn–Gln–Glu–Gln–Val–Ser–Pro–Leu) or a nuclear localization site (from SV40; see Table 7.3-4). The polyplexes were formed with mixtures of the two poly(amino acids) and mixed with fibrinogen, thrombin, and factor XIIIa, resulting in the covalent immobilization of the polyplexes within the fibrin matrix. Transfection of COS-7 cells in a two-dimensional (2D) sandwich assay, in which cells are plated on top of a polyplex/fibrin hydrogel and then a second gel is cast on top, resulted in ~25% of the cells transfected [232]. These hydrogels have been used *in vivo* to deliver a mutant HIF-1α plasmid, which has the transcription factor constantly active, and resulted in enhanced wound healing in a skin wound model [120]. Furthermore, the delivery of a HIF-1α encoding plasmid was able to result in the formation of more mature blood vessels when compared with the delivery of a vascular endothelial growth factor (VEGF) encoding plasmid.

7.3.4 DELIVERY LIMITATIONS AND CURRENT SOLUTIONS

The ultimate applicability of the various biomaterials for gene delivery rests on their ability to effectively deliver the nucleic acids to their target intracellular location (Figure 7.3-1). An effective gene delivery system will protect the nucleic acid from degradation, target the appropriate cell population, be efficiently internalized by the cell, avoid degradative pathways, and ultimately localize to the nucleus (DNA) or cytosol (siRNA or ON, Figure 7.3-1). The materials under development can specifically enhance one or more of these steps in the transfection process. The following sections describe how the materials interact with biological systems and how they can be designed to overcome the obstacles to effective gene transfer. Table 7.3-3 also summarizes this data.

7.3.4.1 Extracellular Limitations

Vector Stabilization and Fast Clearance from Body. Interaction of nonviral formulations with serum components results in the deactivation of the lipoplexes or polyplexes due to aggregation [9, 10]. Furthermore, aggregated lipoplexes and polyplexes can lead to rapid clearance of the polyplexes by phagocytic cells and the reticuloendotheial sytem [8]. Hydrophilic polymers such as poly(ethylene glycol) (PEG) [39, 47, 236], N-(2-hydroxypropyl)methacrylamide) (HPMA) [236–239], and oligosaccharides [40, 41, 43, 236, 240] have been found to stabilize complexes against salt and protein aggregation, which results in longer circulation times. The increased stability probably results from steric effects that (1) prevent interaction

with serum proteins, cells, and tissue; (2) increase solubility of the complexes in aqueous milieu; and (3) prevent particle–particle interactions [241]. Traditional cationic polymers for gene delivery such as PEI, PAMAM, and PLL have been made more biocompatible using this approach [18, 241–245].

Targeted Internalization. The plasma membrane of the cell provides a protective shell that serves to limit the transport of undesired molecules, such as DNA. However, cells must communicate with their environment and have thus developed mechanisms to transport high- and low-molecular-weight macromolecules across the membrane. Nonclathrin-coated pit internalization can occur through smooth invaginations of 150–300 nm or via potocytosis, which involves the invagination of caveolae-rich 50–100-nm-diameter vesicles from the cell surface. DNA complexes are thought to enter cells primarily through clathrin-coated pits. These pits, with diameters of approximately 150 nm, are internalized from the plasma membrane to form coated vesicles. Interestingly, recent studies using a series of inhibitors for different endosomal pathways have elucidated different mechanisms of internalization for lipoplexes and polyplexes [246]. Lipoplex internalization and lipoplex-mediated nucleic acid delivery was strongly inhibited by potassium depletion or using chlorpromazine, indicating that clathrin endocytosis is the primary internalization pathway of lipoplexes [246]. On the contrary, polyplex internalization was inhibited by 25% when the caveolae pathway was inhibited using filipin or genistein and by 20% when clathrin-mediated endocytosis was inhibited [246], indicating that polyplexes use two internalization pathways. Gene transfer mediated by polyplexes was completely abolished when the caveolae pathway was inhibited but not when the clathrin-mediated pathway was inhibited [246], suggesting that internalization via caveolae-mediated endosomes leads to efficient transfection. Particle size also affects the endosomal internalization pathway used. Particles with a diameter <200 nm were found to be internalized via clathrin-mediated endocytosis and were ultimately delivered to the lysosome. In contrast, particles that were >500 nm entered the cells via caveolae and never reached the lysosomal compartment [247]. Furthermore, multiple studies have shown that large PEI/DNA complexes >500 nm were more efficient at mediating high transgene expression than small complexes <200 nm [233, 248], suggesting that it is due to mode of internalization and intracellular trafficking.

Receptor-mediated gene delivery offers a promising approach to create a specific interaction with the cell surface and to target a particular internalization pathway. Synthetic materials termed molecular conjugates are being developed and are composed of two domains: a DNA binding domain and a receptor binding domain. The DNA binding domain is in charge of linking the DNA to the rest of the molecular conjugate molecule. The DNA binding domain is typically composed of a cationic polymer or a cationic lipid, which self-assembles with DNA. The receptor binding domain is frequently attached to functional groups on the cationic polymer or lipid before complexation with DNA [169]; however, complexes can be initially formed and subsequently coupled to a ligand [182, 249]. The function of the receptor binding domain is to direct the DNA/molecular conjugate complex to a receptor and guide the complex through the internalization pathway that leads to endosomal entrapment. The intracellular fate of DNA complexes can depend on the type of endocytic process involved in its internalization [246]. The diversity and abundance

of membrane bound receptors and ligands and the high efficiency of internalization and turnover ratio makes receptor-mediated endocytosis a powerful tool for controlling uptake. Targets for which the attached ligand binds include the receptors for asialoglycoprotein [20, 250, 251], transferrin [47, 252–254] (review [48]), folate [45, 255, 256] (review [46]), manose [49, 50], galactose [51], lectins [257–259], integrins [55, 179] antibodies [52–54, 56] and EGF [57, 260]. The attachment of a targeting ligand to the lipoplex has been shown to increase transfection by 1000-fold as compared with lipid with no targeting ligand [261]. In principle, any monoclonal antibody, Fab fragment of a monoclonal antibody, peptide, peptide mimetic, proteins, or peptide fragment can be added to the molecular conjugate using either a covalent or an ionic attachment.

Maximal gene delivery through the receptor-mediated endocytosis pathway requires that the design parameters be optimized, which includes properties such as the ligand binding affinity, the length of the linker between the ligand and the complex, the complex charge ratio and structure, and the number of ligands per complex [260, 262]. Ligand–receptor interactions can be very specific and may be negatively affected when covalently bound to a molecular conjugate. Knowing whether the receptor binding domain is interacting to its receptor with the same efficiency as the free ligand is important to achieve high gene delivery levels. In a model using an EGF–polylysine conjugate, it was found that a longer spacer arm, between the two domains, resulted in more native-like EGF–receptor binding and higher transfection efficiency than shorter spacer arms [260]. The presence of the ligand can alter the structure of the nucleic acid complex. Incorporation of asialoorosomucoid into PLL/DNA complexes was more efficient at condensing DNA than PLL alone, probably due to an aggregation of many PLLs around the negatively charged protein [122]. At low charge ratios, specific (ligand mediated) and nonspecific endocytosis had insignificant levels of transfection. As the charge ratio was increased to 4, the transfection efficiency by specific binding enhanced transfection by a factor of 3 over nonspecific endocytosis [260]. Finally, the number of ligands per complex can affect the binding of the complexes to cells. An excessive number of ligands may inhibit the binding of complexes [260]. Optimization of the parameters that affect the surface binding of the molecular conjugates improves the specificity and gene transfer efficiency for gene delivery.

7.3.4.2 Intracellular Limitations

The steps after internalization of naked-DNA, polyplexes or lipoplexes, endosomal escape, and nuclear localization are thought to be rate limiting for the transfection of many cell types. Internalization of the plasmid does not necessarily correlate to transfection [263]. Much of the DNA that is internalized into the endosome is either retained or degraded within the endosome. The DNA that does escape the endosome and enters the cytoplasm must subsequently avoid degradation and be transported to the nucleus for successful gene transfer [264]. *In vitro* studies have demonstrated that although greater than 95% of the cells were positive for plasmid (>100,000 copies per cells), less than 50% of the cells were expressing the transgene [25, 265]. The following sections describe how the materials interact with intracellular biological systems and how they can be designed to overcome the obstacles for effective gene transfer. Table 7.3-4 also summarizes this data.

Toxicity. One common drawback of efficient nonviral gene delivery strategies is that they are generally toxic. This finding is not surprising given that efficient nucleic acid delivery formulations are also efficient at getting into the cell and moving through the intracellular space most likely in an unspecific manner. For example, PEI has been found to colocalize with the nucleous and with the delivered DNA, whereas PLL has not [266]. As reviewed, PEI is more efficient at gene transfer than PLL and PEI is more toxic than PLL. Nuclear PEI may nonspecifically interact with genomic DNA, preventing its normal transcription, thus causing toxicity. Furthermore, the efficient endosomal buffering of PEI and PAMAM dendrimers, while improving their effectiveness to deliver DNA, may also contribute toxicity by preventing the natural acidification of endosomal vesicles and degradation of unwanted endosomal cargo. Thus, can we have an efficient nucleic acid delivery strategy without some toxicity? Is it possible to have an effective therapeutic approach with absolutely no side effects? The answer is that it needs to be attempted although the blockbuster of nonviral gene delivery formulations may not be completely nontoxic. Some general characteristics of cationic polymers and lipids make them toxic such as molecular weight, density of positive charges, and lack of degradability. This section briefly outlines the most common features associated with toxicity and their current solutions.

Nonviral formulations are generally more efficient and more toxic as the polymer-to-nucleic acid ratio is increased (higher N/P ratios), suggesting a role of free uncomplexed polymer in the solution in efficient delivery and toxicity. A recent report has shown that polyplexes of DNA and PEI contain an average of 3.5 plasmids (5800 base pairs) and 30 PEI (25 kDa) molecules when prepared at N/P ratios of 6 and 10, assuming that the DNA is completely complexed [267]. Based on these calculations, there is 86% of free PEI in the complex mixture [267, 268]. Purification of the PEI/DNA complexes by dialysis has shown a reduction of toxcicity; however, it also reduced transfection efficiency [269]. Efficient gene transfer was restored when free PEI was added to the mixture [269].

High-molecular-weight cationic polymers are generally more toxic than low-molecular-weight polymers [124], most likely due to aggregation of free polymer with the cell membrane [130] or other cellular components. Together these findings suggest that free high-molecular-weight polymer leads to efficient but toxic gene transfer. Strategies to prevent such toxicity have focused on reducing the density of positive charges (number of primary amines) without affecting the buffering capacity of the polymer and, thus, reducing its interaction with the cell membrane and other cellular components.

Another structural aspect of cationic polymers that contributes to their efficiency as gene transfer agents and their toxicity is the degree of branching and backbone flexibility. Highly branched cationic polymers form smaller particles and mediate more efficient gene transfer than low-branched polymers but are more toxic compared with low-branched or linear polymers [130]. The high toxicity of branched polymers has been associated with polymer backbone stiffness; more flexible, hyperbranched PEI derivatives with additional secondary and tertiary groups show lower toxicity *in vitro* than commercially available branched PEI [270].

One approach that could reduce the toxicity associated with a high molecular weight and a high degree of branching is making the delivery formulation

degradable. Degradable PEIs are of particular interest because the basic structure of PEI is not biologically or chemically degradable. Efforts to make PEI degradable typically involve the cross-linking of low-molecular-weight PEI (600–1800 kDa) with disulfide linkages [61] or oligo(L-lactic acid cosuccinic acid) [60] to form the higher molecular weight PEIs required to achieve efficient transfection. Furthermore, low-molecular-weight PEI has been cross-linked with PEI through a degradable ester bond [242]. Cytotoxicity experiments showed decreased toxicity or complexes formed with degradable PEG–PEI/DNA complexes when compared with complexes formed with 25-kDa PEI [242]. However, transfection studies showed that the degradable PEI was less efficient at mediating gene transfer than 25-kDa PEI [242]. Although PAMAM dendrimers have been found to be three orders of magnitude less toxic than PEI (600–1000 kDa) and PLL (36.6 kDa), they still suffer from toxic effects [124]. The toxicity of PAMAM dendrimers seems to have a different mechanism from that of toxicity caused by linear cationic polymers in that it does not cause membrane hemolysis at a similar concentration of PEI and PLL [271]. It has been reported that primary amines are more toxic than secondary or tertiary amines for PEI-type polymers [10]. However, for PAMAM dendrimers, this relationship was not true. Although cytotoxicity increased with generation (higher molecular weight), it was surprisingly independent of surface charge [272, 273]. Strategies to reduce toxicity of PAMAM dendrimers include quaternization [131], reducing or reversal of surface charge [274], and sterically shielding the surface groups by binding C12 lauroyl groups or PEG2000 [272] Cytoxicity of PLL, although low relative to many nondegradable delivery agents, is not negligible. Dendritic PLL has been found to have cytoxicity that is much lower than that of PLL and is nearly the same as naked DNA, although the PLL itself leads to cell viability of about 80% of naked DNA as determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay [275].

Endosomal Escape. After internalization, the coated vesicle transforms into an early endosome, which is accompanied by acidification of the vesicular lumen that continues into the late endosomal and lysosomal compartments, reaching a final pH in the perinuclear lysosome of approximately 4.5. For lipoplex-mediated delivery, the interaction of the lipids with the endosomal membrane is thought to facilitate escape of the DNA to the cytoplasm before its degradation in the lysosome. Although it is not well understood, some lipoplexes preferentially fuse with the early endosome, whereas others fuse with the late endosome [24]. pH-sensitive liposomes can take advantage of the acidification process to facilitate the release of plasmids into the cytoplasm before lysosomal degradation [276]. Release of the DNA from the complex may occur at the wall of the endosome [179, 277]. Xu and Szoka proposed a model in which destabilization of the endosomal membrane causes a flip-flop of anionic lipids from the cytoplasmic facing monolayer, which diffuse laterally into the complex and form a charge neutral ion pair with the cationic lipid [179]. This pairing results in displacement of the DNA from the cationic lipid and release of the DNA into the cytoplasm. Displacement of the cationic lipid from the DNA before it enters the nucleus is critical for the ultimate expression of the gene.

Materials containing secondary and tertiary amines that are protonated at acidic pH, and not at neutral pH like primary amines, can act as proton sponges that

buffer the decrease in pH and ultimately cause DNA release into the cytoplasm. For example, PEI shows a level of protonation of 20% at pH = 7.4 compared with about 45% at pH = 5 [278]. This proton sponge effect is thought to result from the protonation of amino moieties on the polymer as the pH decreases inside the endocytic vesicle. The influx of counter Cl^- ions, which occurs to maintain electroneutrality, induces osmotic swelling and rupture of the vesicle membrane [29]. Evidence for the proton sponge hypothesis include decelerated acidification of endosomal vesicles, as well as elevated chloride accumulation and a 140% increase in the relative volume in PEI-containing endosomes [279]. Modifications investigated for PLL to introduce endosomal buffering include the partial modification of the PLL side chains with imidazoles [140, 280] or histidine [65]. Both approaches have been found to enhance the release of DNA complexed with PLL from the endosome.

Endosomal disrupting peptides, also termed fusogenic peptides, can be covalently incorporated into DNA/lipid and DNA/cationic polymer complexes to enhance escape from the endosome [281, 282]. Viruses and bacteria have evolved sophisticated endosomal release pathways [283]. Based on the viral and bacterial pathways, peptides for gene delivery have been identified from the viral fusion proteins and have been used successfully to enhance endosomal escape. An extensive list of fusogenic peptides can be found in Ref. 284. The peptides range in length from 15 to 30 amino acids and form stable amphipathic α-helices primarily due to alternating hydrophilic and hydrophobic amino acids. Most peptides are amphipathic pH sensitive being only active at low pH [283]. There are two mechanisms by which fusion peptides disrupt endosomal membranes. First, the peptide causes the rearrangement of the lipid packaging, thereby changing the membrane integrity and causing release of the endosomal contents. Second, the peptide causes pore formation within the endosomal membrane, without affecting the membrane integrity [283]. Most peptides induce endosomal release by membrane disruption rather than by membrane fusion [283]. For example, GALA, which was one of the first synthetic peptides to be designed and synthesized, undergoes a conformational change to form an alpha-helix at acidic pHs [66, 67, 284]. The α-helix formed induces endosomal leakage by disrupting the endosomal membrane. A similar peptide, KALA, also functions to disrupt endosomal membranes but is positively charged and is capable of condensing DNA and mediating gene delivery [63, 64].

More recently, a family of acid responsive polymers based on α-alkyl acrylic acids such as methacrylic acid (MAA), ethylacrylic acid (EAA), propylacrylic acid, and butylacrylic acid (BAA) and their copolymers with alkyl acrylates or methacrylates have been explored for their ability to disrupt membranes and their potential as endosomal disruption polymers. The key feature of these poly(α-alkyl acrylic acids) is that they switch from a hydrophilic to a hydrophobic character as they become protonated (pH sensitive), and the switch to a hydrophobic character has been shown to disrupt membranes [68, 69]. The polymer, PPAA, has been shown to be 15 times more effective than PEAA at membrane disruption and to have maximum hemolytic activity at pH ≤ 6, which is in the range of endosomal pH [68, 285]. PPAA has been successfully been used to enhance lipolyplex-mediated gene transfer [286] *in vitro* and wound healing by altering extracellular matrix organization and greater vascularization *in vivo* [286].

Nuclear Localization. The transport of DNA from the cytoplasm to the nucleus may be the most significant limitation to successful gene transfer. Plasmids injected far from the nuclei (60–90 μm) had less protein expression than plasmids injected near the nuclei [287]. In addition to cytoplasmic transport limitations, the size of DNA is problematic for crossing into the nucleus. The nuclear pores allow free diffusion entry of only small particles (less than approximately 70 kDa) [288]. Entry of the DNA can be facilitated by the breakdown of the nuclear membrane, which occurs during cell divi-sion [289]. However, for delivery to nondividing cells, nuclear localization sequences (NLSs) can be incorporated into the DNA complexes to direct the plasmid into the nucleus.

NLSs are short peptide sequences (5–25 amino acids) that are necessary and sufficient for nuclear localization of their respective proteins [288]. These sequences can be incorporated into complexes with cationic lipids [290] and cationic polymers [291, 292], or they can be directly linked to the plasmid [293, 294]. Some nuclear localization signals have stretches of positive charge, which has led to speculation that cationic polymers function as nuclear localization signals [186]. The cationic polymer PEI rapidly accumulates in the nucleus of cells and to a greater extent than PLL [266]. Nevertheless, the attachment of NLS does significantly enhance nuclear accumulation [291]. For the transfection of nondividing endothelial cells, lipoplex transfection resulted in 5% of the cells testing positive for transfection, whereas the incorporation of an NLS resulted in more than 80% of the cells testing positive [290]. Examples of nuclear localization sequences include PKKKRKVEDPY (SV40) [76], GNQSSNFGPMKGGNFGGRSSGPYGGGGQYFAKPRNQGGY (M9) [77], importin-β (1–643aa) [78], and MRRAHHRRRRASHRRMRGG (mu) [79].

Vector Decomplexation. Recently, vector decomplexation has been viewed as another limiting step to efficient gene transfer [72]. Vector decomplexation involves the events that need to take place for the dissociation of the delivery formulation from the nucleic acid. This step is critical for efficient gene transfer to take place given that without it DNA cannot be transcribed and siRNA/ON cannot efficiently mediate gene downregulation. Strategies to enhance decomplexation involve the introduction of environmentally sensitive bonds (mostly disulfide bonds) [244, 295] and reducing the affinity of the cationic polymer for the DNA [70, 71, 73]. More recently, a thermosensitive copolymer, N-isopropylacrylamide-co-vinyl laurate, was covalently coupled to chitosan and employed to enhance unpacking. At temperatures below the polymer's critical solution temperature, the polymer extended and was soluble, causing the enhanced unpackaging of the chitosan/DNA polyplexes [75]. Furthermore, enzymatically degradable formulations (chitosan) have been used to enhance unpackaging and gene transfer by encouraging intracellular enzymatic degradation (via chitosinase) of the polyplexes [74].

7.3.5 OUTLOOK

The design and construction of ideal formulations for nonviral gene delivery will continue to focus on generating materials that are "smarter," taking advantage of the cell's natural environments and processes. One approach to the design and

synthesis of smarter nonviral gene delivery formulations is to better understand the intracellular and extracellular limitations at the molecular level and to understand the role (positive or negative) of the intracellular and extracellular molecules and environments that the lipoplexes and polyplexes come in contact with during the transfection process. The cell is a complex structure that contains a myriad of molecules and events occurring simultaneously, which result in specific cell phenotypes. How the addition of lipoplexes and polyplexes affect this harmonious environment is essential for the design and generation of nonviral formulations that are less toxic and more effective, and this design is likely to be different for different cell types. For example, recent studies have shown that the rigidity of the matrix where the cells are attached affects polyplex uptake and transgene expression, with stiffer materials resulting in enhanced uptake, unpackaging, and gene expression [296]. Although the molecular mechanism for this enhancement was not elucidated in this study, it is clear that the cellular environment (extracellular and intracellular) and cell "state" affects the effectiveness of nonviral formulations. During the past decade, nonviral gene delivery has identified key limiting steps to polyplex and lipoplex formulations and has addressed these limitations with clever solutions such as the attachment of specific cell binding ligands, fusogenic peptides, nuclear localization sequences, and degradability. The next decade will undoubtedly come with more advances for nonviral formulations that can more elegantly bypass the different barriers encountered during gene transfer.

7.4.1 INTRODUCTION: NUCLEIC-ACID-BASED THERAPEUTICS

Nucleic-acid-based therapies include various forms of gene and antisense therapeutics. Gene therapy encompasses the use of plasmid vectors, retroviral and lentiviral vectors, adeno-associated virus (AAV) and other methods of introducing a gene expression or gene silencing nucleic acid sequence into a target tissue or cell. Gene silencing has been achieved with ribozymes, small interfering double-stranded RNAs (siRNAs), and synthetic antisense oligonucleotides (ASOs), whether these are unmodified or chemically modified DNA or RNA structures (Figure 7.4-1). Additional chemically synthesized, but not natural, oligonucleotides include DNA-like peptide nucleic acids (PNAs) and phosphorodiamidate morpholino oligonucleotides (PMOs) (Figure 7.4-1). Some nucleic-acid-based therapeutics are designed to influence the splicing of pre-mRNA to modify or alter the protein produced, rather than to silence the gene expression entirely [1, 2, 3]. Many gene therapy and antisense approaches have unique applications based on local delivery, which limits the distribution of the therapeutic in the body and precludes considerations of their pharmacokinetics (PK). We have included key citations describing PK for some gene-based and oligonucleotide-based approaches in Table 7.4-1, but the remainder of the chapter is limited to ASOs and siRNAs for brevity and clarity.

Most PK studies of nucleic-acid-based therapies are, in fact, devoted to description of the PK properties of ASOs. Many academic and industry researchers have chosen to focus on the use and development of synthetic ASOs as therapeutics. RNA- and DNA-based ASOs designed against a large number of targets have progressed through preclinical stages and into clinical trials. As a consequence, there is a large body of literature describing the PK properties of these ASOs in animals and humans. We will first discuss the various chemical structures of ASOs being developed as therapeutics, and then we will focus on the published animal and human PK data regarding ASOs of two chemistries, exemplified by Genasense (Oblimersen, G3139, targeting the mRNA for the anti-apoptotic protein Bcl-2) and OGX-011 (targeting the mRNA encoding the chaperone protein clusterin).

The second major (and more recent) focus in the literature is on the PK properties of various embodiments of siRNA therapeutics. Excitement has grown recently with our increased understanding of the mechanisms responsible for the endogenous pathways of posttranscriptional gene silencing, also known as RNA inter-

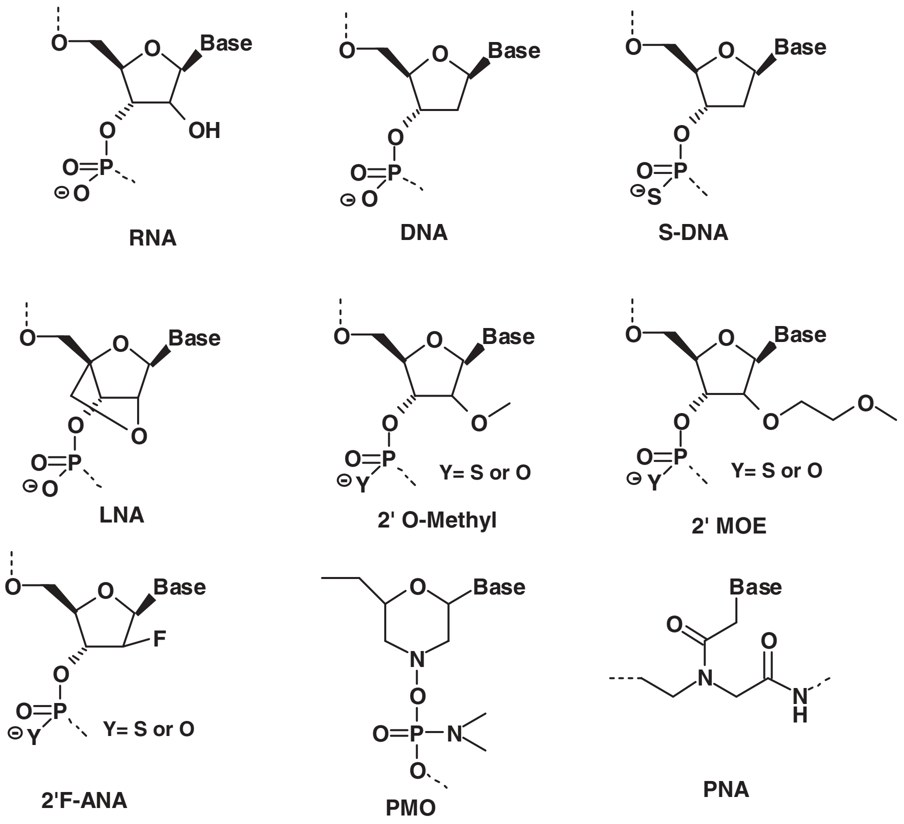

Figure 7.4-1. Nucleic acid analogs and artificial backbones commonly used in ASOs and siRNAs.

ference (RNAi). This understanding has led to design and synthesis of expression vectors, short hairpin RNA (shRNA), and small interfering RNA (siRNA) molecules to reduce or silence expression of target genes. Although use of RNAi technology is widespread in laboratories, therapeutic applications are not yet as far advanced as for ASOs. Studies describing PK properties of siRNA in animal

models are limited, and only three siRNA molecules are currently in human clinical trials. The relevant preclinical PK studies and the ongoing clinical trials are discussed in the latter portion of the chapter.

7.4.2 ANTISENSE CHEMISTRIES—MODIFICATIONS TO DNA/RNA STRUCTURE

ASOs are designed to reduce expression of a target protein based on double-stranded Watson–Crick base pairing with the mRNA coding for the protein. RNA-based ASOs act by inhibiting translation of the target mRNA, and subsequent normal protein turnover (degradation) results in reduced target protein levels in cells [21, 22]. DNA-based ASOs, also known as oligodeoxynucleotides (ODNs), mediate mRNA degradation by activation of endogenous ribonuclease H and subsequent exonuclease cleavage of the target mRNA [23–26]. Again, routine protein turnover reduces target protein levels in cells in the absence of the mRNA to provide template for new protein synthesis. Advantages of ASOs over other nucleic-acid-based strategies include ease of delivery into cells and tissues, improved specificity for individual mRNA target molecules, flexibility in target choice and reagent design, and relative ease of chemical synthesis that facilitates large-scale production of pharmaceutical-grade material [22, 27–29].

Early studies with unmodified phosphodiester (PD) DNA ASOs revealed various problems, including delivery into target cells and nuclease sensitivity in body fluids and in cells. Since then, numerous chemical modifications to the DNA structure have been incorporated into ASOs (see Figure 7.4-1). One of the first improvements was inclusion of phosphorothioate internucleotide linkages (PS DNA), where the nonbridging oxygen is replaced with a sulfur atom. This improved stability against endo- and exonucleases inside cells and in body fluids [22, 30]. “Second generation” ASOs were designed to include 2′-methoxyethoxylation (2′-MOE), 2′-O-methyl, or other modifications of the ribose sugar group [31–33]. These modifications at the 2′ position enhance uptake and stability of antisense ODNs [22, 32], but they preclude RNase H activity. ASOs containing 2′ modifications at the 5 or 6 nucleotides on each end, with DNA bases in the central region (called “gapmers”), retain the ability to provide a suitable target for ribonuclease H [25, 32, 34, 35]. Several PS DNA ASOs and gapmer ASOs have progressed through preclinical development stages, including PK and toxicological studies, and many are currently in human clinical trials (see Table 7.4-2).

In terms of PK properties, ASOs of the same chemistry but with different nucleotide base sequences seem to behave identically. In contrast, differences in PK profiles depend critically on the ASO chemistry and modifications. That is, ASOs with the same base sequence but having PS versus PD, or DNA versus RNA versus 2′-MOE modifications will have slightly or vastly different PK profiles [32, 34]. Furthermore, separately from PK properties, differences in the nucleotide sequence incorporated into ASOs with identical chemistry do affect physiological responses, including toxicities and off-target effects. For example, ASOs containing CpG dinucleotide motifs often activate particular toxicities and immune responses [62–64]. Toxicological changes are also dependent on backbone and sugar modifications, such as activation of the complement cascade by ASOs with PS inter-

nucleotide linkages but not by those with PD backbones [45, 65, 66]. These toxicological issues are not discussed in detail here, but they have been reviewed recently elsewhere [62, 65, 67].

7.4.3 ADDITIONAL SYNTHETIC CHEMISTRIES

Several groups of researchers have been pursuing alternative synthetic chemistries to achieve the desirable properties of an ideal ASO. Some of these designs that are in more-advanced stages of development as potential drug candidates are shown in Figure 7.4-1. These include locked nucleic acids (LNAs) [16, 17, 68–71], 2′-fluoroarabinonucleic acids (FANAs) [72–74], PNAs [75–79], and PMOs [13, 14, 80–83]. Only a limited number of ASOs with these chemistries have progressed to PK studies in rodent models, primate models, or human clinical trials. Relevant PK studies regarding this group of nucleic-acid-based ASOs are given in Table 7.4-1. For brevity and due to the lack of human PK data, we will limit our discussion of these other chemistries.

7.4.4 METHODS FOR DETECTION OF ASOs IN TISSUES AND FLUIDS

7.4.4.1 Labeled ASOs

In our work [84], we have used T4 polynucleotide kinase to end-label ASOs using radioactive [^{32}P]-γ-adenosine triphosphate (ATP). Methods to end-label or synthesize ASOs with biotin, fluorescein, digoxigenin, and so on, are also available. ASOs are amenable to internal labeling with radioactive halogens [85]. Radioactively labeled ASOs are tracked using phospho-imaging, gel electrophoresis, and other techniques. Fluorescence microscopy is used to monitor fluorescently labeled ASOs, whereas detection of biotin-labeled ASOs is done with anti-biotin antibodies or avidin-conjugated enzymes and appropriate substrates.

7.4.4.2 Nondenaturing Polyacrylamide and Capillary Gel Electrophoresis

Acrylamide gels (15% to 20%) can be used effectively to separate ASOs from longer intact nucleic acids and shorter degradation products [72]. Radioactively labeled ASOs are detected using standard autoradiography or phospho-imaging techniques [35]. Using acrylamide gels cast in capillary tubes, ASOs can also be separated, identified, and quantified after electrophoresis. Absorbance at 260 nm, mass spectrometry, and so on, can be used to detect ASOs as they leave the capillary gels [35, 86–88].

7.4.4.3 Hybridization-Based Approaches

Methods have been developed to detect ASOs in plasma and other biological samples, based on hybridization with labeled complementary probes [89]. The probes are tagged at one end with biotin and the other end with digoxigenin. After hybridization and binding to neutravidin-coated 96-well plates, nuclease S1 is added to degrade unhybridized probe. Anti-digoxigenin antibodies and enzyme-linked secondary antibodies are then added sequentially, followed by enzyme substrate (for example, AttoPhos, which fluoresces after enzymatic cleavage) for detection and quantitation [60, 61].

We have developed a hybridization approach to monitor the intracellular uptake and distribution of ASOs in cell culture experiments [R. Berg et al., unpublished]. Cells treated with ASOs were fixed in paraformaldehyde and then biotin-labeled complementary oligonucleotides were added in hybridization buffer. Detection was with an avidin–horseradish peroxidase conjugate, which cleaves diaminobenzidine to produce a colored precipitate within the cells. An alternative detection approach uses fluorescein-labeled streptavidin, which is visualized by fluorescence and/or confocal microscopy [S. Fard et al., manuscript submitted]. We are currently adapting this protocol for use on tissue and tumor sections taken from mice treated systemically with ASOs.

A hybridization-based approach has also been developed to quantitate levels of ribozymes in serum using paired complementary oligonucleotide probes, one labeled with biotin and the other with digoxigenin [90]. The annealed “triplex” is first collected on streptavidin-coated 96-well plates, then an anti-digoxigenin antibody conjugated with alkaline phosphatase is added, followed by addition of the enzyme substrate p-nitrophenyl phosphate, which is cleaved into a soluble colored product that is quantitated by absorbance at 405 nm.

7.4.5 ROUTES OF ADMINISTRATION

As with any drug, the PK profile of nucleic-acid-based therapeutics varies according to the route of administration. Before focusing on the PK properties of ASOs administered intravenously, we briefly discuss the published PK analysis of topical, inhaled, and oral formulations of ASOs.

Topical administration of ASOs has been investigated for a small number of indications, and it has been the subject of several recent reviews [91–93]. To date, topical administration has not progressed past preclinical animal models, although these include human skin transplanted (grafted) onto immunocompromised mice [81, 94]. The distribution of ASOs applied to the skin is generally limited to epideri-

mis and dermis, and it may be limited in intact skin but more advantageous in conditions that include inflammation or other damage, especially psoriasis [93, 95]. Distinct chemistries of ASOs, such as second-generation versus PMOs, may behave differently when applied topically. Furthermore, the formulation of the application compound [96–98] and the use of delivery methods such as sonophoresis (ultrasound) [99, 100] may also affect the delivery and PK properties of ASOs applied topically.

Respirable, or inhaled, ASOs have been developed as potential therapeutics for treatment of asthma, allergic rhinitis, and other pulmonary diseases [101–104]. In animal models including rodents and rabbits, inhaled ASOs are detectable in all cell types in the lungs but only in small amounts (<5–10% of the administered dose) in extra-pulmonary organs, and they exhibit minimal systemic bioavailability of intact, full-length ASO [103, 105, 106]. Less than 5% of the delivered dose was detected in the lung 72 hours after treatment (the elimination half-life is approximately 30 hours). At 72 hours, nearly 70% of the administered dose was excreted in the urine, the major pathway of elimination. ASOs designed and formulated for delivery by inhalation may have particular strengths as potential therapeutics for pulmonary diseases. One ASO, EPI-2010 (targeting the adenosine signaling pathway in asthma), completed phase I and II human trials, but further development was not pursued due to reduced efficacy in important patient markets [103].

Stability of unmodified DNA ASOs is limited after oral administration, due to degradation in the stomach and small intestine. Although backbone and ribose modifications substantially improved the stability of ASOs administered orally [107], intestinal permeability of ASOs is limited due to hydrophilicity, high negative charge, and high molecular mass [108, 109]. Formulation of ASOs in sodium caprate further improves stability and intestinal permeability of orally administered ASOs [108, 110]. Oral formulations have progressed to animal studies in rodents, pigs, and dogs [107–110], but not yet to human trials.

Lipid delivery vehicles such as stealth liposomes [111] and cationic liposome formulations [112–114], and additional vehicles such as polymers of chitosan [115], are being pursued as potential means to improve uptake and distribution of ASOs. Although these novel formulations and alternative routes of administration might ultimately prove to be more successful, the intravenous route has been the most successful thus far in the development of therapeutic ASOs.

7.4.6 PK (ADME) OF ASOs ADMINISTERED BY INJECTION

The PK properties of PS ASOs in animal models have been extensively studied and reviewed [33, 62, 116–118]. Several routes of administration, including intraperitoneal (i.p.), intravenous (i.v.), intradermal (i.d.), or subcutaneous (s.c.) injection, have been compared in animal models. PK profiles of ASOs in animals correlate well with those observed in human clinical trials, where ASOs are usually administered by i.v. or s.c. injection.

7.4.6.1 Absorption and Distribution

ASOs are highly bound to albumin and α2-macroglobulin in the blood, with binding affinities in the micro- to millimolar range [32, 65, 119]. In mice, rats,

monkeys, and humans, more than 96% of administered PS ASO was bound to plasma proteins [32, 119]. This high protein binding affinity limits renal clearance, but PS ASOs are rapidly cleared from plasma to tissues. Plasma clearance is dose-dependent, with plasma half-life ranging from 30 to 60 minutes [32, 119]. Widespread systemic distribution of ASOs is observed after i.d. and s.c. injections [65], but s.c. injection resulted in increased bioavailability and steady-state ASO levels [120]. Minimal differences in distribution were observed when comparing i.p and i.v. injection [116, 118]. In animal models, ASOs accumulated to highest levels in the liver and kidney, followed by spleen and lung, with only minor distribution to the brain and testes [65, 120, 121]. Distribution was independent of ASO length and nucleotide sequence [65]. Subcutaneous tumor xenografts accumulated levels of ASOs similar to spleen and lung [84]. Recent clinical trials of G3139 also measured similar disposition of intact and partially shortened ASO in humans, as discussed below [122, 363].

7.4.6.2 Metabolism and Elimination

Metabolism of ASOs occurs primarily through degradation by exonucleases and endonucleases. Degradation products have lower protein binding affinity and higher solubility, facilitating their excretion in urine and exhaled air [65, 121, 123–125].

7.4.6.3 PK Properties of 2′-MOE, PS, and PD ASOs

In a recent study the PK profiles of three distinctly modified ASOs were compared after i.v. injection into monkeys [34]. They compared a PD ASO with 2′-MOE modifications on all nucleotides, a PS ASO with 2′-MOE modifications only on the eight 3′-end residues, and a PS ASO with 2′-MOE modifications on the six nucleotides on each end (i.e., a gapmer). The plasma half-lives of the two PS ASOs were similar (~45 minutes), whereas that of the PD ASO was markedly shorter (~14 minutes). The two PS ASOs also had very similar tissue distribution, with the highest concentrations in kidney, liver, lymph nodes, and spleen. However, the gapmer exhibited a significantly longer tissue half-life, compared with the ASO with only the 3′ MOE modifications (~22 days vs. ~5 days). This suggests that the presence of both 5′-end and 3′-end MOE modifications on the gapmer protects the ASO from degradation in tissues and that the position of the modifications could significantly affect biological lifetime and efficacy in a clinical setting. This study confirmed that the chemistry of the ASO contributes to PK behavior and nuclease sensitivity, as suggested by earlier studies [119]. Although the extent of the 2′-MOE modification did not alter the distribution properties, the presence of this modification is important in the tissue distribution patterns and in determining nuclease resistance within tissues.

7.4.6.4 PK Analyses from Selected Clinical Trials

Several clinical trials using Genasense (G3139, a PS DNA ASO targeting the anti-apoptotic protein Bcl-2) have included detailed PK analyses. One of the earliest trials of G3139 used a 14-day continuous subcutaneous infusion at doses ranging

from 4.6 to 195.8 mg/m^2/day [126]. The mean plasma half-life of G3139 was 7.46 hours. More recent trials measured PK profiles of G3139 administered at 7 mg/kd/day by continuous i.v. infusion for 8 days [36], 10 days [37], or 5 days [122]. All showed similar PK results for plasma clearance, metabolism, and urinary excretion.

The first report of administration into humans of a 2′-MOE gapmer (ISIS 104838, targeting tumor necrosis factor α) included extensive PK analysis of blood and urine samples [60]. This trial also compared i.v. and s.c. dosing regimens. The plasma half-life of the ASO was 1 to 1.8 hours at doses greater than 1 mg/kg. Urinary excretion of full-length ASO during the initial 24 hours postadministration was less than 10%, whereas excretion of 8 to 12 nucleotide metabolites (i.e., degradation products) increased over time thereafter.

Similarly, a recent clinical trial of the 2′-MOE gapmer OGX-011 (targeting the chaperone protein clusterin) in prostate cancer patients indicated dose-dependent PK and pharmacodynamic properties [61]. Plasma distribution half-lives ranged from 0.476 to 3.83 hours, and other plasma PK parameters were similar to the PS ASO G3139 [126]. Estimates of ASO concentrations in the target tissue ranged from 1.67 to 4.82 μg/g of prostate tissue, depending on the dose of ASO delivered. Metabolism and elimination were not measured in the study.

7.4.6.5 Target Downregulation in Tissues of Interest

Drug efficacy for ASOs can be measured in terms of reductions in target mRNA and protein. The outcomes of drug treatment are not formally PK issues, but they are within the realms of pharmacodynamics and toxicology. It is important to consider, however, how the PK profile of a systemically administered ASO affects the pharmacodynamic and toxicological properties of the drug. Many clinical trials of ASOs include some measures of target mRNA and protein in target or surrogate marker tissues. In one of the early trials of the PS DNA ASO G3139 in patients with non-Hodgkin’s lymphoma, Bcl-2 mRNA and protein were demonstrably reduced in isolated peripheral blood lymphocytes, but only in 7 of 16 patients [126]. Recent clinical trials have shown similar interpatient variability in target downregulation [36, 37]. In the case of ASOs targeting clusterin, *in vitro* experiments revealed the improved efficacy of 2′-MOE modified gapmers compared with PS DNA ASOs [35]. Superior target downregulation and increased antitumor activity were also demonstrated in animal models of prostate cancer tumor growth [35]. Dose-dependent reductions in clusterin mRNA and protein in prostate tumor samples were also shown in the phase I clinical trial of OGX-011 [61], indicating that the intended biological activity was achieved in the intended target tissue. This represents a tremendous success for antisense therapeutics and should provide encouragement for others developing ASOs as potential clinically useful drugs.

7.4.7 RNA INTERFERENCE

RNA interference (RNAi) is a cellular regulatory mechanism in which double-stranded RNA (dsRNA) induces the specific degradation of its homologous target mRNA. This process was discovered by Guo et al. who found that injection of both

antisense and sense RNAs into *Caenorhabditis elegans* resulted in a decrease of their target mRNA [127]. Several years later, Fire et al. demonstrated that this observation was due to the single-stranded RNA populations containing small amounts of double-stranded RNAs. Using highly purified RNA preparations, they showed that dsRNA injected into *C. elegans* resulted in specific and potent interference of cellular gene expression [128]. This inhibition was much greater than that observed with injection of either the antisense or the sense strands by themselves. The molecular mechanism of RNAi involves cleavage of dsRNAs by an RNase III-like endonuclease termed Dicer into 21–25 nucleotide (nt) dsRNAs. These small interfering dsRNAs (siRNAs) are bound in a multiprotein RNA-induced silencing complex (RISC), which unwinds the siRNA, and one strand is then used as a guide to target complementary mRNAs for degradation [129–131].

RNAi gained rapid acceptance as a tool for functional genomics in *C. elegans* and *Drosophila* model systems. It was initially unclear as to whether RNAi existed in mammalian cells, because treatment of mammalian cells with dsRNA results in global degradation of RNAs and repression of protein synthesis. As researchers toiled diligently to understand the detailed molecular mechanisms involved in the RNAi pathway, Elbashir et al. identified 21- to 22-nt dsRNAs as the effector molecules that induce RNAi in *Drosophila* embryos [132]. Additionally, they demonstrated that chemically synthesized siRNAs could be transfected into mammalian cells and induce RNAi without inducing global RNA degradation [133]. Since this discovery, the field of siRNA and related methodologies has grown at an exponential rate. Although siRNAs have competed with ASOs as tools for functional genomic analysis and target validation, one primary interest is to develop siRNAs as therapeutic agents.

7.4.7.1 siRNA Specificity

One of the most important issues regarding development of new pharmaceuticals is their specificity of effect. The overall intent is to design molecules that inhibit their intended target without undesirable side effects. As with ASOs and other nucleic-acid-based therapies, demonstrating that the observed cellular affects are due to inhibition of the intended mRNA target remains a challenge. Initial studies suggested that one or two mismatches could alleviate the silencing ability of an siRNA [132]. However, recent studies have identified siRNAs with effects on unintended targets with as little as seven complementary nucleotides [134]. Moreover, in addition to the G:U wobble base pair, it has been shown that mismatches formed between adenine (A) and cytosine (C) are well tolerated [135]. Thus, the ability of siRNAs to specifically downregulate predicted targets is being called into question. Many investigators have turned to microarray analysis to validate the specificity of their siRNAs. This approach may nonetheless provide researchers with a false sense of specificity. Saxena et al. showed that siRNAs with multiple mismatches located in the center of the molecule can function as micro-RNAs that inhibit expression of the target protein through translational arrest and not mRNA degradation [136]. Thus, the microarray patterns from two different siRNAs targeting the same mRNA may be similar, but the siRNAs could still inhibit protein expression through translational inhibition. It remains unclear to what extent each of these potential nonspecific effects may impact their potential therapeutic use. With

a more thorough understanding of the RNAi mechanism, new selection guidelines will identify optimal target sites that account for these sequence-based nonspecific effects. Identification of the most active siRNA with limited nonspecific effects will be critical for the success of siRNA molecules as therapeutic agents.

7.4.7.2 Cell Culture

Since their discovery only a few years ago, many researchers in both academic and industrial settings have used siRNAs to knock down mRNA targets within cultured cells. Unlike ASOs, which can enter cells by themselves when used at high concentrations, siRNAs cannot cross the cellular membrane by themselves due to their two negatively charged phosphate backbones. Cationic lipids such as Lipofectamine 2000 (L2K) and Oligofectamine are commonly used to complex the siRNA and allow uptake into cultured cells. However, a recent publication has demonstrated that cationic lipids can have unintended effects. Fedorov et al. transfected siRNAs into HeLa cells using either L2K or electroporation and performed microarray studies [137]. Although both transfection methods resulted in a similar knockdown of the target mRNA, the number of genes affected by each method differed significantly. Lipid transfection resulted in increased expression of 65 genes, whereas electroporation increased only 11 genes. Over 50% of the upregulated genes could be directly attributed to L2K. Because L2K is also commonly used for transfecting DNA plasmids and ASOs, investigators should thoroughly examine the effect that the transfection reagent has on gene expression patterns. In addition to these lipids, other cationic molecules such as cell-penetrating peptides and polyethyleneimine have also been used to transport siRNAs across the cell membrane [138, 139]. Further studies are needed to determine what affects these transport molecules have on global gene expression.

7.4.7.3 *In vivo* Studies with "Naked" siRNAs

Although most siRNA researchers will readily acknowledge that the siRNAs are more potent than the ASOs and result in a more potent and reproducible target suppression, others have shown siRNAs to be equivalent to ASOs [140]. The real difference between these two approaches becomes clear once the nucleic acids are injected into animals. ASOs have therapeutic activity even when they are injected intravenously without any cationic carrier molecule, as discussed in the preceding section. Although most studies show that naked siRNA injections have no effect, some have demonstrated that uncomplexed, unmodified siRNAs can be injected into animals and inhibit the target protein in tissues. Verma et al. intravenously injected approximately 3 μg of a β-catenin-targeted siRNA into the tail vein of tumor-bearing nude mice. After 72 hours, tumors were harvested and significant decreases in β-catenin protein levels could be observed by Western blot analysis [141]. Similarly, Filleur et al. injected intraperitonealy 3 μg of siRNAs targeting either luciferase or vascular endothelcal growth factor (VEGF) and could demonstrate a 50% reduction in luciferase activity and a 70% reduction in VEGF expression. VEGF siRNA injections also delayed the onset of tumors [142]. Furthermore, Duxbury et al. delivered similar amounts of an siRNA targeting ribonucleotide reductase mRNA. After 6 weeks of biweekly tail vein siRNA injections, the levels

of target protein in the tumor were suppressed and a small decrease in the tumor growth rate was observed. More importantly, the combination of the siRNA and gemcitabine resulted in a synergistic suppression of tumor growth. The control siRNA did not enhance the antitumor affect of gemcitabine [143]. All of these results using naked siRNAs are surprising because siRNAs are rapidly degraded in plasma with a half-life of about 3 minutes [144]. Given that many investigators have shown that unmodified, uncomplexed siRNAs have little to no activity (as discussed below), it remains unclear as to whether systemic injection of unprotected siRNAs is a viable therapeutic option.

7.4.7.4 Hydrodynamic High-Pressure "Naked" siRNA Injection

To overcome the problem of siRNA delivery into tissues, several investigators have employed the high-pressure hydrodynamic method. This method involves rapid injection of siRNA in a large volume (1–2 mL) of saline or phosphate-buffered solution (PBS). Surprisingly, the mice can tolerate this harsh administration quite well [145]. Song et al. was able to reduce Fas mRNA and protein levels in mouse liver for up to 10 days after hydrodynamic injection (50 μg siRNA in 1-mL PBS). They also demonstrated that Fas siRNA in-jection could protect mice from fulminant hepatitis [146]. Another group targeted caspase 8 with siRNAs and showed decreased liver expression of caspase 8 and prevented Fas (CD95)-mediated apoptosis after hydrodynamic injection (120-μg siRNA in 2-mL PBS). As with the previous Fas-targeted approach, caspase 8 siRNAs improved the survival of two animal models of acute liver failure [147]. Layzer et al. used quantitative whole-body imaging to demonstrate that hydrodynamic coinjections of luciferase reporter plasmids and luciferase-targeted siRNAs could reduce luciferase expression by 85%. Injection of a nuclease-resistant 2′-F siRNA resulted in a similar reduction in luciferase expression. However, if siRNAs were injected under low pressure, no decrease in luciferase activity was observed [148]. Although the use of hydrodynamic injection in animal models is relatively simple and effective, it is not feasible in the clinical setting. An additional limitation of this methodology is that the liver is the primary organ for siRNA uptake with only limited uptake in other tissues.

7.4.7.5 Chemically Modified siRNAs

Contrary to the studies demonstrating activity with unmodified siRNAs, the major limitation for the use of nucleic acids as therapeutic agents is their susceptibility to attack from serum and intracellular nucleases. The antisense field has identified a host of ribose ring and phosphate backbone modifications that enhance the stability of ASOs [Figure 7.4-1]. Extensive analysis has been performed to demonstrate which chemical modifications enhance siRNA stability and still allow for efficient silencing [149–151]. Altering the phosphate backbone of an siRNA to phosphorothioate reduces its ability to induce RNAi by 50% and increases nonspecific cellular toxicity. Designing siRNAs entirely with 2′-O-methyl moieties improves their nuclease stability dramatically and eliminates their silencing ability. One nucleotide modification that seems to be the most promising is the 2′-fluorine modification on the cytidines and uridine residues. 2′-F-modified siRNAs have plasma half-lives of days instead of minutes and can inhibit their targets with similar potency as the

unmodified siRNAs. Researchers at Sirna Therapeutics have developed siRNAs in which all 2′-OH groups have been substituted with deoxy-, 2′-O-methyl-, or 2′-fluoro-nucleotides, which are termed "short interfering nucleic acid" (siNA). In human serum, siNAs have a half-life on the order of 3 days [144]. Using a hepatitis B viral mouse model, they injected HBV-targeted siNAs by standard low-pressure tail vein injections (60–600-μg siRNA) thrice daily for 2 days. After 24 hours, the levels of serum HBV DNA were significantly reduced in a dose-dependent manner. The inverted control siNA had little to no effect on serum levels of HBV DNA. No significant antiviral activity was observed with unmodified siRNAs at any dose. Although this study demonstrated *in vivo* activity of a fully modified siRNA, it is uncertain whether these siNAs are effectively taken up into tissues by standard intravenous injections. One assumes that lower serum titers are the result of lower viral production from the tissues, but no data were presented regarding decreased HBV tissue expression. Given the high doses required for activity, more studies are needed to validate the therapeutic effectiveness of siNAs.

7.4.7.6 Ligand-Mediated siRNA Delivery

Another approach to improve tissue delivery of siRNAs is to attach small molecules on the end of the siRNA. Soutschek et al. conjugated a cholesterol molecule on the 3′-end of the sense strand of a partial chemically modified siRNA to generate "chol-siRNA" [152]. A chol-siRNA targeting luciferase could reduce luciferase expression in HeLa cells with an IC50 of about 200 nM without any transfection reagents. Upon intravenous injection into animal models, the addition of cholesterol improved the siRNAs pharmacokinetic properties by increasing the elimination half-life and reducing plasma clearance in rodents. Chol-siRNAs, as detected by RNase protection assay, were broadly distributed throughout the tissues of the mouse confirming the improved pharmacological properties. No detectable amounts of unconjugated siRNAs were observed in any tissues. Intravenous injections of a chol-siRNA targeting apolipoptrotein B (1 mg) daily for 3 days resulted in inhibition of apoB mRNA in liver and intestine, decreased serum levels of apoB protein, and a reduction of total plasma cholesterol. Hence, this study demonstrated the importance of conjugating a small molecule to the siRNA that will enhance tissue uptake. However, further optimization is required to identify modifications that will permit more clinically acceptable doses and schedules.

7.4.7.7 Intranasal siRNA Injection

As an alternative approach to systemic siRNA injections, several groups have demonstrated that intranasal administration of siRNA can be effective for certain disease applications [153–155]. X. Zhang et al. [154, 155] were the first to demonstrate that unmodified siRNA could be administered intranasally and silence the intended target mRNA without the need for transfection agents. Bitko et al. [153] designed siRNAs targeting the respiratory syncytial virus and parainfluenza virus. A single intranasal siRNA administration (70 μg) provided significant protection against respiratory infection from viral challenge. Two days after intranasal injection, siRNAs could still be detected in the mouse lungs. There are several advantages for this route of administration. It is relatively painless and noninvasive. The

risk of potential side effects is also reduced because no cationic carrier molecules are required for cellular uptake. It remains unclear as to the mechanism of cellular uptake after intranasal siRNA administration.

7.4.7.8 *In vivo* Studies with Encapsulated siRNAs

An alternative approach for *in vivo* delivery of siRNAs is to encapsulate or complex the siRNA with cationic molecules. These positively charged molecules serve several functions. After interacting with the negatively charged phosphate backbone of the nucleic acid, they condense the nucleic acid into a more compact structure, protect against degradation by plasma nucleases, and enhance tissue uptake. The use of these cationic synthetic molecules is not limited to siRNA delivery. ASOs and DNA plasmid vectors can also be delivered with these molecules. As well, it remains unclear as to whether chemical modifications to the siRNA are necessary if one is using cationic molecules for delivery. In cell culture, lipid-complex siRNAs are protected from degradation by serum nucleases. One benefit of using natural, unmodified siRNAs is that when they actually do degrade, the nucleotides should not have any nonspecific effects of cellular metabolism.

7.4.7.9 Linear Polyethylenimine

The cationic molecule polyethylenimine (PEI) has been shown to effectively transport nucleic acids into cells in both the *in vitro* and the *in vivo* setting. PEI condenses nucleic acids into 0.2–0.4-nm positively charged particles, is taken up into cells by endocytosis, and then releases the nucleic acid contents into the cytoplasm efficiently via a process called the "proton sponge" [156]. Urban-Klein et al. demonstrated that PEI complexation of an unmodified siRNA protects the siRNA from nuclease degradation. In cultured ovarian carcinoma cells, they showed that linear low-molecular-weight PEI could transport their HER2-targeted siRNA into cells, inhibit HER2 protein expression by 70%, and reduce colony formation by 50% with a single PEI/siRNA transfection. In a tumor-bearing nude mouse model, intraperitoneal injection of PEI/siRNA resulted in a rapid uptake of the P32-labeled siRNA into the tumor, muscle, liver, and kidney with little uptake into the lungs. No siRNA was observed in the tissues after injection of uncomplexed siRNAs. As they observed no histological changes in the lungs and the absence of visible side effects, intraperitoneal injections of PEI/siRNA seem to avoid systemic PEI-associated toxicity previously reported [157]. Furthermore, they showed that intraperitoneal injections of PEI/HER-2 siRNA (10 μg) two to three times a week significantly reduced growth of tumor xenografts. HER2 mRNA levels were inhibited by 50% by this treatment regimen. As important controls for specificity, injection of either a nonspecific siRNA complexed with PEI or uncomplexed HER-2 siRNA had no effect on tumor growth. However, a recent report demonstrated that tail vein injections of PEI along with other cationic molecules can have antitumor activity by themselves [158]. Although this effect may be cell-line dependent, caution should be used when interpreting the therapeutic effects of siRNAs when cationic molecules are used for delivery.

One main concern with using PEI as a nucleic acid transporter is the lack of tissue specificity. To improve the ability of PEI to target tumors, Schiffelers et al.

designed ligand-targeted, sterically stabilized nanoparticles (RPPs) for complexation with siRNAs [159]. These particles comprise branched PEI that is PEGylated with an RGD peptide on the end of the polyethylene glycol (PEG). Once the siRNA is complexed in the nanoparticles, the RGD peptide should preferentially target the tumor neovasculature. One hour after intravenous injection of a fluorescently labeled siRNA complexed with RPP, significant siRNA uptake was observed in the tumor with poor liver and lung accumulation. Conversely, siRNA complexed with only branched PEI did not accumulate in the tumor to any appreciable extent but did accumulate in the liver and lung. To verify whether the siRNA distributed into the tumor was active, they evaluated the expression of luciferase in the tumor and its knockdown by a siRNA specific for luciferase. Thus, luciferase was complexed with either PEI or RPP particles and injected into tumor-bearing mice. Although luciferase levels in the tumor were equivalent for both PEI and RPP particles, only RPP could selectively target the tumor. Two hours after plasmid injections, luciferase siRNA–RPP nanoparticles were injected into the same mice. After 24 hours, the luciferase activity had decreased by 90% demonstrating sequence-specific inhibition. To evaluate whether these nanoparticles have therapeutic potential, siRNAs targeting the VEGF receptor were complexed with RPP and injected into tumor-bearing mice every 3 days at a dose of 40 μg administered in the tail vein. They observed a strong inhibition of tumor growth, a reduction in blood vessel formation around the tumor, and a decrease in the expression of tumor VEGF R2 protein levels. The control siRNA had no effect, demonstrating specificity.

7.4.7.10 Cationic Lipids

In addition to PEI-related molecules, various cationic lipids have been used for nucleic acid transport *in vivo*. Lipids such as the commercially available DOTAP have been effective in delivering siRNAs into tissues such as kidney and spleen [160]. Others have developed their own delivery lipids. Yano et al. designed a less-toxic cationic liposome (LIC-101) and demonstrated its *in vitro* ability to deliver a Bcl-2-targeted siRNA into four different cell lines and inhibit Bcl-2 protein expression [161]. Furthermore, tail vein injection of LIC-101/Bcl-2 siRNA inhibited tumor growth in two different mouse models. Chien et al. developed a novel cationic liposome based on a synthetic cationic cardiolipin analog (CCLA) [162]. They showed their lipid had significantly less-toxic side effects than DOTAP and could suppress tumor growth by >70% in a severe combined immunodeficiency (SCID) mouse xenograft model. Injection of a mismatched siRNA complexed with CCLA had no effect on tumor growth. Morrissey et al., in an attempt to improve delivery of their HBV-targeted siRNA, incorporated their siRNA into a specialized liposome to form a stable nucleic-acid–lipid particle (SNALP) [163]. In a mouse model, an unmodified siRNA had a plasma elimination half-life of approximately 2 minutes. Injection of a nuclease-stabilized siRNA improved substantially the elimination half-life to 49 minutes. However, siRNA encapsulation in SNALP improved the plasma pharmacokinetics most dramatically with an elimination half-life of 6.5 hours. They demonstrated that SNALP–siRNA could significantly suppress serum levels of HBV in HBV-challenged mice with much lower doses and reduced dosing frequency than previously shown with uncomplexed siRNA [144].

7.4.7.11 siRNAs in Clinical Trials

Although some uncertainly remains for the feasibility and effectiveness of siRNA therapeutics, several companies are rapidly moving ahead with siRNA molecules in clinical trials. In the Fall of 2004, Acuity Pharmaceuticals initiated the first human siRNA clinical trial for treatment of wet age-related macular degeneration (AMD) with their lead compound Cand5, which silences VEGF. Phase I studies showed that intravitreal injections of an unmodified siRNA, Cand5, was safe and well tolerated [164]. Pharmacokinetic analysis revealed that the siRNA was not detected in the plasma of any patient. Lack of systemic exposure due to localized siRNA injection likely prevented the adverse side effects of anti-VEGF therapy. However, given that unmodified siRNAs are very unstable in plasma, it is unclear whether the siRNA could not escape the vitreal cavity or whether it was degraded so rapidly after entry into the bloodstream that it could not be detected in plasma. Acuity Pharmaceuticals has already initiated phase II studies with its lead siRNA candidate. The second siRNA to enter clinical trials was Sirna-027 from Sirna Therapeutics. Although both Cand5 and Sirna-027 are being investigated for treatment of AMD, Sirna-027 targets the VEGF receptor as opposed to VEGF, and is chemically modified to enhance stability. Interim phase I results were recently reported and demonstrated that Sirna-027 seems to be safe and well tolerated [165]. All patients experienced improvement or stabilization of visual acuity, and 23% of the patients showed a clinically significant improvement in visual acuity. A third company (Alnylam Pharmaceuticals) has recently initiated a phase I study with its siRNA (ALN-RSV01), which targets respiratory syncytial virus. Using their Direct RNAi approach, the siRNA will be administered directly to the lungs and silence a key RSV gene, which hopefully will prevent spreading of the viral infection.

Other pharmaceutical companies are also seeking to initiate their own siRNA clinical trials. An Australian company (Benitec) in collaboration with the City of Hope is planning to enter their RNA-based HIV drug into clinical trials sometime in 2006. Unlike Cand5 and Sirna-027, which are siRNA molecules, Benitec specializes in RNAi plasmid and vector expression systems. Patients who have become resistant to HAART therapy would receive a transplant of their own stem cells containing an RNAi expression system targeting HIV to generate HIV resistance. Nucleonics, Inc. also uses RNAi expression systems for gene silencing and expects to file its first IND for hepatitis B and hepatitis C in 2006. CytRx Corporation is rapidly advancing their preclinical siRNA studies for the treatment of obesity, type 2 diabetes, and Lou Gehrig's disease. Thus, many pharmaceutical companies have decided to develop siRNAs as therapeutic agents. However, as with ASOs, the fate of therapeutic siRNAs will be determined from the initial siRNA clinical trials.

7.4.8 CONCLUSIONS

7.4.8.1 Nucleic Acid-Based Therapeutics

Plasmids and viral vectors have been developed to deliver gene therapy in animal models and human clinical trials. These approaches aim to express a gene of interest in target tissue. Many of these approaches use local delivery, and thus, PK analysis is limited to the short-range disposition, metabolism, and excretion of the

nucleic acid therapeutic. ASOs and siRNA molecules are being developed as gene therapeutics to reduce the expression of target genes, through double-stranded nucleic acid interactions with target mRNA. Development of orally bioavailable formulations and lipid-encapsulated antisense molecules is being pursued, but most preclinical studies and clinical trials employ intravenous injection to deliver these therapeutics.

7.4.8.2 PK (ADME) and Toxicology Differences

For ASOs, the differences in PK and toxicology properties depend largely on the chemistry of the backbone and the modifications to the sugars. Thus, the ADME characteristics are independent of nucleotide base sequence and, therefore, do not change significantly according to the gene or protein being targeted. The toxicological properties do depend to a certain extent on the nucleotide sequence, for example, the effects of CpG dinucleotides and G-quartets. Whether these principles will hold for siRNA therapeutics will likely been seen in the next few years, as the development of siRNA with novel chemical modifications progresses.

7.4.8.3 Relative Clinical Utility of the Different Approaches

The relative effectiveness of ASOs and siRNAs, in terms of target downregulation, have been studied in cell culture and animal experiments [29, 140, 166, 167]. Although it seems that siRNA may be more effective than ASOs in most experimental circumstances, the development of modified ASOs with improved PK properties, including stability to nucleases, uptake into target tissues, and tissue half-life, has progressed much further than for siRNA. Indeed, although many ASOs of various chemistries have progressed into phase II and III clinical trials and thus the PK studies are widely reported, siRNAs are just now entering human clinical trials and their PK properties are not yet fully described or understood. It seems likely that both types of antisense therapeutics will demonstrate clinical utility in a variety of indications in the coming years.

7.5.1 INTRODUCTION

The human genome is estimated to consist of 30,000 genes, up to 20% of which are considered to be expressed in a cell at a certain time. The human genome has now been completely sequenced, and huge amounts of data are being presented in public databases [1, 2]. However, these data do not provide information about the function of the genes or the significance of their expression in the specific state of

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

a disease. Thus, to fully exploit the massive DNA sequence information, smart technologies are necessary for rigorous analysis of gene expression. The collection of genes that are transcribed from genomic DNA, referred to as the "transcriptome," is a major determinant of cellular phenotype and function. The transcription of genomic DNA to produce mRNA is the first step for protein synthesis, and differences in the process are responsible for both morphological and phenotypic differences as well as indicative of cellular responses to environmental stimuli and perturbations. Unlike the genome, the transcriptome is highly dynamic and changes rapidly and dramatically in response to perturbations or during normal cellular events [3, 4]. Understanding the function of genes with respect to the time, location, and degree of expression is central to elucidating the activity and biological roles of its encoded protein. In addition, changes in the multigene expression patterns can provide clues about regulatory mechanisms and broader cellular functions and biochemical pathways. Thus, the knowledge gained from these types of measurements through implementation of proper and efficient technology can help determine the causes and consequences of disease, how drugs and drug candidates work in cells and organisms, and what gene products might have therapeutic uses or may be appropriate targets for therapeutic intervention.

Oligonucleotides have emerged as essential tools in pharmaceutical biotechnology by virtue of their small size, low-cost chemical synthesis, and precise base pairing capability with other complementary sequences either in the transcriptome or in the genome, according to the Watson–Crick model. Functional genomics-based screening, identification, and validation of drug targets, development of target protein-specific new generation therapeutics, and genotyping of many polymorphisms to develop tailor-made drugs for individuals are all being accomplished by many smart technological appro-aches using synthetic oligonucleotides of variable sizes and sequences.

7.5.2 OLIGONUCLEOTIDES IN FUNCTIONAL GENOMICS FOR DRUG TARGET DISCOVERY

The classic sciences of chemistry, pharmacology, microbiology, and biochemistry have shaped the course of drug discovery. Additionally, molecular biology has exerted a profound influence on drug discovery, allowing the concept of genetic information to be dealt with in very concrete chemical and biochemical terms. Although the earlier influence of molecular biology was restricted to cloning and expressing genes that encode therapeutically useful protein drugs (mostly recombinant proteins and monoclonal antibodies), recently the main promise of molecular biology for drug discovery lies in the potential to understand disease processes at the molecular genetic level and determine the optimal targets of drug intervention. The next step is to design novel pharmaceutical compounds either by high-throughput screening (HTS), a process in which batches of compounds are tested for binding activity or biological activity against target molecules, or simulation of drug–target interactions in order to design a drug to fit a target structure precisely.

However, the molecular biology techniques that are most commonly used for drug target discovery are fully or partially based on synthetically designed oligo-

nucleotides for detection and quantitation of specific mRNAs as representatives of target proteins.

7.5.2.1 Northern Blotting

Northern analysis remains a standard method for detection and quantitation of mRNA levels despite the advent of powerful techniques, such as reverse transcriptase–polymerase chain reaction (RT–PCR), real-time PCR, and microarray. It is used to quantitate a specific mRNA, determine transcript size, detect alternative splice variants of a gene, and identify closely related species. RNA samples are first separated by size via electrophoresis in an agarose gel under denaturing conditions, transferred to a membrane, cross-linked, and hybridized with a labeled probe, such as oligonucleotide (cDNA or RNA can also be applicable). Sensitivity can be improved with oligo deoxythymidine (dT) selection for enrichment of mRNAs because the dT oligonucleotide anchor prime [oligo(dT)] in a column hybridizes to the 3′-poly(A) tail of the mRNA. The radiolabeled or nonisotopically labeled probe has a sequence complementary to that of target mRNA facilitating efficient hybridization between them. Nonisotopic labeling of oligonucleotides can be broadly classified into two categories: indirect and direct. The indirect method involved the incorporation of a hapten into the probe molecule that is subsequently detected by affinity recognition with an antibody or a binding moiety, such as streptavidin. The binding moiety is, in turn, coupled to a signaling enzyme, such as horseradish peroxidase. Direct methods, on the other hand, covalently attach the signaling enzymes to the probe molecules. Factors that influence the hybridization efficiency include temperature, ionic strength, destabilizing agents, mismatched base pairs, duplex length, viscosity, and base composition. High salt favors hybridization reactions (i.e., less specificity and greater background), whereas decreased salt and/or increased detergent or temperature increases hybridization specificity and reduces background.

7.5.2.2 Polymerase Chain Reaction (PCR)

The PCR is a test-tube system for DNA replication that allows a "target" DNA sequence to be selectively amplified several million-fold in just a few hours. During PCR, high temperature is used to separate the DNA molecules into single strands, and synthetic sequences of single-stranded DNA (20–30 nucleotides) serve as primers to enable DNA polymerase to synthesize the complementary strand. Two different primer sequences are used to bracket the target region to be amplified. One primer is complementary to one DNA strand at the beginning of the target region; a second primer is complementary to a sequence on the opposite DNA strand at the end of the target region. Thus, PCR technology consists of three steps: denaturation of double-stranded target DNA at 94–96°C, annealing (hybridization) of primers to their complementary sequences on either side of the target sequence at 50–65°C and finally extending a complementary DNA strand from each primer with the help of a heat-stable DNA polymerase at 72°C. As amplification proceeds, the DNA sequence between the primers doubles after each cycle. After 30 such cycles, a theoretical amplification factor of one billion is attained.

For the discovery of drug target proteins based on functional genomics, some advanced PCR techniques are now playing the vital roles.

Reverse Transcriptase (RT)–PCR. RT–PCR is the most sensitive technique currently available for mRNA detection and quantitation. Compared with the two other commonly used techniques (Northern blot analysis and RNase protection assay) for quantifying mRNA levels, RT–PCR can be used to quantify mRNA levels from much smaller samples. In fact, this technique is sensitive enough to enable quantitation of RNA from a single cell. RT–PCR is a technique in which an RNA strand is "reverse" transcribed into its DNA complement, followed by amplification of the resulting DNA using PCR. Transcribing an RNA strand into its DNA complement is termed reverse transcription (RT), and it is accomplished through the use of an RNA-dependent DNA polymerase (reverse transcriptase). Afterward, a second strand of DNA is synthesized through the use of a deoxy-oligonucleotide primer and a DNA-dependent DNA polymerase. The complementary DNA and its antisense counterpart are then exponentially amplified via PCR. The original RNA template is degraded by RNase H leaving behind DNA only.

Real-Time PCR. Over the last several years, the development of novel chemistries and instrumentation platforms enabling detection of PCR products on a real-time basis has led to widespread adoption of real-time RT–PCR as the method of choice for quantitating changes in gene expression. It enables quantitation of the initial amount of the template most specifically, sensitively, and reproducibly by monitoring the fluorescence emitted during the reaction as an indicator of amplicon production during each PCR cycle (i.e., in real time), and it is a preferable alternative to other forms of quantitative RT–PCR that detect the amount of final amplified product at the endpoint [5, 6]. Furthermore, real-time RT–PCR has become the preferred method for validating results obtained from array analyses and other techniques that evaluate gene expression changes on a global scale.

The real-time PCR system is based on the detection and quantitation of a fluorescent reporter [7, 8]. This signal increases in direct proportion to the amount of PCR product in a reaction. By recording the amount of fluorescence emission at each cycle, it is possible to monitor the PCR reaction during the exponential phase where the first significant increase in the amount of PCR product correlates to the initial amount of target template. The higher the starting copy number of the nucleic acid target, the sooner a significant increase in fluorescence is observed. A significant increase in fluorescence above the baseline value measured during the 3–15 cycles indicates the detection of accumulated PCR product.

Real-time quantitative PCR analysis can be performed with oligonucleotide-based hydrolysis probes or hybridization probes. Hydrolysis probes include TaqMan probes [9], molecular beacons [10, 11], and scorpions [12]. They use the fluorogenic 5′ exonuclease activity of Taq polymerase to measure the amount of target sequences in cDNA samples (Figure 7.5-1). TaqMan probes, Molecular Beacons, and Scorpions depend on fluorescence resonance energy transfer (FRET) to generate the fluorescence signal via the coupling of a fluorogenic dye molecule and a quencher moiety to the same or different oligonucleotide substrates.

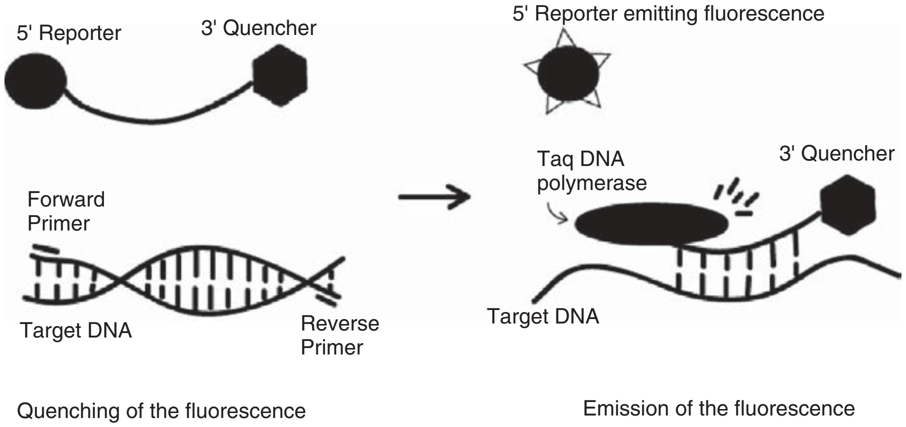

Figure 7.5-1. A model for dual-labeled fluorogenic probes for real-time PCR. The probe is labeled with two different dyes: A reporter dye is located on the 5′ end, and a quencher dye is located on the 3′ end. The quencher dye inhibits the natural fluorescence emission of the reporter dye by FRET. During the elongation step, Taq DNA polymerase 5′–3′ exonuclease activity hydrolyzes the probe bound to the specific DNA template, releasing the reporter dye from the target/oligonucleotide-quencher hybrid and causing an increase of fluorescence in proportion to the amount of target DNA.

Hydrolysis Probes

TAQMAN PROBES. These are oligonucleotide probes longer than the primers (20–30 bases long with a Tm value of 10°C higher) that contain a fluorescent dye usually on the 5′ base and a quenching dye (usually TAMRA) typically on the 3′ base. When irradiated, the excited fluorescent dye transfers energy to the nearby quenching dye molecule in the FRET mechanism [13]. Thus, the close proximity of the reporter and quencher prevents emission of any fluorescence while the probe is intact. TaqMan probes are designed to anneal to an internal region of a PCR product. When the polymerase replicates a template on which a TaqMan probe is bound, its 5′ exonuclease activity cleaves the probe [14]. This ends the activity of quencher (no FRET), and the reporter dye starts to emit fluorescence, which increases in each cycle proportional to the rate of probe cleavage. Accumulation of PCR products is detected by monitoring the increase in fluorescence of the reporter dye. Because the cleavage occurs only if the probe hybridizes to the target, the origin of the detected fluorescence is specific amplification.

MOLECULAR BEACONS. Like TaqMan probes, molecular beacons also use FRET to detect and quantitate the synthesized PCR product via a fluorescent dye coupled to the 5′ end and a quencher attached to the 3′ end of an oligonucleotide substrate. Unlike TaqMan probes, molecular beacons are designed to remain intact during the amplification reaction, and they must rebind to the target in every cycle for signal measurement. Molecular beacons form a stem-loop structure when free in solution. Thus, the close proximity of the fluorescent and quencher dyes prevents the probe from fluorescing. When a molecular beacon hybridizes to a target, the fluorescent and quencher dyes are separated, FRET does not occur, and the fluorescent dye emits light upon irradiation.

SCORPIONS. With scorpion probes, sequence-specific priming and PCR product detection is achieved using a single oligonucleotide. The scorpion probe maintains a stem-loop configuration in the unhybridized state. The fluorophore is attached to the 5′ end and is quenched by a moiety coupled to the 3′ end. The 3′ portion of the stem also contains a sequence that is complementary to the extension product of the primer. This sequence is linked to the 5′ end of a specific primer via a nonamplifiable monomer. After extension of the Scorpion primer, the specific probe sequence can bind to its complement within the extended amplicon, thus opening the hairpin loop. This prevents the fluorescence from being quenched and a signal is observed.

Hybridization Probes

LIGHTCYCLER. A LightCycler probe (Roche Applied Science, Indianapolis, IN) is a pair of single-stranded fluorescent-labeled oligonucleotides. Oligo Probe I is labeled at its 3′ end with a donor fluorophore dye, and Oligo Probe 2 is labeled at its 5′ end with one of two available acceptor fluorophore dyes. The free 3′ hydroxyl group of Probe 2 must be blocked with a phosphate group to prevent Taq DNA polymerase extension. To avoid any steric problems between the donor and the acceptor fluorophores on both sides, there should be a spacer of one to five nucleotides to separate the two probes from each other. During the annealing step, the PCR primers and the LightCycler probes hybridize to their specific target regions, which causes the donor dye to come into close proximity to the acceptor dye. When the donor dye is excited by light from the LightCycler instrument, energy is transferred by FRET from the donor to the acceptor dye, which causes the acceptor dye to emit light at a longer wavelength than the light emitted by the instrument. The acceptor fluorophore's emission wavelength is detected by the LightCycler instrument's optical unit. The significant increase of measured fluorescence signal is directly proportional to the amount of target DNA.

Differential Display (DD)–PCR. DD–PCR is a PCR-based technique that can detect differentially expressed genes. It provides a picture of the transcript pool of cells or tissues by displaying subsets of mRNAs. Subsets obtained from different cell types or tissues can be compared and used for isolation of the genes of interest. The general strategy for DD–PCR consists of the combination of (1) reverse transcription using a dT oligonucleotide anchor primer (oligo$(dT)_n$) to produce cDNA; (2) performing PCR using the cDNA as a template with the anchor primer and an arbitrary primer; and (3) separation of the PCR product by electrophoresis and visualization. The differential display method is thus far unique in its potential to visualize all expressed genes in a eukaryotic cell in a systematic and sequence-dependent manner by using multiple primer combinations.

Serial Analysis of Gene Expression (SAGE). SAGE analysis is a method derived to provide a readout, via sequencing, of the spectrum of genes being expressed in a cell or tissue in both a qualitative and a quantitative manner [15, 16]. Three principles underlie the SAGE methodology:

1. A short sequence tags (10–15 bp) contains sufficient information to uniquely identify a transcript provided that the tag is obtained from a unique position within each transcript.

2. Sequence tags can be linked together to form long serial molecules that can be cloned and sequenced.
3. Quantification of the number of times a particular tag is observed provides the expression level of the corresponding transcript.

A detailed description of SAGE is provided in Figure 7.5-2.

Important advantages of SAGE over DD–PCR are that SAGE data are quantitative and cumulative. Accurate, quantitative transcript profiles describing the abundance of all genes expressed in a cell or tissue are generated by SAGE, provided sufficient sequencing is completed. The resulting data may then be compared with all existing and future SAGE databases constructed in a similar manner.

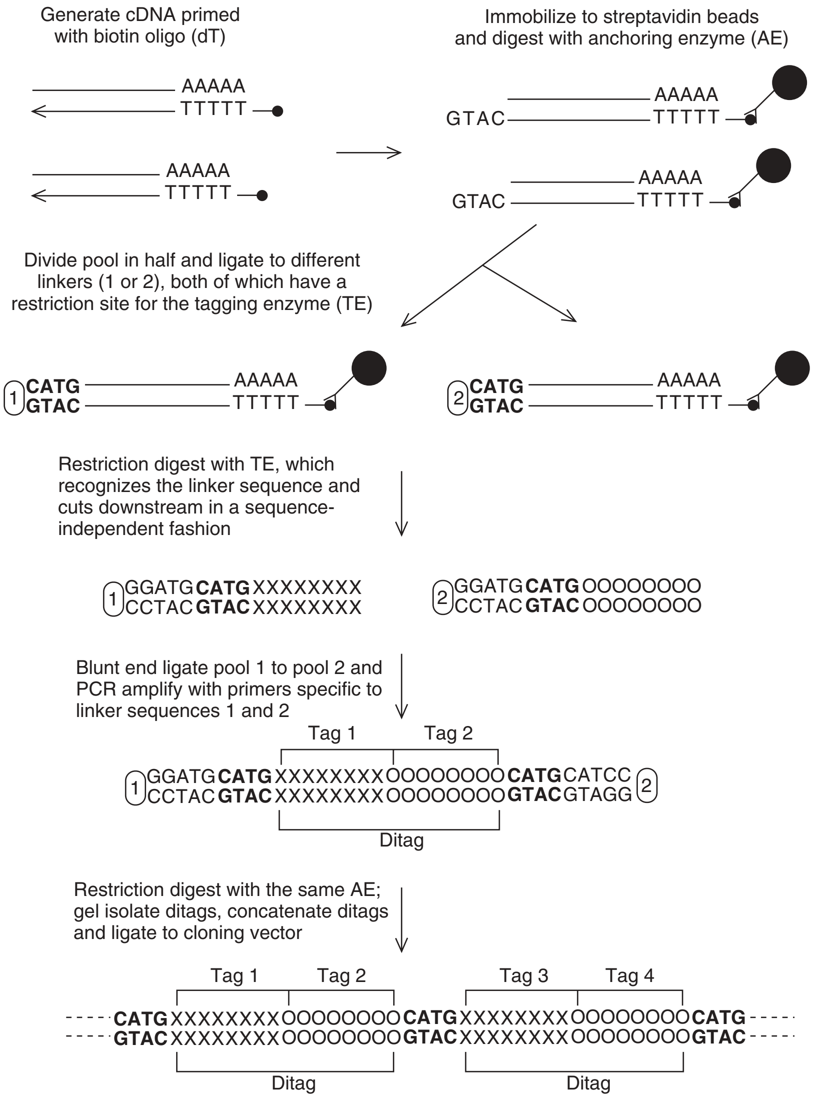

Figure 7.5-2. The steps involved in SAGE.

7.5.2.3 High-Density Oligonucleotide Arrays

High-density arrays of oligonucleotides are the most powerful and versatile tools for functional genomics. They work by hybridization of labeled RNA or DNA in solution to DNA molecules attached at specific locations on a surface. So DNA microarrays may be defined as miniaturized, ordered arrangements of nucleic acid fragments derived from individual genes located at defined positions on a solid support, which enables the analysis of thousands of genes in parallel by specific hybridization. DNA microarrays provide information on how several genes are abnormally regulated in a disease. For example, a microarray of 100 genes that have a role in inflammation was used to examine rheumatoid tissue. The analysis revealed the upregulation of genes encoding interleukin 6 and several matrix metalloproteinases [17]. The microarray technology will continue to contribute to the understanding of responses to drug treatments [18]. Based on the fabrication technique used, planar microarrays can be broadly classified into microarrays prepared by *in situ* synthesis of oligonucleotides and direct spotting of oligonucleotides on glass, membrane, or other derivatized surfaces by microspotting or inkjet printing methods.

Microarrays Fabrication by in-situ Synthesis. A combination of photoli-thography and combinatorial chemistry is used to develop very high-density DNA chips by Affymetrix (http://www.affymetrix.com, Santa Clara, CA). Fused silica wafers are hydroxylated and then silanized. The silanes contain a linker molecule and a protective group that can be activated by light. The silane film provides uniform hydroxyl density to initiate the microarray fabrication process. Photolithographic masks are then used to illuminate specific locations on the silanized wafer. Ultraviolet (UV) exposure causes the deprotection of groups on the silane, after which the activated groups couple nucleotides onto the silica wafer. Additional capping steps prevent unattached molecules from becoming probes. The side chains on the nucleotides are protected to prevent branched-chain formation. These steps of deprotection, coupling, and capping are continued until probes of full length are fabricated (Figure 7.5-3).

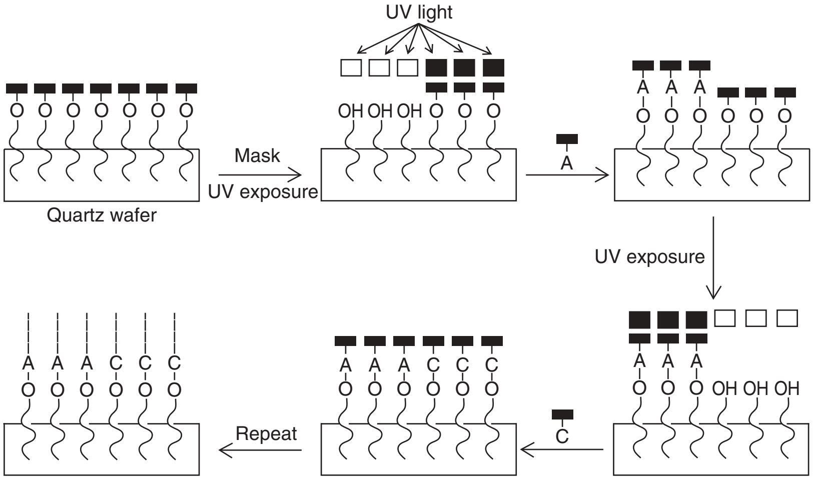

Figure 7.5-3. Fabrication of high-density oligonucleotide array by photoactivation and deprotection of nucleic acids. Photomasks are used to pattern UV light at localized regions to selectively synthesize patterned array.

In an alternative approach developed by NimbleGen (http://www.nimblegen.com/, Madison, WI), arrays are built using photodeposition chemistry based on a maskless array synthesizer (MAS). The MAS system is a high-density DNA fabrication instrument that uses a maskless light projector as a "virtual mask" instead of the physical chromium masks used by Affymetrix. The virtual mask is an array of hundreds of thousands of individually addressable aluminum mirrors on a computer chip. These mirrors function as virtual masks that reflect the desired pattern of UV light and are controlled by the computer.

In situ synthesized oligonucleotide probes generally do not exceed 25 bases in length because of reaction efficiency limits. As a result, mismatches and spurious target-probe binding can take place due to the limited specificity and binding affinity for a 25-residue oligonucleotide. To overcome this problem, a series of oligonucleotides that differ by a one-base mismatch from the gene-specific probe is also included on the array and can be used to determine the amount of mismatch hybridization, which can then be substracted from the signal [19, 20]. The Affymetrix arrays contain between 40,000 and 60,000 probes (including multiple mismatch controls for each gene) and provide the highest density of probes of any array.

Microarrays Fabrication by Direct Spotting. Microarrays can be fabricated by directly spotting oligonucleotides on microscope glass slides, membranes, or other surfaces. Various types of spotters and derivatized substrate surfaces have been developed to fabricate microarrays [21–23]. The surface groups on the derivatized surface determine how the oligonucleotides will be immobilized on the surface. DNA molecules contain phosphate groups, which are commonly used for immobilization on positively charged surfaces. Amine surfaces carry a positive charge at neutral pH. Therefore, negatively charged DNA molecules form ionic bonds with the positively charged amine-derivatized surface. Often, UV or thermal treatment is used to covalently link the DNA molecules to amine-derivatized slides that are most suitable for immobilizing long oligonucleotides. Sometimes, to improve the binding efficiency, a longer chain spacer is attached to the aminated surface to provide sufficient separation between the amino groups and substrate surface. Poly-1-lysine-coated slides containing a dense layer of amino groups are similarly used to attach DNA molecules via ionic interactions. Additionally, amino-modified can be covalently immobilized on aldehyde- and epoxy-derivatized glass slides.

Microarray is now an essential tool in functional genomics for drug target discovery. However, in addition to the obvious use of functional genomics in basic research and target discovery, there are many other specific uses, including biomarker determination to find genes that correlate with and presage disease progression; pharmacology to determine differences in gene expression in tissues exposed to various doses of compounds; toxico-genomics to find gene expression patterns in a model tissue or organism exposed to a compound and their use as early predictors of adverse events in humans; target selectivity to define a compound by the gene expression patterns; prognostic tests to find a set of genes that accurately distinguishes one disease from another; and disease subclass determination to find multiple subcategories of tumors in a single clinical diagnosis [24].

7.5.3 OLIGONUCLEOTIDES IN DRUG TARGET VALIDATION AND POTENTIAL THERAPEUTICS

Because their sequence is complementary to that of mRNA, antisense oligonucleotides (ON) form a very powerful weapon for studying gene function (functional genomics) and for discovering new and more specific treatments of human diseases (antisense therapeutics). The binding or hybridization of antisense nucleic acid sequences to a specific mRNA target will interrupt normal cellular processing of the genetic message of a gene through at least three mechanisms: (1) the oligonucleotide: RNA duplex may form substrate for endogenous RNase H, leading to mRNA cleavage; (2) the duplex may prevent the productive assembly of the ribosomal complex preventing translation; and (3) the duplex may arrest a ribosomal complex already engaged in translation leading to a truncated protein [25]. However, the successful therapeutic application of antisense ONs has been delayed because of delivery problems. Natural ONs are not membrane-permeable, and even after delivery into cells with the help of amphipathic cations or liposomes, antisense ONs can still be hydrolyzed by cellular nucleases before reaching their intended target mRNAs. To improve their bioavailability, various types of chemically modified antisense ONs have been produced [26–29]. However, chemical modification has also led to undesirable complications such as decreased sequence-specificity and general toxicity. On the other hand, the discovery of RNA interference (RNAi) started a new era in antisense technology [30–32]. Double-stranded short interfering RNAs (siRNA) could silence their target mRNA almost 100 times more effectively than single-stranded ONs [33]. However, delivery of siRNA is still a problem as successful administration often requires the use of plasmids or viral vectors, leading to the risk of random integration into chromosomal DNA, which is a serious threat to therapeutic safety [34].

7.5.3.1 Diversity in Antisense Technology

Many types of chemically modified antisense ONs have been manufactured with the changes in the overall electronic charge as well as the incorporation of nonphosphate oligonucleotide backbones. They are commonly grouped into three "generations" based on the type of modifications (Figure 7.5-4).

First-Generation Antisense ONs. These ONs were manufactured through the substitution of one nonbridging oxygen atom in the phosphate group of ONs with either a sulphur or a methyl group. Those DNA analoges with a sulfur group are known as phosphorothioate ONs, which is the most widely used antisense ON to date. The main advantages of phosphorothioate ONs are resistance against nucleases, ability to recruit RNase H to cleave target mRNA, ease of synthesis, and attractive pharmacokinetic properties. The first U.S. Food and Drug Administration (FDA)-approved antisense drug, Vitravene from Isis (Carlsbad, CA), which treats a condition called cytomegalovirus (CMV) retinitis in people with AIDS, and the majority of antisense compounds in clinical trials to date are based on this chemical design.

Second Generation Antisense ONs. These contain nucleotides with alkyl modification at the 2′ position of the ribose. 2′-O-methyl and 2′-O-methoxyethyl

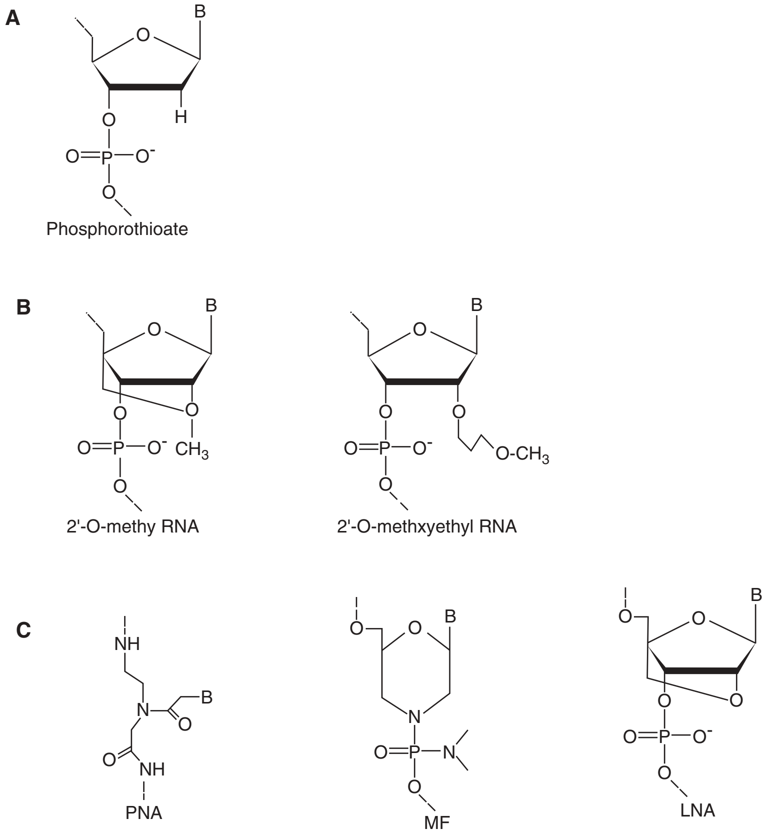

Figure 7.5-4. Nucleotide modifications for use in antisense technology. (A) The first-generation phosphorothioate backbone modification. (B) The second ribonucleotides modified at the 2′ hydroxyl by adding a methyl or methoxy–ethyl group. (C) The third-generation modifications involving the complete replacement of phosphodiester linkages as in PNA and MF or the conformational lock as in LNA.

RNAs are the most important representatives. The significant improvements are a reduction in general toxicity, increased hybrid stability, and increased nuclease resistance. However, the only disadvantage is that 2′-O-methyl RNA cannot induce the RNase H cleavage of the target mRNA. To induce RNase H cleavage, mixed backbone ONs (MBOs) were developed by surrounding a phosphorothioate-modified deoxyribose core that retains RNase H activity with nuclease-resistant arms, such as 2′-O-methyl ribonucleosides [35, 36]. The antisense activity, pharmacokinetics, *in vivo* degradation, and safety profile of an MBO can be modulated by combining appropriate oligonucleotide segments and backbone modifications at defined sites. GEM231, which targets the RI(alpha) subunit of protein kinase A (PKA), is built on an MBO platform and is being developed by Hybridon (Cambridge, MA) as a cancer therapeutic [37]. It is an 18-mer oligonucleotide with four 2′-O-methyl ribonucleosides at both the 3′- and the 5′-ends surrounding the remaining deoxynucleosides, all with phosphorothioate internucleotide linkages.

Third-Generation Antisense ONs. These are DNA and RNA analoges with modified phosphate linkages or ribose as well as nucleotides with a completely different chemical moiety replacing furanose ring. Peptide nucleic acids (PNAs), morpholino phosphoroamidates (MFs), and locked nucleic acids (LNAs) are three interesting RNA/DNA analoges in this class. These compounds are essentially nuclease resistant while maintaining good hybridization affinity with their complementary mRNA.

PNA and MF possess the structures where the phosphodiester linkages are completely replaced, respectively, with a polyamide (peptide) and phosphoroamidate backbone (Figure 7.5-4) [38, 39]. They both form tight bonds with their RNA targets and probably exert their effects by blocking translation, as neither molecule effectively activates RNase H. Noncharged backbones prevent PNA and MF from binding to proteins that normally recognize polyanions in a nonspecific manner. However, due to the electrostatically neutral property, solubility and cellular uptake are serious problems for both PNA and MF. The ability of PNA to recognize duplex DNA makes PNA more promising candidates for modulating gene expression or inducing mutations by strand invasion of chromosomal duplex DNA [40] because the PNA:DNA duplex is more stable than a DNA:DNA duplex [41]. Effective gene knockdown has also been shown by antisense MF, and one such MF targets the *c-myc* oncogene [42] and is being developed by AVI BioPharma (Portland, OR).

LNAs [also known as bridged nucleic acids (BNAs)] are another type of novel high-affinity molecules that provide major improvements in several key properties. They contain a methylene bridge connecting the 2′-oxygen of the ribose with the 4′-carbon (Figure 7.5-4), leading to improved binding to complementary DNA and RNA sequences [43]. Although the 2′–4′ linkage reduces or eliminates activation of mRNA cleavage by RNase H, it is straightforward to synthesize chimeric "gapmers," in which a central DNA portion is flanked by LNA to enhance the stability of binding and enable recruitment of RNase H. LNAs have been successfully used to suppress the expression of an RNA polymerase, resulting in the inhibition of tumor growth in a xenograft model [44].

siRNAs and Traditional Antisense Technology. siRNA are the effector molecules of the RNAi pathway in which endogenously produced double-stranded RNA is cleaved by the Dicer enzyme within the cells into 21- to 28-nucleotide siRNA for targeted degradation of complementary mRNA through the formation of RNA-induced silencing complexes (RISCs). siRNA can be synthetically produced or expressed from vectors transcribing short double-stranded hairpin-like RNAs that are processed into siRNAs inside the cell. Unlike ONs, siRNA cannot effectively target pre-mRNA for degradation in mammalian cells [45]. However, siRNA is now a reliable gene-silencing tool in functional genomics for the validation of potential drug targets identified by the techniques described above. The low concentration of siRNA required to elicit effective gene silencing and the fact that siRNAs are specifically and rapidly incorporated into RISC diminish the potential for the nonspecific binding with proteins as happened in phosphorothioate-modified ONs, which makes them toxic at a high concentration. However, it is important to identify effective siRNAs so that the lowest possible concentration of siRNA can be allowed for gene silencing [46–48]. If siRNAs are to be used for therapeutic

purposes, methods must be developed that protect the possible side effects of siRNAs by either modification of the siRNA backbone [49–51] or avoidance of immunostimulatory sequence motifs [51, 52].

7.5.4 OLIGONUCLEOTIDES IN GENOTYPING POLYMORPHISMS

Single nucleotide polymorphisms (SNPs), the most frequent DNA sequence variations found in the human genome (about 1 per 350-bp frequency), are being uncovered and assembled into large SNP databases that promise to enable the dissection of the genetic essence of disease and drug response [53–57]. The identification of a complex set of genes that cause a disease will require both linkage and association analyses of thousands of polymorphisms across the human genome in thousands of individuals. In addition, certain genetic polymorphisms cause significantly different responses among individuals on exposure to a particular drug [58]. Understanding the role of genetic polymorphisms in drug responses will help to increase drug efficacy and decrease adverse effects by tailoring medications to patients' genetic makeup. Advances in the field, which is known as "pharmacogenetics," have important clinical implications and practical value for the design of dosing regimens. There are two broad areas in pharmacogenetics, specifically pharmacokinetics (PK) describing drug adsorption, distribution, metabolism and elimination, and pharmacodynamics (PD) elucidating the pharmacological effects of a drug on the body (either desired or undesired) and differences in either PK or PD can lead to variable drug efficacy or toxicity risk [59]. The Human Genome Project has provided a windfall of sequence polymorphism data, and because of the collaborative SNP discovery initiatives such as the SNP Consortium (TSC), millions of human SNPs have been catalogued, many of which are publicly available in the TSC and NCBI dbSNP repositories (http://snp.cshl.org; http://www.ncbi.nlm.nih.gov/SNP/). The high-density SNP map will allow researchers to expand their capabilities for identification of critical diseases and drug-response genes. Genotyping SNPs in large-scale pharmacogenetic studies is an integrated part of the drug discovery and development process. Advanced technologies to identify genetic polymorphisms rapidly, accurately, and economically are becoming a priority in the implementation of pharmacogenetics to drug development, clinical trials, and clinical monitoring for drug efficacy and toxicity [60]. SNP genotyping is now performed by several advanced technologies, most of which are based on synthetic oligonucleotide primers or probes.

7.5.4.1 Gel-based Genotyping for Detecting Known Polymorphisms

PCR–Restriction Fragment Length Polymorphism (RFLP) Analysis. Commonly used methods include gel-electrophoresis-based techniques such as PCR coupled with RFLP analysis. Specific regions of DNA sequences can be PCR amplified by using specific primers. The PCR products are then digested with appropriate restriction enzymes and visualized by staining the gel after electrophoresis. If the genetic polymorphism produces a gain or loss of the restriction site, a different restriction digestion pattern will be obtained [60]. A major limitation is the requirement that the polymorphisms alter a restriction enzyme cutting site [61].

Oligonucleotide Ligation Assay (OLA) Genotyping. OLA relies on hybridization with specific oligonucleotide probes that can effectively dis-criminate between the wild-type and variant sequences. Three oligonucleotide probes are used in OLA: two allele-specific probes (one specific for the wild-type allele and the other specific for the mutant allele) and a fluorescent common probe. The 3′ ends of the allele-specific probes are immediately adjacent to the 5′ end of the common probe. The gene fragment containing the polymorphic site is amplified by PCR and incubated with the probes. In the presence of thermally stable DNA ligase, ligation of the fluorescent-labeled probe to the allele-specific probe(s) occurs only when there is a perfect match between the variant or the wild-type probe and the PCR product template. These ligation products are then separated by electrophoresis, thus enabling the identification of the wild-type genotypes, the variants, the heterozygotes, and the variants (Figure 7.5-1). By varying the combinations of color dyes and probe lengths, multiple mutations can be detected in a single reaction [62].

7.5.4.2 Non-Gel-Based High-Throughput Genotyping Technologies

TaqMan Genotyping. The assay is based on TaqMan real-time PCR technology as described above. However, SNP genotyping requires two TaqMan probes that differ at the polymorphic site, with one probe comple-mentary to the wild-type allele and the other to the variant allele. A 5′ reporter dye and a 3′ quencher dye are covalently linked to both wild-type and variant allele probes. During the PCR annealing step, the TaqMan probes hybridize to the targeted polymorphic site. During the PCR extension phase, only the perfectly hybridized probe will be cleaved by the 5′ nuclease activity of the *Taq* polymerase, leading to an increase in the characteristic fluorescence of the reporter dye. A mismatched probe will not be recognized by the *Taq* polymerase, resulting in the quenching of fluorescence due to the physical proximity of the reporter and quencher dyes.

Molecular Beacons. As described, the ends of molecular beacons are complementary to each other, forming a stem structure, whereas the intervening loop is complementary to a sequence within the PCR amplified product. When hybridized to the right target sequence, the two fluorescent dyes (donor and acceptor) at opposite ends of the probes are separated and the fluorescence is increased dramatically [63]. Mismatched probetarget hybrids dissociate at a substantially lower temperature than exactly complementary hybrids. This thermal instability of mismatched hybrids increases the specificity of molecular beacons. For SNP genotyping, two molecular beacons with exact sequence matches to the wild-type and variant alleles are used in the same PCR reaction. These two molecular beacons are labeled with different fluorophores that emit fluorescent light at distinct optical wavelengths. The use of two differentially labeled molecular beacons in the same PCR reaction allows simultaneous determination of three possible allelic combinations.

Invader Assay. The Invader assay developed by Third Wave Technologies, Inc. (Madison, WI) is an attractive FRET-based technique to genotype SNPs without PCR amplification (Figure 7.5-5). Two oligonucleotides, a wild-type or variant signal probe plus an upstream Invader probe, are used in each reaction. These

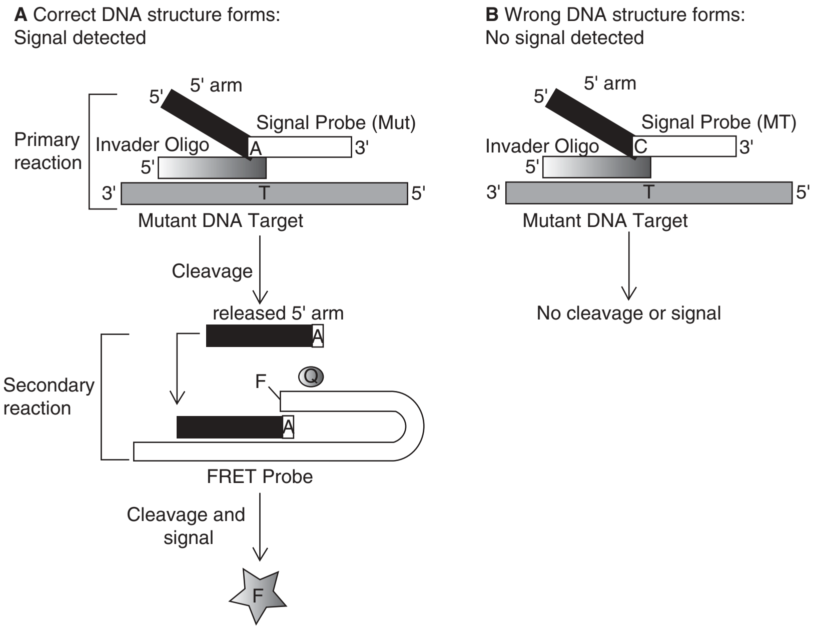

Figure 7.5-5. Invader SNP assay.

probes hybridize in tandem to a specific region of genomic DNA. When the 3′ end of an upstream oligonucleotide (Invader probe) overlaps the hybridization site of the 5′ end of a downstream oligonucleotide (signal probe) by at least one base pair, the structure will be recognized and cleaved by Cleavase [64, 65]. A single-nucleotide mismatch immediately upstream of the cleavage site renders the conformation unrecognized by Cleavage. Each cleavage product then serves as an invader oligonucleotide in a secondary reaction where it directs the cleavage of a combined labeled FRET probe-template construct. The secondary oligonucleotide probe is 5′ end-labeled with the donor flurophore, which is quenched by an internal acceptor dye. When the DNA is cleaved, the donor and acceptor dyes are no longer in close proximity, the quenching is abolished and fluorescence is generated. The whole process repeats multiple times, producing linear amplification of the fluorescent signal. Assays are read with a fluorescence plate reader and genotypes are assigned after determination of the net wild-type/variant signal ratio for each sample [64, 66].

FRET-based PCR–OLA. The three dye-labeled ligation probes for each SNP are designed to have low melting temperatures. A 5′ donor dye-labeled common probe terminates one base immediately upstream from the polymorphic site. Two allele-specific 5′-phosphorylated, 3′-acceptor dye-labeled probes have polymorphic nucleotides at the 5′ end. A thermostable DNA polymerase with no 5′ nuclease activity and a thermostable DNA ligase are used. The first stage of PCR reaction is kept at high temperature, and the ligation probes cannot to anneal. After sufficient PCR products are generated, the second stage of the reaction, with a low annealing temperature, allows ligation to occur. By analyzing the fluorescence signals of all dyes, individual genotypes can be determined directly after one reaction using

real-time PCR or by endpoint signal analysis using a fluorescent plate reader [67].

Rolling Circle Amplification (RCA). Like the Invader assay, RCA is also sensitive enough to work directly from genomic DNA [68, 69]. For each SNP, two linear, allele-specific probes are designed that circularize when they anneal to the target sequence. Each probe consists of a single oligonucleotide, 80–90 bases in length. The 5′-end of the probe is phosphorylated and bears a sequence of 20 nucleotides that will hybridize to the region immediately 5′ of the SNP. The 3′-end of the probe contains 10–20 nucleotides complementary to the region immediately 3′ of the SNP. Both allele-specific probes are identical with the exception of the 3′-base, which is varied to complement the polymorphic site. Sandwiched between the allele-specific probe arms is a generic backbone sequence of 40–50 nucleotides that provides binding sites for two RCA amplification primers to be used in the second stage of the assay.

The first stage of the assay is the allele discrimination step. Target genomic DNA is denatured to make it single stranded and then hybridized with a pair of single-allele-specific, open-circle oligonucleotide probes resulting in circularization of the probe. Allele discrimination is performed by a thermophilic DNA ligase. Ligation of the probe will preferentially occur when the 3′-base exactly complements the target DNA. If there is a mismatch between the 3′-allele-specific base and the target, the ligation product will be produced at a much-reduced rate. In a homozygous sample, the ligation of one allele-specific probe predominates over the other, and in a heterozygous sample, both probes are ligated with equal efficiency.

Subsequent detection of the circularized oligonucleotide probes is by RCA, using the two non-cross-reacting primers. The first primer is complementary to 20 bases of the circularized oligonucleotide probe in the backbone region and is extended by an exonuclease-deficient DNA polymerase. The extending probe eventually displaces itself at its 5′-end once one revolution of the circularized probe is completed. Continued polymerization and displacement result in the generation of a single-stranded product of complementary concatamers. The second primer is the same sense as the probe. It binds to each tandem repeat of the first strand product at sites corresponding to a second region of the backbone, where it primes DNA synthesis at each site. As these multiple binding events elongate, strand displacing activity of the DNA polymerase causes these nascent strands to be displaced and a multitude of new recognition sites for the first primer are exposed in a process known as branching. Eventually, strand displacement results in the release of double-stranded DNA fragments from the parent molecule, thus generating up to 10^9 copies of each circular oligonucleotide probe under isothermal conditions. A FRET-based RCA assay called SNIPER has been developed by Amersham Pharmacia Biotech. [70], in which the second amplification primer is an Amplifluor labeled oliogonucleotide with a 5′-hairpin loop containing FRET dyes. As the complementary strands to the hairpin primers are synthesized, the polymerase reads through the stem of the hairpin loop and opens out the 5′-end. In this linearized conformation, the fluorophore is no longer quenched and fluorescence can be detected. Probes that fail to hybridize do not give fluorescence signal in solution, eliminating the need for purification or separation steps, which makes automation of the RCA assay easier.

DNA Microarray Genotyping. A high-density oligonucleotide microarray offers simultaneous analysis of many polymorphisms. The DNA sample of interest is PCR amplified to incorporate fluorescently labeled nucleotides and then hybridized to hundreds of thousands of oligonucleotides attached to a solid silicon surface in an ordered array. Each oligonucleotide in the high-density array acts as an allele-specific probe. Perfectly matched sequences hybridize more efficiently to their corresponding oligomers on the array and, therefore, give stronger fluorescent signals over mismatched probe-target combinations [71, 72]. The hybridization signals are quantified by high-resolution fluorescent scanning and analyzed by computer software.

Sequencing by hybridization can be an efficient method to monitor many SNPs. It is possible to array a set of short oligonucleotides covering the entire DNA fragment on a DNA chip. Because the precise sequence of the oligonucleotide at each location on the chip is known, the pattern of hybridization can be determined using fluorescently labeled DNA probes. The advantage of this method is that a large DNA fragment or a large collection of small PCR products can be scanned in one hybridization. More than 100 such arrays have been used for high-throughput screening of SNPs covering 2.3 Mb of genomic DNA [73] and thousands of SNPs have been screened rapidly by use of chip-based resequencing [74].

As mentioned, almost all currently available SNP genotyping starts with a locus-specific amplification step, followed by an allele discrimination step [59, 73, 75]. At capacities of 1000 SNPs or less, locus-specific amplification is economically feasible in terms of oligonucleotide synthesis and other reagent costs. At capacities of 10,000 SNPs and greater, the costs of designing, synthesizing, and managing such an enormous number of oligonucleotides become prohibitive. Additionally, large amounts of starting sample DNA are required to genotype tens of thousands of SNPs in a locus-specific manner. Thus, considering the high complexity of human genome, the most common strategy is now to reduce the complexity by amplifying portions of the genomic DNA by PCR. This can be done in a random or semi-random fashion, for example, by using restriction enzyme-based adapter ligation PCR [76]. This representational approach, which is used to detect changes in genomic copy number, has also been applied to genotyping of 10^4–10^5 or more SNPs from a single sample preparation [77, 78]. Genomic complexity reduction assay involves five primary steps, starting with restriction digestion, ligation of adaptor, amplification, fragmentation, and labeling, before hybridization to the oligonucleotde array [78]. Highly multiplexed PCR-based approaches have recently been developed to genotype specific loci of interest, enabling targeted genotyping of 10^3–10^4 or more SNPs from a single sample [79]. These targeted genotyping approaches include a pre-PCR enzymatic SNP scoring step, the addition of universal priming sites by ligation, and subsequent universal primer PCR. Today, almost all high-throughput genotyping is done using one of these methods [80].

7.5.5 CONCLUSION

The automated oligonucleotide synthesizers now enable large-quantity, low-cost synthesis of precisely designed different sequences of oligonucleotide based in a parallel fashion. On the other hand, depending on the specificity of sequences for

precise base pairing to each other, oligonucleotides have the enormous potential to facilitate manufacturing of innovative numerous molecular machinery with the help of molecular biology enzymes, for being used as genomics tools as well as therapeutic tools. It should be emphasized that the new high-throughput approaches, such as microarrays, do not replace the conventional standard methods. The standard methods, such as northern blots or RT–PCR, are simply used in a more targeted fashion to complement the broader measurements and to follow up on the genes, pathways, and mechanisms implicated by array results.

7.6.1 INTRODUCTION

Advances in medical technology have depended on cellular and molecular research to gain an in-depth understanding of the basic mechanisms of homeostasis. Medical investigators have used their knowledge of cellular processes to search for small chemical compounds that can alter specific biochemical reactions in cells and tissues. Many of these compounds function in a general fashion through an alteration in biochemical pathways or via stimulation of the immune system. Drugs that can modulate gene expression in a targeted fashion, however, offer the potential of a much higher level of specificity and control over cellular processes. The newest laboratory method for modulating gene expression, RNA interference (RNAi), has gained rapid interest throughout the world of molecular research, in general, and is being actively pursued as the next "gene-targeted medicine."

RNAi is a process in which double-stranded RNA (dsRNA) directs the specific degradation of a corresponding target mRNA. The mediators of this process are small dsRNAs, of 21 bp in length, called short interfering RNAs (siRNAs). The phenomenon of RNAi was first reported in 1998, by Fire et al. [1], who observed that dsRNA could inhibit gene expression in *Caenorhabditis elegans*. Although the underlying mechanism of this effect was poorly understood at the time, the generality of the phenomenon and its utility in the laboratory as a method of posttranscriptional gene silencing were quickly confirmed by the work of several groups [2–8]. The process whereby dsRNA is cleaved into siRNAs was initially described in plants [9] and then in *Drosophila* [10, 11]. The cellular protein factors associated with this conversion in the cell were identified soon afterward ([12] and recently reviewed in Refs. 13 and 14).

The rapid growth and popularity of RNAi as a research topic of interest and as a useful tool in the laboratory is evidenced by the tremendous yearly increase in publications on the subject since its initial description less than a decade ago. A current search of the scientific literature, using the terms "RNAi" and "siRNA" as keywords, reveals that over 10,000 articles have been published on the subject within the last 5 years, since the beginning of this century (Figure 7.6-1). This type of response to a technical discovery is wholly unprecedented and could only perhaps be reasonably compared with the "explosion" of significant and widespread advances that the invention of the polymerase chain reaction (PCR) [15–17] contributed to biological research and current biotechnology toward the end of the last century.

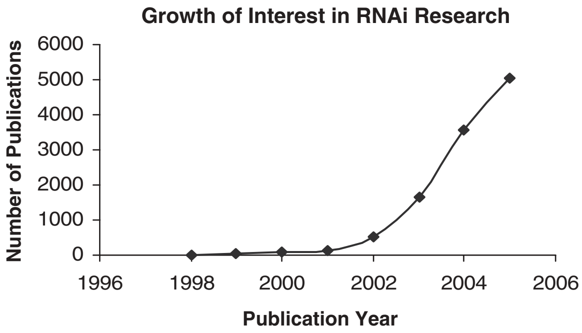

Figure 7.6-1. Growth of interest in RNAi research.

Our aim in this chapter is not to give an extensive review of the rapidly expanding literature in this field but, rather, to describe the main ideas, approaches, and technological directions that may guide the medical research-er interested in using RNAi methodologies to identify and/or develop new drug candidates. We have included several examples and discussions of the concepts involved to provide a clear picture of the potential advantages and limitations of specific RNAi-based gene-targeted medicine.

7.6.2 BASIC PRINCIPLES AND MOLECULAR MECHANISMS OF RNAi

For many years scientists involved in biomedical research have searched for simple methods for targeting the regulation of a gene's activity. These methods would be used for characterizing gene functions as well as for developing targeted medicines to treat and correct a variety of diseases and disorders. In 1990, when Napoli et al. reported on the specific repression of the chalcone synthase (CS) gene in petunia flowers by introduction of a chimeric CS gene and demonstrated that it was the result of a reduction in the level of CS mRNA [18], it would have been almost impossible to suggest that in just a few years time there would be a revolution in our ability to specifically regulate the expression of virtually any gene in any cell and in many organisms.

Work starting from that of Andrew Fire et al. [1] describing the phenomenon of RNAi in *C. elegans* in 1998, up until now, has shown that RNAi is a conserved and universal mechanism of defense [19] (against viruses and mobile genetic elements, retrotransposons) and gene regulation that is widely spread among different biological kingdoms [20]. For the efficient silencing of any target gene, a corresponding homologous dsRNA can be delivered into the cells and tissues of organisms by several different methods: direct injection, feeding, soaking, electroporation, transfection, and so on. RNAi occurs by two parallel and, in many respects, similar pathways involving many common cellular proteins: the so-called short interfering RNA (siRNA) and microRNA (miRNA) pathways (Figures 7.6-2 and 7.6-3). Both pathways lead to the specific silencing of genes, either through degradation or a translational block of the corresponding mRNA.

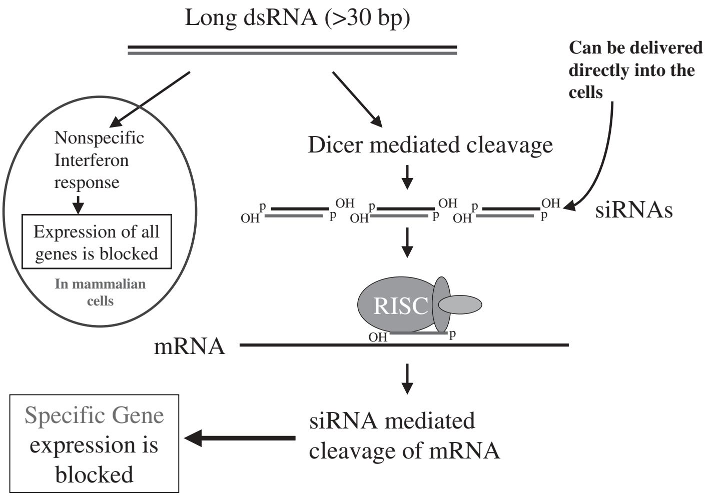

Figure 7.6-2. Mechanism for inhibition of gene expression via the siRNA branch of the RNAi pathway. Short interfering RNAs can be delivered directly into the target cells to avoid nonspecific interferon (IFN) response.

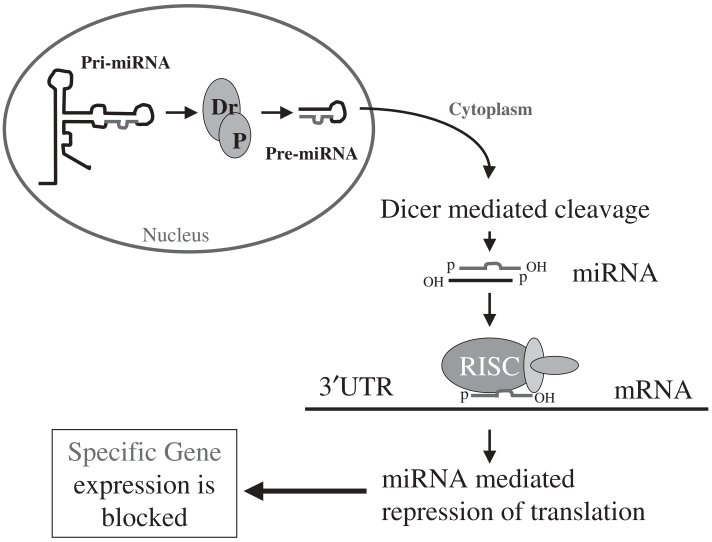

Figure 7.6-3. Mechanism for inhibition of gene expression via the miRNA branch of the RNAi Pathway. Proteins involved in Microprocessor: Dr—Drosha, P—Pasha, UTR—untranslated region of mRNA.

The first step in the siRNA pathway is degradation of the long dsRNA into short double-stranded fragments, later termed siRNAs (Figure 7.6-2). siRNAs, which have two overhanging 3′-nucleotides and 5′-phosphate groups [9–11, 21], are converted from longer dsRNAs by a cellular enzyme with RNase III activity called dicer ([22] and reviewed in Ref. 23). At the next step, siRNAs bind to the cellular complex called the RNA-induced silencing complex (RISC) [22, 24], of which the

main component is a protein called argonaute [19, 24]. Only one strand of the siRNA molecule specifically interacts with, and hence "enters," RISC [25, 26] and determines the specificity of target RNA cleavage.

With the success of RNAi-dependent targeted inhibition of gene expression in different lower organisms, immediate efforts were made to apply this technology in mammalian cells and organisms by the intracellular delivery of long dsRNAs cognate to the gene assigned to downregulation. However, in mammalian cells, there is a well-known nonspecific antiviral defense mechanism based on activation of the interferon (IFN) pathway in response to intracellular invasion by viral dsRNA [27]. In this pathway, several IFN-induced genes (including the RNA-dependent protein kinase (PKR), the 2′,5′-oligoadenylate synthetase (OAS) and RNase L, and the Mx protein GTPase) orchestrate a complex cascade of events leading to the degradation of the foreign dsRNA, a general arrest of the translational machinery of the host cell, and other downstream effects important for host cell defenses over viral infections. Moreover, PKR can be differentially modulated by different species of dsRNA. This effect may depend on the sequence and secondary structure of a dsRNA, and PKR can be stimulated with as few as 11 bp of dsRNA [28]. In any case, this complex mixture of different nonspecific responses can completely abolish the sequence-specific gene-targeted effects of dsRNAs.

Nonetheless, an understanding of the molecular mechanisms of RNAi proceeding through the endogenous generation of siRNAs [10, 21] allowed Elbashir et al. [29] to design a smart way to avoid most of these nonspecific IFN-related effects. They designed and delivered into the cells gene-specific dsRNA as short dsRNAs (siRNAs, 21–22 bp), as they occur in their mature form during the natural RNAi mechanism. Using this modification, most of the IFN response, which is induced by longer dsRNAs (>30 bp), is avoided. Their experiments demonstrated the use of siRNA compounds as efficient and specific downregulators of gene expression. This breakthrough began a new era for the use of RNAi technology in biomedical research for pathway profiling, drug candidate identification, and targeted therapy using mammalian cells and organisms. Nevertheless, some types of nonspecific effects still present a concern for the use of RNAi technology for therapeutic applications, as will be discussed later on in this chapter.

A detailed understanding of the molecular mechanism underlying RISC activity has led to improvements in the design of siRNA compounds. The current principles for siRNA design are (1) the strand with the more loosely base-paired 5′ end in the siRNA duplex enters RISC, (2) the 5′ end of this strand has to be phosphorylated, and (3) the siRNA duplex needs to have 3′ overhanging ends of 2-nucleotides in length. Despite this knowledge, only about 20% of siRNAs designed are active in RNAi, and hence, all require experimental validation of their activity. Furthermore, the efficiency of repression of the target gene by siRNA may not be absolute, as the degree of inhibition observed depends on several factors. These factors include the chemical stability and specific activity of the siRNA compound; the "effective" concentration delivered to the cells, which depends on the number and duration of treatments; the physiological state of the target cell; the level of target mRNA; and, especially, the level and turnover rate of the target protein in the cell or tissue. A number of these factors will be discussed in detail below.

With intense research efforts in the field of RNAi, it became clear that another cellular pathway of gene regulation, discovered earlier in *C. elegans* and based on

the transcription of small untranslated RNAs [30, 31], is closely related to siRNA-dependent gene regulation [32]. This second branch of RNAi, which has also remained extremely conserved during evolution, was termed the microRNA, or miRNA, pathway (Figure 7.6-3). MicroRNAs have been identified across many different biological kingdoms (from plants to nematodes to humans), and they function to regulate the expression of different genes. Both pathways, siRNA and miRNA, share common elements of their core machinery [33], such as dicer and RISC; however, there are some obvious differences and specialized components. The miRNA process begins in the nucleus, where long (up to several thousand bp [34]) capped pri-miRNA molecules are transcribed by RNA-polymerase II from corresponding miRNA genes. These complex RNA molecules are processed into hairpin-like pre-miRNA molecules (about 65–70 bp) by a multiprotein complex, called microprocessor, containing at least an RNaseIII enzyme Drosha and its partner Pasha [35]. Pre-miRNA molecules are then transported to the cytoplasm where they are converted to miRNAs by dicer (Figure 7.6-3) [23, 32]. The main difference between the two pathways is that miRNA molecules are not 100% homologous with the target mRNA and may contain up to several mismatches. In addition, miRNA-dependent inhibition of expression, which most likely takes place in specialized subcellular compartments called P-bodies [36], occurs through the interaction of RISC-bound miRNAs with the 3′-untranslated region of the target mRNA and results in an arrest of translation rather than degradation of the message, as in the siRNA pathway.

Currently, it is not clearly understood what targets a short dsRNA down the miRNA pathway. It is possible that the presence of some nonhomologous regions between an siRNA molecule and some unintended target RNA may direct this complex into the miRNA pathway and produce some off-target effects. In any case, a more detailed understanding of the miRNA pathway will clearly provide additional insights for the further development of powerful RNAi-based tools for gene regulation and therapy, and for the evasion of nonspecific and off-target effects.

Since its discovery less than a decade ago, the RNAi field has progressed at an incredible pace, permitting manipulations of gene expression that were previously impossible. As a result, this technology immediately acquired an important role in pharmaceutical science for the screening, identification, and validation of drug targets, a process that, before the discovery of RNAi, usually expended several years of intense effort. Moreover, the specific features of RNAi technology, such as high target specificity, efficiency, and to some extent, the ease of compound design, have implicated this technology as a potential instrument for therapeutic use. In the following sections we discuss a variety of biological and technical aspects of applying RNAi technologies to the discovery and development of customized, state-of-the-art, gene-targeted medicines of the future.

7.6.3 RNAi AS A TOOL FOR IDENTIFYING AND VALIDATING DRUG TARGETS

The traditional drug discovery process implemented by many pharmaceutical companies includes drug target identification, characterization of the target, high-throughput screening (HTS) of small-molecule libraries, and medicinal chemistry

optimization. The bottleneck of this scheme has traditionally been the identification of targets due to the absence of appropriate high-throughput screening approaches. The recent discovery and development of RNAi technology, however, has provided a new approach that will accelerate the rate and efficiency of the initial and overall screening process.

With the emergence of siRNA technology, its first useful application was obvious: to switch off (or downregulate) a certain gene of interest to determine what phenotypic changes might occur within the cell (or organism). These phenotypic changes can be monitored at different levels by measuring (1) the relative expression of selected genes of interest or the global changes in expression of all (or most) genes within the cell (organism), and (2) the inhibition or stimulation of other physiological parameters of the cell or organism, such as its growth rate, shape, biochemical markers, and specific functions. If downregulation/switching off a particular gene leads to the desirable phenotypic effect, this gene or gene product is then selected as a target for the development of a drug, which will have a similar effect on the inhibition of activity of the corresponding protein. By screening multiple genes (one by one, or in combinations) for downregulation of their expression and estimating the presence and magnitude of the desirable phenotypic outcome, novel genes can be identified as targets for the future development of therapeutic compounds. In this respect, systematic genome-wide screens using RNAi technology and libraries of siRNA compounds seem to offer the most powerful approach for the identification of multiple drug target genes [37].

At the same time, RNAi technology may also make it possible to identify any undesirable effects due to the downregulation of certain genes of interest, which could have detrimental effects upon the pathway, cell, or organism. Therefore, this approach may provide an effective means for the early elimination of such genes from the list of drug target candidates; which is likely to save time and money in the subsequent drug development process. Below, we will review the methods currently being employed using siRNA technology for drug target identification and validation, as well as the specific target genes and respective diseases that are currently under investigation using this approach.

The most common way of exploiting the siRNA approach for target validation is to perform experiments in cultured cells. There are several methods of introducing siRNAs into mammalian cells. Chemically synthesized siRNAs or siRNAs prepared by *in vitro* transcription can be delivered into cells through a process similar to cell transfection with DNA vectors, using several different agents to facilitate such delivery [38]. Recently, several companies have developed transfection reagents specifically designed to improve the delivery of siRNA oligonucleotides in cell culture (Ambion, Austin, TX; Invitrogen, Carlsbad, CA; QIAGEN, The Netherlands).

The second popular method for induction of RNAi is to transfect cells with vectors containing siRNA expression constructs. This is similar to the expression of exogenous genes using vector-mediated transfection except that the result of this process is not the translation of the transcribed mRNA but the assembly of a double-stranded siRNA or hairpin loop siRNA, called shRNA, within the cell. Both forms can efficiently inhibit the expression of target genes [39–43]. A major advantage of "DNA-directed" RNAi is its potential for a more sustained effect, because the siRNA-expression vector may persist in the cells for several

generations providing a constant supply of siRNA molecules. Also, the recombinant expression of the siRNA can be controlled by specifically selected regulatory elements incorporated into the vector, providing more precise control over the timing, dose, and cell specificity of target gene inhibition. It is also possible to introduce siRNA vectors into cells using DNA electroporation [44]. This method is not as convenient as transfection when working with cell cultures *in vitro*, but it may be especially well suited for the localized delivery of siRNAs when working *in vivo*.

7.6.3.1 Low-Throughput Screening for Drug Targets

The first direct approach to identifying plausible drug targets would be the application of siRNA technology to well-characterized biochemical pathways involved in some disease of interest. When proteins involved in a particular pathway are known as well as their functions, it is straightforward to select a few target mRNAs against which siRNAs can be prepared and optimized for their effect. Also, with fewer initial targets, the outcome of RNAi screening can be studied in greater detail. Below, we describe several examples where siRNA technology has been used to identify critical checkpoints in a known pathway and to test whether desirable phenotypic effects could be obtained.

Cancer. Grillo et al. [45] used siRNA to validate the cyclin D1 and CDK4 protein complex as a drug target for cancer drug discovery. The inhibition of endogenous cyclin D1 or CDK4 expression by RNAi resulted in hypophosphorylation of the retinoblastoma gene product and accumulation of MCF-7 breast cancer cells in G1. These results support the prevailing view that pharmacological inhibition of cyclin D1/CDK4 complexes is an effective strategy for inhibiting the growth of tumors.

Another recent example demonstrates that inhibition of an enzyme in the same pathway in cells of different species may have different, and even opposite, effects on phenotypic outcome. This emphasizes that careful selection of model cells and characterization of molecular detail of the biochemical pathway, including tissue- or cell-specific expression of different proteins, is critical to selecting a suitable drug target. Hill et al. [46] demonstrated that rat (NMU and 13762), but not human (MCF-7 and T47D), breast cancer cell lines express Heme oxygenase-1 (HO-1), whereas indoleamine 2,3 dioxygenase (IDO) is expressed by both. IDO inhibition with siRNA resulted in diminished proliferation of rat cells, whereas HO-1-negative human cell lines increased proliferation upon IDO inhibition. As IDO inhibits the antiproliferative effects of HO-1, these authors concluded that IDO has the opposite effect on proliferation, dependent upon the co-expression of HO-1. This example clearly shows that results obtained on cells from other organisms are not automatically transferable to human cells, even if they seem to have highly homologous proteins and very conserved pathways. It also shows that a drug specifically targeting the expression or activity of a particular gene might have the opposite effect in cell types that differ in their expression profiles. These potential problems need to be considered when screening for therapies directed at a particular target protein.

Respiratory Diseases. An interesting example of hypothesis-driven identification of a potential drug target *in vivo* using siRNA is described in the work of

Lomas-Neira et al. [47]. In their study of acute lung injury (ALI), they hypothesized that local silencing of keratinocyte-derived chemokine (KC) or macrophage-inflammatory protein-2 (MIP-2), via the local administration of siRNA against KC or MIP-2, after traumatic shock/hemorrhage would suppress signaling for the influx of polymorphonuclear neutrophils (PMNs) to the lung, thereby reducing ALI associated with a secondary septic challenge (cecal ligation and puncture). This hypothesis was tested using intratracheal instillation in an *in vivo* model (mice). They found that 24 h after this treatment intratracheal MIP-2 siRNA significantly reduced tissue and plasma interleukin-6, tissue MIP-2, as well as neutrophil influx. In contrast, KC siRNA treatment reduced plasma KC, tissue KC, and IL-6 but produced no significant reduction in plasma IL-6 or neutrophil influx, thus identifying MIP-2, but not KC, as a potent drug target. In addition, this study demonstrates the potential use of siRNA as a therapeutic.

Inflammation. The exact roles of many cytokine genes that influence rheumatoid arthritis are still unknown. Inhibition of some of these genes can strongly reduce joint inflammation [48]. In an *in vivo* arthritic mouse model, Schiffelers et al. [49] used electroporation [44] to deliver a tumor-necrosis factor alpha (TNFα) siRNA-coding vector into joint tissue. They demonstrated not only that TNFα is an effective target for reducing joint inflammation, but also a new strategy for therapeutic intervention for rheumatoid arthritis. This approach, hence, may clearly serve as a model for the study of arthritis disease pathways through gene-specific loss-of-function phenotypes.

Parkinson's Disease. Animal disease models play an extremely important role in identification of drug lead candidates. Some animal models can be created simply by making gene knockouts. However, if the targeted gene is an essential gene for survival of the organism, these animals cannot be easily created. For example, mice in which the gene encoding tyrosine hydroxylase (TH) has been knocked out die shortly after birth, making it impossible to study the neurological effects of this alteration in the fully developed animal. RNAi technology can help to overcome this obstacle by creating an animal disease model through the local and/or temporal knocking out of essential genes. Hommel et al. [50] demonstrated that injection of an adeno-associated virus encoding a TH-specific shRNA into the midbrain of 9-week-old mice generated an attenuated locomotor response to amphetamine, an effect that is also characteristic for toxin-induced rat models of Parkinson's disease. These authors, hence, suggest that similar knockout strategies may be effectively used in other disease model systems. In addition, as we mentioned above, because the RNAi effect obtained by treatment with siRNA compounds may not be absolute, there may also be a certain advantage in a knock-down vs. knockout phenotype; in that, a knock down might be more appropriate for modeling some complex human diseases [51].

7.6.3.2 High-Throughput Screening for Drug Targets

The second valuable approach to using RNAi for drug target identification is a high-throughput strategy (HTS), where a library of siRNAs directed against many genes is screened simultaneously or sequentially to identify target genes and their products for further evaluation as drug leads. As described above, this approach might

be used against a restricted set of genes that are members of a certain pathway, for example, a "pathway approach," or against most of the genes in the genome, a "global approach." For these approaches, traditional HTS equipment, such as robotic systems, can be implemented, facilitating the processing of thousands of cell-based screening protocols a day [52]. Both chemically synthesized siRNAs as well as vectors coding for functional si/shRNAs can be delivered into the cells using this high-throughput format. Retroviral [53] and lentiviral [54] vectors have been shown to be particularly useful vehicles for high-throughput screening of siRNA and shRNA libraries due to their robust infection and expression in a wide range of mammalian cell types. To simplify the transfection procedure on multiwell plates or slides, Chang et al. [55] suggested the pretreatment of surfaces with cationic polymers. This provides for the simple addition of naked DNA vectors or siRNAs directly to the cells in these pretreated wells in order to achieve efficient transfection. Another method of high-throughput screening using vector-encoded or chemically synthesized siRNAs is the so-called "reverse-transfection," or solid phase, method [56–58], originally designed for the expression of cDNA libraries [59]. In this method, a number (up to several thousands) of individual siRNAs or siRNA-encoding vectors are spotted in a predetermined array onto a microscope glass slide, which is then treated with transfection reagent and covered with recipient cells. Individual cells seeded directly over each spot of material take up only the siRNAs or vectors localized at that spot. That, hence, results in a virtual array of siRNA-treated cell colonies. After 24–48 hours, the array of treated cells is evaluated for the desired phenotype to identify effective siRNAs and, more importantly, the corresponding target gene. It has been estimated that, by this method, between 100 and 500 reverse-transfections could be performed using the same amount of reagents required for a single transfection in a well of a 96-well plate [58].

Cancer. Using a human cell line and an shRNA library (containing 23,742 distinct shRNAs, 3 shRNAs per gene) cloned into a retroviral vector and directed against of 7914 genes, Berns et al. [60] identified genes involved in the p53 pathway. This protein is a known tumor-supressor and induces cell cycle arrest in cells that have undergone DNA damage. By inhibiting an array of genes using their shRNA library, the authors identified five new genes, and p53 itself, whose expression are required for proliferation arrest of cells. After infection of cells with the pooled shRNA library, the relevant genes associated with this specifically desired phenotype were rapidly identified by unique "molecular bar-codes," which were introduced into each siRNA construct.

The HTS–RNAi approach is extremely promising in providing rapid identification of proteins, which control or are associated with disease-relevant phenotypes. A lentiviral library of shRNA targeting 9610 human and 5563 mouse genes (human homologues) was efficiently used to identify proteins that compromise the 26S proteasome function [61]. The 26S proteasome, a well-studied biochemical machinery involved in the critical degradation of many unwanted proteins including some oncoproteins (e.g., c-Myc), has been implicated in certain diseases. About 30 proteins, mostly proteasome subunits, including five out of five proteasome ATPases and the two largest non-ATPases, were identified in their screen. This work also exploited a "mole-cular bar-coding" system, which facilitated the identification of effective shRNAs.

A single, well-constructed library can be used to screen for gene products involved in completely different disease-relevant pathways. The most important step in applying this approach is the design of a functional assay that will clearly discriminate between the genes whose inhibition results in the desired phenotypes to be obtained by screen. In each case, the specialized development of an appropriate cell-based assay is required. Principles and strategies for developing such assays for the identification of drug-targets for different diseases, including rheumatoid arthritis, osteoarthritis, asthma, osteoporosis, Alzheimer's disease, and cancer, are discussed in the recent review by van Es and Arts [62].

The combination of a high-throughput microarray analysis of differential gene expression followed by RNAi inhibition of selected genes also represents a powerful methodology for the identification of new drug targets [63]. Using this approach, Williams et al. [64] analyzed the differential expression of genes in normal tissue versus colon tumors and polyps isolated from 20 patients. In this study, they identified 574 genes that were upregulated in tumor patients. Out of this large set, they selected a single gene, survivin, a potent inhibitor of apoptosis, and downregulated its expression by RNAi. Inhibition of survivin expression via RNAi resulted in severely reduced tumor growth *in vitro* as well as in an *in vivo* mouse xenograft model. Future analyses using RNAi inhibition of other upregulated genes will undoubtedly make it possible to identify additional precise targets for drug development.

Using this combined approach plus the construction of gene knockout mice, Gunton et al. [65] identified the transcription factor ARNT as an important factor involved in impaired glucose-stimulated insulin release and in causing changes in gene expression similar to those in human type 2 islets. Hence, RNAi was used here to identify and validate a new mouse model for type 2 diabetes.

The reverse application of these two technologies, where cells are first subjected to RNAi treatment and the resulting changes in global gene expression are then assessed by microarray analysis, allows for the dissection of cellular pathways of interest [66]. Such analyses are extremely important: (1) for understanding the global changes that occur in the cellular response to the downregulation of the selected target, (2) for elucidating the role of the target gene in intracellular pathways, (3) for identification of unwanted or detrimental effects, and (4) for selecting the best checkpoints for therapeutic intervention.

These examples demonstrate that RNAi technology offers scientific promise for the identification of effectual drug targets and an excellent perspective for pursuing the development of corresponding small molecules to modulate these targets. Nevertheless, some caution should be reserved in its application because, although RNAi technology may provide a clear understanding of a particular protein's role in a pathway and the phenotypic effects of its downregulation, a small drug directed at the same cellular checkpoint or mechanism might produce different effects [67].

7.6.4 RNAi AS AN INSTRUMENT FOR THERAPEUTIC USE

With the apparent great success of using RNAi technology for the inhibition of specific genes in cultured cells, and in some animal models, there has been a

corresponding great expectation of efforts to directly transfer this technology for therapeutic use in humans. Several companies are currently developing RNAi-based drugs to target different diseases (see Table 7.6-1, and discussion below). A variety of serious challenges for the development of such drugs will be discussed in the next two sections. Herein we will review the basic principles and methods for therapeutic treatment, as well as a few prospective directions for the application of RNAi in medicinal therapies.

The most important aspect of using siRNAs as therapeutic agents is their specificity to the target RNA. An optimally designed siRNA for therapeutic use should cause the destruction or repression of only its specific target RNA. This principle puts particular restrictions upon the choice of potential target sequences. For example, if several variants of a protein exist, among which only some forms are disease-relevant and, hence, represent a subset of targets for repression, the drug must be designed based on sequential differences between the intended target and the nontarget forms of the protein. Such variants can be the products of different alleles of the same gene, the results of alternative splicing of a single gene, or the products of a family of related genes. In this respect, dominant mutations that define specific disorders are particularly good candidates for RNAi-based treatment due to the inherent potential ability of an siRNA to discriminate between the normal gene product and the "mutant target" RNAs containing just a few, or even a single, nucleotide mutation(s) [68–70].

As RNAi acts at the RNA level, either through the degradation of the target mRNA by an siRNA-directed mechanism or through the inhibition of the target mRNA's translation by the miRNA pathway, its final phenotypic effect will depend significantly on the amounts, stabilities, and turnover rates of the target RNA and its corresponding protein. In the general case, when the ultimate goal of treatment

TABLE 7.6-1. Companies Developing RNAi Drugs

Company	Targeted Disease or Agent and Stage
Sirna	AMD—phase I
	HC, Asthma, DB, Cancer—preclinical
	HD—proof of principle
Alnylam Pharmaceuticals	RSV—phase I
	AMD, DR, DME, SCI—preclinical
	INFL, CF, PD—research
Acuity Pharmaceuticals	AMD, DR—phase I
Benitech	HC, HIV—preclinical (scheduled for phase I in 2006)
Genesis R&D Corp. Ltd.	Allergy—preclinical
ToleroTech Inc.	Transplant rejection—preclinical
Intradigm Corp.	Cancer (anti-angiogenesis)—preclinical, IND in 12 months
CytRx	Obesity, Type 2 DB, ALS, CMV—research

Data obtained from company websites.

Abbreviations: AMD, age-related macular degeneration; HC, Hepatitis C; DB, Diabetes; HD, Huntington's Disease; RSV, Respiratory Syncytial Virus; DR, diabetic retinopathy; DME, diabetic macular edema; SCI, Spinal Cord Injury, INFL, Influenza; CF, Cystic Fibrosis; PD, Parkinson's Disease; HIV, Human Immunodeficiency Virus; ALS, amyotrophic lateral sclerosis; CMV, Cytomegalovirus.

is to completely abolish a target protein, a successful siRNA compound should be targeted to a gene encoding a relatively short-lived protein with a high turnover rate, preferably one with a low total amount in the cell or organism. Following these criteria, the inhibition of the production of the targeted gene product will most effectively result in a significant decrease in the concentration of this protein in the cell and, hence, will optimally affect the downstream biochemical events in order to treat the disease condition.

A promising class of gene target candidates for siRNA intervention is genes with temporal profiles of expression. If an siRNA drug is delivered to cells before or at the beginning of expression of these genes, there are better chances that the production of their products will be inhibited sufficiently to produce the desirable therapeutic effect; even better if these proteins are normally produced in small quantities. A good example of such genes is viral genes that start to express early after viral infection. Certain specific viral transcription factors, generally expressed in small quantities, should be particularly well suited as targets for siRNA treatment. Several examples have demonstrated that siRNA directed against viral transcription factors can efficiently inhibit viral replication. Lee et al. successfully inhibited the replication of human immunodeficiency virus type 1 (HIV-1) by Tat-specific siRNA [71]. Simultaneous inhibition of viral transcription factor and surface antigen by a vector expressing two siRNAs specific for HBx and HBs significantly reduced hepatitis B virus replication in cell culture [72].

Another suitable group of targets for siRNA treatment in the case of viral infection is host proteins involved in infection and propagation of the virus. The key consideration here is that downregulation of these molecules must not be detrimental to the host. In the study mentioned above, by Lee et al. [71], inhibition of HIV-1 was achieved not only by Tat-specific siRNA but also by siRNAs specific for the CCR-5 cellular coreceptor. Using RNAi, Chiu et al. [73] inhibited expression of human positive transcription elongation factor P-TEFb. P-TEFb is involved in transcriptional regulation of cellular genes as well as HIV-1 genes. Targeting of endogenous P-TEFb resulted in the inhibition of Tat transactivation and HIV-1 replication in host cells. Interestingly, P-TEFb knockdown was not lethal to the host cells, which showed normal P-TEFb kinase activity. These authors suggested that there may be a different critical threshold of P-TEFb activity required for cell viability than for HIV replication. This example shows that RNAi-mediated gene inhibition may provide an opportunity to specifically inhibit a disease-causing agent while minimizing the effect on normal cellular function. Nevertheless, the inhibition of any cellular gene for the purpose of disease treatment or prevention should be considered very carefully, not only at cellular level but at the level of the whole organism as well.

As mentioned in Section 7.6.2, using siRNA it is rare to achieve an effect of 100%, where the target RNA is completely abolished or "knocked out." More often the result is a "knock-down" effect. In some cases, such a partial reduction of gene expression is sufficient for obtaining the desired phenotypic or therapeutic effect. It is also prudent to be able to switch "on" and "off" the expression of siRNA at certain times or in specific tissues. Fritsch et al. designed a CRE-lox-based strategy that allows one to repress gene activity through shRNA expression in a time-dependent manner in cells, and in a time- or tissue-dependent manner in animals [74, 75]. Other vectors with chemically inducible promoters have been designed for the

controlled expression of shRNAs using tetracycline [76, 77], ecdisone [78], macrolide [77], and butyrolactone [79]. Still, in some cases, an incomplete shut-off of the target gene may not produce the desired therapeutic effect. In these cases, RNAi therapy could be used effectively in combination with other drugs directed to the same, or a different, checkpoint in order to achieve a more satisfactory therapeutic effect. Such parallel treatments, with drugs having different modes of action, also make it possible to overcome potential antagonistic factors due to mutations or alternative pathways leading to a disease.

A prolonged treatment with any drug may encounter the emergence of mutations causing resistance to the treatment. RNAi technology is inherently susceptible to this problem. However, expression vectors able to express two shRNAs simultaneously have been designed and used to help overcome potential loss of RNAi-drug efficacy [80]. Using two siRNAs directed against the 3D-RNA-dependent RNA polymerase of coxsackievirus B3, Shubert et al. obtained efficient inhibition of virus propagation in HeLa cells and reduced virus titers by up to 90%. Introducing point mutations into either target site can abrogate the inhibitory effect of that siRNA, when used separately. These authors constructed an siRNA double-expression vector (SiDEx) to achieve simultaneous expression of both siRNAs from a single plasmid. Their “double-drug” construct successfully downregulated the point-mutated target gene. In addition, these vectors could be used for the simultaneous knockdown of two different targeted genes for functional studies or therapeutic use.

In Section 7.6.3, we described the application of RNAi for drug target identification and validation in different diseases. In examples where inhibition of expression of specific genes led to the desirable phenotypic effects, those targets may consequently be considered for RNAi therapeutic use. Below we provide additional examples of how the principles and methods described in this section can be applied to the development of therapies for different diseases.

7.6.4.1 Cancer

A significant proportion of all cancers result from mutations in cellular proto-oncogenes. Nearly half of these cancers contain point mutations in the tumor-suppressor gene, p53. The ability of an siRNA compound to discriminate between wild-type (WT) and mutated forms of p53 mRNA allowed for the specific knockdown of a dominant-negative mutation, resulting in an inhibition of tumor growth and restoration of WT protein function [68].

Fusion proteins, which result from chromosomal translocations, are commonly associated with the growth transformation that occurs in some cancers. Leukemic fusion gene AML1/MTG8 is associated with up to 15% of all *de novo* cases of acute myeloid leukemia. Heidenreich et al. [81] used a human leukemic cell line, Kasumi-1, to demonstrate that efficient suppression of the disease-associated fusion protein AML1/MTG8, but not WT AML1, can be achieved by siRNAs directed against the fusion site of the AML1/MTG8 mRNA. This treatment, in combination with TGF beta(1)/vitamin D(3), significantly reduced the clonogenicity of Kasumi-1 cells.

One subtype of acute lymphoblastoid leukemia is characterized by a t(1;19) chromosomal translocation resulting in the expression of a novel fusion protein

E2A-Pbx1. This mutant protein activates the expression of a secreted Wnt16 glycoprotein [82], which is widely involved in cell proliferation, differentiation, and oncogenesis, and promotes transformation and leukemogenesis. Mazieres et al. [83] demonstrated that only one of two Wnt isoforms (Wnt16b) is overexpressed in t(1;19)-containing cell lines. Using isoform-specific siRNAs and an anti-Wnt16 antibody, they showed that targeted inhibition of the overexpressed Wnt16b leads to apoptotic cell death.

A common problem in modern cancer therapy is the development of cellular resistance to conventional chemotherapeutic compounds. In many cases, this resistance is due to the overexpression of the multidrug resistance gene, MDR1. Targeting of this gene using RNAi technology may significantly decrease or even completely reverse the multidrug-resistance phenotype [84–86]. Thus, again, suggesting the potential utility of using RNAi in combination with traditional strategies.

Inhibition of oncogene expression, or of other components of molecular pathways involved in cell proliferation, may slow the growth of cancer cells in a tumor without leading to apoptotic cell death; and hence, it may not always eliminate these cells from the organism. In addition, because RNAi rarely leads to the complete knockout of target gene expression, it might be advantageous to use a combined regimen of RNAi and a small drug and/or radiation treatments for more efficient combat against cancer. RNAi compounds can be directed against genes responsible for anti-apoptotic effects [87–89], against tumor-suppressor genes [90], against dsDNA-brake repair proteins [91, 92], or against other genes in cellular survival pathways [93]. In this scheme, RNAi-induced suppression of normally protective, repair-activated, or damage-induced genes in tumor cells may result in even greater increases in proliferation of tumor cells and, hence, an increased sensitivity to the combined chemotherapeutics or radiation.

7.6.4.2 AIDS and Other Viral Infections

Interestingly, to date, almost all HIV-1 genes have been targeted by RNAi, at least in cell culture experiments. It has proven possible to block the replication of HIV-1 in cultured cells by siRNAs targeted to viral sequences [94, 95]. The main obstacle to therapy, though, is the specific delivery of siRNAs to cells infected or susceptible to HIV-1 infection *in vivo*. We shall discuss this problem of cell-specific targeting in detail later. However, it has been shown recently that HIV-1 can suppress the function of the host cellular RNAi machinery [96]. This suppression of RNA silencing may potentially affect the efficiency of RNAi drugs directed against HIV-1 gene targets, and against other target viruses that may have evolved similar anti-host mechanisms. In addition, HIV infections are particularly difficult to treat, in part, due to the viruses' extreme ability to transform as a result of high mutation rates, especially of surface receptors, which gives rise to the high sequence diversity of HIV genomes among infected subjects. One measure against this tendency for viral sequence diversity might be the simultaneous use of several siRNAs directed against several viral genes. On the other hand, nonvariable human cell receptors for HIV infection represent a great target for siRNA treatment. Martinez et al. [97] demonstrated that RNAi directed against CD4 coreceptors CXCR4 and CCR5 efficiently blocked acute infection by X4 (NL4-3) and R5 (BaL) HIV-1 strains but

had no effect on CD4 cells or control green fluorescence protein expression. In another example, Nair et al. [98] presented evidence that siRNA directed against the CD4 independent attachment receptor (DC–SIGN) significantly inhibits HIV infection of dendritic cells. Nevertheless, as mentioned above, any targeting of host genes should be evaluated for unwanted or detrimental effects, especially at the organism level. Some negative effects could significantly restrict the usage of endogenous gene targets.

Many other viral infections, including the ones most threatening to humans, like hepatitis C, B, and A viruses (HCV, HBV, HAV), human papillomavirus viruses (HPVs), West Nile virus, and human herpes viruses (i.e., HSV, CMV, EBV, and HHV-8) are also the targets of intense research for the development of effective RNAi treatments. It has been demonstrated that RNAi can disrupt the replication of many viruses, including HCV, HBV, and HAV in cell culture [99, 100] and, as later demonstrated in mouse models, *in vivo* [101, 102]. The major limitation, again, is the delivery and stability of RNAi compounds for application as human therapies in clinically relevant systems, which will be discussed further below. These examples demonstrate, however, that RNAi technology has great potential for the treatment of viral disease, yet clearly requires further development for clinical applications.

7.6.4.3 Parasite Infections

Despite the biotechnological and drug development booms of the last several decades, parasite infections (malaria, African sleeping sickness, leishmaniasis, Chagas disease, etc.) remain the foremost health burden and source of mortality and morbidity on our planet, especially in the tropics. Malaria, alone, contributes to about 500 million cases of disease per year that result in more than 2–2.5 million deaths, mostly in sub-Saharan Africa [103]. Not only are newer drugs still expensive and unavailable to most of the population in these regions, but parasites also develop drug resistance rapidly, especially to the drugs extensively used, like chloroquine [104]. Due to many reasons, vaccine development has not yet been successful against these diseases. Therefore, the appearance of RNAi technology was perceived with great interest and was immediately explored in studies aimed at defining treatments for parasite infections.

It was quickly discovered that RNAi works in *Trypanosome brucei* as well as it does in *C. elegans* [105]. Since that time, RNAi mechanisms have been extensively studied in *T. brucei* [106]. The technology is now being used extensively to dissect different biochemical pathways in *T. brucei* [107] as well as to study potential therapeutic applications [109–110].

Unfortunately, it is still not clear whether RNAi functions in malaria parasites. Very few publications have described RNAi in malaria [111–114]. Genomic data mining does not clearly identify any members of the RNAi machinery in these parasites by homology searches. Given the enormous increase in the number of publications on RNAi in other systems, and the likely numerous efforts made in malaria research to use RNAi, there seems to be a surprising lack of published evidence demonstrating RNAi in malaria. It is possible that in this parasite the RNAi pathway was lost or has diverged during evolution to perform other functions in the organism, which is incompatible with the classic utilization of the RNAi mechanisms being explored in other organisms [106]. It is also possible that the

effects described in the papers published on malaria actually reflect other processes and pathways, such as the abundant presence of antisense RNAs [106] as recently described in malaria [115, 116].

7.6.4.4 Neurological Disorders

Many neurological disorders, including Alzheimer's disease, Parkinson's disease, fragile-X syndrome, and amyotrophic lateral sclerosis (ALS), result from dominant mutations in a single allele. Therefore, as discussed above, this class of "disease genes" is perfectly suited as candidates for treatment by sequence-specific RNAi therapy. In the example of ALS, given below, stepwise improvements led to progress in the development and use of RNAi technology for therapeutic treatment of the disease in an animal model.

ALS is a familial neurodegenerative disease characterized by motor neuron degeneration, paralysis, and death. One cause of this disease (2–3% of cases) is mutations in the Cu,Zn superoxide dismutase (SOD1) gene. Ding et al. [117] identified a specific shRNA that could specifically degrade mutant SOD1 mRNA. Later, Maxwell et al. [118] investigated the functional effects of RNAi-mediated silencing of mutant SOD1 in cultured murine neuroblastoma cells and found that silencing of mutant SOD1 protects these cells against cyclosporin A-induced cell death. Recently, Raoul et al. [119] demonstrated that in SOD1 (G93A) transgenic mice, a model for familial ALS, intraspinal injection of a lentiviral vector that produces RNAi-mediated silencing of SOD1 substantially retards both the onset and the progression rate of the disease. Another group [120] injected lentiviral vector expressing SOD1 RNAi compound into various muscle groups of SOD1 (G93A) mice. This treatment also resulted in an efficient and specific reduction of SOD1 expression and improved survival of vulnerable motor neurons in the brain stem and spinal cord. They observed a considerable delay in the onset of ALS symptoms by more than 100% and an extension in survival by nearly 80% of their normal life span. Despite this success in mice, there is an additional complexity with this disease in humans. There are more than 100 different known mutations in the SOD1 allele. Whereas it is difficult even to propose to design efficient RNAi compounds to address each of these mutations in individual patients, Xia et al. [121] suggested another elegant approach based on RNAi technology to overcome this problem. They designed a replacement RNAi strategy, where all mutant and wild-type forms of the gene are inhibited by RNAi. The wild-type SOD1 function is then replaced by a custom designed wild-type SOD1 gene that is resistant to the RNAi. These ALS studies clearly demonstrate how therapeutic strategies based on RNAi technology can be improved over a short period of time with the accumulated incorporation of different molecular aspects of a certain disease into improvements in the application of the technology itself.

7.6.5 BASIC THEORETICAL AND PRACTICAL CONCERNS FOR APPLICATION OF RNAi IN THERAPY

Despite the great potential of RNAi technology for therapeutic applications, there are a number of intrinsic features of this process, which present a considerable challenge to its practical use.

7.6.5.1 Variable Efficiency of Different siRNAs

As discussed in the second section, different dsRNA fragments cognate to the target RNA have different efficiencies in inducing its degradation. Even more uncertainties exist about the miRNA-dependent mechanism of inhibiting mRNA translation. Because the relative efficiencies of different siRNAs in RNAi may differ significantly, currently there is no way to predict their individual potentials. Screening for the most efficient siRNAs using cell cultures can be a laborious and expensive procedure. In addition, natural nucleotide polymorphism and mutations in a gene target site may affect the efficacy of RNAi [122–124]. Therefore, efforts have been made to overcome this problem of variable efficiency of different siRNAs.

Several methods based on the use of siRNA mixtures, which may contain a particular efficient siRNA (or several), have been developed. These include the preparation of siRNA mixtures using RNaseIII [125] or dicer [126] enzymes to digest longer dsRNAs. The short RNAs produced as a result of these digestions have been found to be efficient in RNAi. The disadvantage of these digestive approaches, however, is in their potential for nonspecific effects. If a randomly chopped long dsRNA contains areas of homology to other genes, or splice variants of the same gene, the expression of these genes might also be inhibited by cognate siRNAs (see below). In addition, obtaining long dsRNAs also adds to the potential total cost of, and time required for, these approaches.

It would be more advantageous to use defined mixtures of siRNAs, complex enough to inhibit the desired gene with high probability, but devoid of any siRNAs with unwanted homologies. Besides creating higher target efficiency, the use of such mixtures would also alleviate the need to screen for individually active compounds. We developed a simple, fast, and inexpensive method for the preparation of defined-siRNA mixtures using custom DNA oligonucleotide microarrays as a starting material [127]. In this study, we demonstrated that siRNA pools, prepared using array-derived DNA oligonucleotide mixtures, are an efficient tool for the inhibition of exogenous as well as endogenous genes in cell cultures [128]. In this approach, many (up to 30) different siRNAs are designed against a single gene. As the sequence of the human genome is known, any unwanted homologous siRNA sequences could be excluded from the designed pool. Many different siRNA pools can be synthesized using a single DNA oligonucleotide microarray, which makes this approach extremely affordable relative to the construction of defined complex mixtures via the synthesis and/or cloning of many different individual siRNA species.

Although the approaches using siRNA mixtures prepared as described above are efficient for use in cultured cells for pathway validation and drug target identification experiments, their use as therapeutic agents might, nevertheless, be problematic due to manufacturing issues as well as issues related to the specific delivery of siRNAs to the target cell or tissue (see below). In any case, the identification of an efficient single or a mixture of RNAi compounds requires a careful selection process and experimental testing to maximize gene silencing and minimize potential off-target and nonspecific effects.

7.6.5.2 Nonspecific Systemic and Off-Target Effects, and the Potential for Pleiotropic Effects

We described, in the second section, how long dsRNAs may induce nonspecific effects in mammalian cells due to the activation of interferon and the induction of

the cellular dsRNA-dependent protein kinase response. Therefore, to avoid these nonspecific effects, the use of siRNA (<~30 bp) was proposed [29] and proved to be an efficient technology for posttranscriptional gene silencing. Nevertheless, it was later noted that even the short dsRNAs used to generate RNAi effects, and designed in the form of either siRNA or shRNA, can still induce some mammalian genes involved in the interferon response [129], although results from different laboratories were conflicting [130]. To circumvent these effects, different measures can be implemented, including different administration routes, dose of vectors, selection of promoters, and use of additional immunosuppression [131].

Interferon-independent nonspecific effects also exist. Scacheri et al. found that siRNAs could induce dramatic and significant changes in the levels of p53 and p21 proteins that were unrelated to silencing of the target gene [132]. These authors speculated that partial complementary sequence matches to off-target genes may have resulted in a microRNA-like inhibition of translation. In this respect, it is, actually, difficult to distinguish between nonspecific and sequence-specific off-target effects (see below). It has also been reported that si/shRNAs induce immune activation in macrophages and dendritic cells through toll-like receptor 3 [133, 134]. Moreover, Persengiev et al. [135] found that 21-bp siRNAs nonspecifically stimulated or repressed more than 1000 genes involved in diverse cellular functions. The effects on gene expression were dependent on siRNA concentration and were stable throughout the course of siRNA treatment. Again, here too, it is difficult to distinguish the nonspecific systemic effects from off-target effects. In addition, there is a potential for pleiotropic effects due to a genuine physiological response of downstream genes due to the downregulation of the target genes. If off-target genes become downregulated, these may also produce a cascade of unintended physiological responses. Such a cascade of multiple events could result in the global dysregulation of many unrelated genes. Therefore, potential widespread, nonspecific effects on mammalian gene expression must be carefully considered in the design of therapeutic RNAi applications.

Besides nonspecific cellular effects due to the RNAi compounds themselves, there are additional sources for potential nonspecific effects; these include the vehicles for, and methods of, delivery of RNAi compounds to cells and tissues. For example, viral vectors, as well as other components such as transfection reagents [136], chemical modifications to RNAi compounds, or chemical substances used to facilitate the delivery of RNAi compounds, might produce unwanted immune and other cellular responses [137]. These responses should be considered as additional possible sources for nonspecific effects in therapeutic applications of RNAi.

In addition to the aforementioned nonspecific effects, one additional problem has recently become evident: that the cellular RNAi machinery, normally involved in the regulation of some endogenous genes' expression and in maintaining a stable chromosome structure, might be indirectly affected by large amounts of exogenous siRNAs introduced by transfection or vector-directed transcription, for example. This may result in an imbalance or saturation of the cellular resources of endogenous molecules in the pathway.

The possibility of saturating the RNAi machinery was raised in early studies [122], and it has recently been supported by several observations [138–140]. Moreover, it has been suggested that perturbation of the cellular RNAi machinery might

be involved in different disorders and diseases [141]. Therefore, exploiting the RNAi machinery for therapeutic interventions could present additional nonspecific complications for cellular and organismal homeostases that should be carefully evaluated in the design and use of RNAi compounds, including the consequences of the dosage and timing of treatment.

Off-target effects are another serious concern in the application of RNAi for therapy. Such effects might be due to the partial homology of an RNAi compound to an irrelevant, or related but different, gene, which is not a target for downregulation. These effects will clearly be different for different sequences, and the parameters and degree of homology, which confer the extent of off-target effects caused by a particular RNAi compound, are complex and not fully understood. It has been shown that, depending on the sequence, most RNAi compounds can tolerate one [142], or even several [143], mismatches, though, typically with reduced efficiency. Moreover, it was shown recently that in some cases mismatches can even enhance the activity of RNAi compounds, possibly through the miRNA-regulatory pathway [144]. In fact, as few as 11 base pairs of homology with single-stranded RNA can be sufficient to produce an inhibitory effect [145]. Therefore, careful elimination of possible antagonistic homologies is an important consideration in the design of RNAi compounds. This is feasible with the great wealth of sequence data and bioinformatics currently available from human and pathogen genomes. In this respect, treatment with complex mixtures of defined siRNA molecules [128] may also offer a unique advantage over current methods. Because each efficient siRNA has an optimum concentration when its effect is maximal (the practical effective concentration range in cell culture is 10 to 100 nM), if such an siRNA molecule, homologous to an off-target gene, were present in a defined mixture, it is likely that its individual concentration would be well below the effective range. Thus, because a complex mixture targeted at a single gene may include 30–50 different siRNAs at an active total concentration of 10–100 nM, this may, theoretically, lessen the off-target effects of each siRNA molecule contained within the mixture. Nevertheless, despite the incorporation of even the most conscientious theoretical design elements to minimize nonspecific and off-target effects, the empirical testing of each compound is requisite for its evaluation and development for therapeutic application.

7.6.6 TECHNICAL CHALLENGES OF SIRNA THERAPY: *IN VIVO* DELIVERY AND STABILITY

The use of any drug for clinical application involves two important issues: the delivery of the drug to the affected cells or tissues, and the stability of the drug while in the organism. These factors directly influence the determination and choice of effective dosage, delivery time, and routes. RNAi compounds are not unique in this respect, and their physical–chemical and biological characteristics determine the limits and specifics of RNAi therapy. The physical stability of any compound might depend significantly on its particular route of delivery, and therefore, these parameters are potentially restrictive to each other and may, hence, limit different options for use.

7.6.6.1 Delivery of RNAi Compounds

RNAi compounds for therapeutic treatment can be generated in two ways: chemically synthesized si/shRNA molecules and vector-encoded molecules, which are synthesized by the cells after intracellular delivery of the corresponding expression vectors. The choice between these two approaches will determine the specifics of treatment: different targets and routes of delivery, different stability of compounds and efficiency of treatment, different possible side effects, etc. In many respects, vector-encoded delivery seems to offer advantages over the more traditional "pharmaceutical" approach of drug delivery. For example, the duration of effect delivered by chemically synthesized si/shRNA molecules might be shorter than the duration expected from vector-encoded molecules due to their continuous supply by intracellular transcription. In addition, these "internally synthesized" RNAi compounds are not subject to the potentially destructive environments of the organism, such as chemically synthesized and systemically or locally delivered siRNAs might be, for example, through gastrointestinal (GI), intravenous, or intramuscular delivery routes. It is usually sufficient to deliver only a small number of siRNA-expressing vector molecules per cell to obtain efficient silencing. Therefore, the delivery of RNAi compounds by these two approaches should have completely different dosage and timing strategies. In turn, the vectors for delivering RNAi compounds can be constructed using viral or DNA plasmid systems, which also might provide for or necessitate different delivery routes. It is also probable that siRNA-expression vectors will have to be customized for the delivery of targeted compounds to specific tissues (i.e., employing tissue-specific promoters, or viruses with tissue-type limited host ranges). There are currently three kinds of viral vectors in use for RNAi compound delivery: adenovirus, adeno-associated virus, and lentivirus [146]. In general, plasmid and viral RNAi-vectors, as methods of gene therapy, could have some advantages over siRNA oligonucleotides in delivery, stability, and efficacy. However, vector-associated gene therapies have their own long history of safety concerns and potential for nonspecific effects [147].

There are two fundamental means of drug delivery: local delivery and systemic delivery; each with its inherent advantages and disadvantages. Local delivery is not always practical or feasible, although it might be conceptually preferred for its potential efficiency in targeting the specific tissue or even a pool of target cells. Systemic delivery suffers from low efficiency of the relevant cells being targeted. Morrissey et al. [148] calculated that only 1% of intravenously administered (30 mg/kg) siRNAs reached the targeted organ (liver). Combined with the aforementioned differences in the forms of RNAi compounds, all these issues make the delivery problem quite complex. In these respects, nasal delivery represents one of the most convenient and powerful methods of delivery for both local and systemic delivery [149]. The substantial previous experience gained by advances made in the delivery of antisense drugs (one of which, Vitravene, was approved by the FDA in 1998) may contribute significantly to the related RNAi-based therapies [150].

Recently, substantial success in the targeted delivery of chemically synthesized siRNAs was achieved using siRNAs in the form of a supramolecular complex with a fusion protein consisting of a protamine-antibody directed at a specific cell-surface receptor [151, 152]. These complexes were found to be efficient in silencing target genes when delivered either locally (by intratumoral injection) or

systemically (by intravenous injection). The use of viral vectors might also prove efficient for systemic delivery and, as discussed above, are likely to provide long-term efficacy. Moreover, specially designed viral vectors, targeting specific tissues or even specific cells within the target tissue, might significantly improve delivery of RNAi compounds to the intended target cells. Gou et al. [153] recently demonstrated, both *in vitro* and *in vivo*, that the use of a cell-specific promoter introduced into an adenoviral vector could direct the specific expression of shRNA in one type of cell without interfering with other cell systems present. This approach seems extremely useful for the delivery of RNAi drugs. For example, as these authors suggested, to target the expression of an oncogene in cancer cells, but not in normal cells, a telomerase reverse transcriptase promoter (active in cancer cells, but inactive in normal somatic cells) [154] could be used to drive shRNA expression specifically in cancer cells.

7.6.6.2 Stability of RNAi Compounds

As with any drug delivered into an organism, an RNAi compound is subject to inactivation, degradation, and elimination. The good news, though, is that because RNAi drugs share the same basic chemical composition independent of the targeted disease, any findings on stabilization of compound(s) in one model should be applicable to other models and compounds, if the compounds are delivered through a similar route.

si/shRNAs are subject to enzymatic degradation in the body, as are any RNA molecules. Due to their small size and double-stranded nature, though, these structures seem to be more stable than many types of RNA and even more stable than the single-stranded DNA oligonucleotides used as antisense drugs [155]. Nevertheless, because degradation is a common problem, several different approaches have been undertaken to create compounds that may resist destruction in the cell. One way to stabilize a nucleic acid compound in the biological environment is to chemically modify it so that it will become resistant to enzymatic degradation while maintaining its intended biological function. Several such modifications to siRNAs, and the influence of these modifications on their pharmacokinetic properties, have been described [148, 156–158]. Another way of stabilizing RNAi compounds is the formation of supramolecular complexes, such as nanoparticles, which have been extensively explored for the delivery of RNAi compounds [159–163], or of liposome-based complexes, which also can be used for plasmid vector-based siRNA delivery [164–166]. Despite the method(s) chosen for delivery of chemically prepared si/shRNAs, the achievement of intracellular delivery at therapeutically effective concentrations in the target cells still represents a major challenge to the practicable use of RNAi technology for therapy, especially via systemic delivery routes.

7.6.7 RNAi DRUGS UNDER DEVELOPMENT

No RNAi drugs are currently on the market for use in humans. Only a few compounds have entered phase I clinical trials, and some will be starting soon (see below). In the last few years, a tremendous investment has been made in the development and application of RNAi compounds as drugs. Several recent reviews

describe these extensive efforts and the progress made in several small animal models [51, 167–169]. The effective use of RNAi–*in vivo* animal models may not only lead to considerable savings for the drug industry in the expensive development of small drugs, but it will also likely indicate whether particular RNAi compounds have significant potential for further development into drugs. Our aim in this section is to describe several interesting recent examples of RNAi drugs under development for different diseases in animal models. These studies illustrate the application of many principles and concerns discussed above.

7.6.7.1 Cancer

Hu-Lieskovan et al. [170] described systemic RNAi therapy for metastatic cancer in a murine model of metastatic Ewing's sarcoma. They prepared siRNA against the EWS-FLI1 gene product and delivered it using a targeted, nonviral delivery system. SiRNA was packaged into cyclodextrin-containing polycation complexes, which contained not only siRNA but also transferrin as a targeting ligand for specific delivery to transferrin receptor-expressing tumor cells. This delivery system transiently reduced expression of the target gene in metastatic cells and slowed tumor growth. Using long-term twice-weekly treatments, they demonstrated absence of any tumor growth in 80% of mice. Control experiments revealed that only the transferrin-targeted system was efficient in antitumor effects. Moreover, they found that low-pressure, low-volume tail-vein administrations were efficient in the delivery of RNAi compounds and resulted in significant improvements over the high-pressure, high-volume intravenous injections previously used in many studies of RNAi therapy in mouse models [171–173], but that are untenable and unacceptable in humans in routine clinical settings. It was also very important to the success of this study that no abnormalities in interleukin-12 and IFN-alpha, liver and kidney function tests, complete blood counts, or pathology of major organs, i.e., no off-target side effects, were observed from the treatments described. This delivery system was found to be ineffective for brain tumors, however, because the siRNA complexes used did not cross the blood-brain barrier. Consequently, different RNAi approaches will have to be developed to specifically address the treatment of brain tumors.

Yano et al. [174] used mouse models for liver metastasis and prostate cancer to test a human bcl-2 oncogene-specific siRNA complexed with a novel cationic liposome, LIC-101. These complexes were delivered by bolus intravenous injections into the livers of disease-model mice and completely suppressed the growth of liver tumors. The injection volume used was 0.1 mL per 10 g of body weight, which is normally acceptable for human therapy. In addition, in their prostate cancer model, siRNA complexes were administered subcutaneously (0.1 mg in 0.1 mL per mouse) near the tumor five times a week for 2 weeks in mice bearing PC-3 xenografts. The average tumor volume on day 36 of the treatment was 1300 mm^3 in the control group, compared with 487 mm^3 in the siRNA compound-treated group. The authors of this study also indicated that other cationic liposomes caused much greater toxicity than LIC-101, as judged by hemolysis activity on human erythrocytes, although these data were not presented.

KITENIN, a member of the Tetraspanin family, is expressed by many different tumors. Its expression is correlated with the acquisition of metastatic phenotypes

[175]. Lee et al. [176] treated mice with established colon tumors with KITENIN-targeted siRNAs cloned into pSUPER vectors. Weekly, or semiweekly, injections of these siRNA-encoding vectors, delivered in suspension with FuGENE 6 transfection reagent (Roche) for 1 month into tail veins, resulted in a marked regression of tumor size and inhibited metastases. Delivery of this siRNA also significantly prolonged the survival of mice compared with the vector alone (77 ± 12.2 versus 25 ± 9.9 days, $p < 0.01$). In this study, it was demonstrated that the antitumor effects of KITENIN siRNA derived from both the generation of a tumor-specific immune response *in vivo* and the suppression of tumor invasion.

7.6.7.2 Viral and Respiratory Diseases

Hepatitis B virus (HBV) infections cause acute and chronic hepatitis and hepatocellular carcinomas. Uprichard et al. [177] demonstrated, in a mouse model of established Hepatitis B infection, that infection with an adenovirus vector carrying shRNA directed at HBV-specific viral RNA could suppress preexisting HBV gene expression and replication to almost undetectable levels for at least 26 days. Morrissey et al. [148] obtained similar results in a study using hydrodynamic tail vein injections of HBV RNA-specific siRNA stabilized by means of chemical modifications.

Influenza A virus infects about 15–20% of the population each year and is a major source of morbidity and mortality worldwide. Antiviral vaccines only afford protection against a limited range of strains, due to substantial mutation rates in these viruses. Ge et al. [178] demonstrated that siRNAs specific for conserved regions of influenza virus genes can be used to treat and prevent influenza virus infections in mice. In this study, slow i.v. administration of small volumes containing siRNAs complexed with a polycationic carrier was used. Virus titers in lungs were reduced from 10- to 1000-fold by single doses of 60–120 μg of siRNA. Similar effects were also observed when mice were given DNA vectors by i.v. or intranasally, from which siRNA precursors were transcribed. In another study using the same siRNAs, but different carriers, doses, strains of mice, and virus strains, Tompkins et al. [179] observed a significant increase in the survival of mice after lethal challenge with viruses. In both studies, the effects were siRNA-specific and not due to nonspecific antiviral IFN responses. These experiments provide a good basis for studies of prophylaxis and therapy of influenza virus infections in human populations using siRNA compounds.

Respiratory syncytial virus (RSV) and parainfluenza virus (PIV) are leading causes of respiratory disease in infants, young children, immuno-compromized patients, and the elderly. Bitko et al. [140] used viral-specific siRNAs for the treatment of these respiratory syndromes in an animal model. In this study, either, or both, viral infections could be specifically prevented and inhibited when corresponding siRNAs were infused intranasally in mice, with or without transfection reagents. These investigators noted an excellent correlation between the activities observed in their siRNAs in *in vitro* cell cultures and those observed in their animal model. This type of approach presents a fast screen for efficient siRNA sequences before more expensive and demanding applications are pursued in animals. In addition, nasal administration of siRNA compounds seems to provide a convenient

and potent route for delivery of these drugs directed against, at least, respiratory viral diseases in humans, and perhaps against many others.

7.6.7.3 Arthritis

We described, in Section 7.6.3, the use of electroporation for the local delivery of αTNF-specific siRNAs to inhibit joint inflammation in a mouse model of collagen-induced arthritis [50]. In another example, Inoue et al. [180] used electro-transfer of an αTNF-specific siRNA-polyamine complex to significantly ameliorate collagen-induced arthritis in rats. As αTNF plays an important role in many processes in different organs, local delivery was used, in this case, to restrict the effects to the target organ, the joint, and minimize the potential effects on other αTNF-dependent processes elsewhere in the organism.

7.6.7.4 Autoimmune Diseases

Autoreactive T cells play an important role in many autoimmune diseases, such as multiple sclerosis (MS), type 1 diabetes, systemic lupus erythematosus (SLE), psoriasis, asthma, and experimental autoimmune encephalomyelitis (EAE). Lovett-Racke et al. [181] studied inhibition of T-bet, a member of the T-box family of transcription factors, which is expressed in Th1 cells, but not Th2 cells, in EAE, an inflammatory and demyelinating disease of the central nervous system and model for the human disease MS. A single injection (20 or 50 µg) into the tail vein of T-bet-specific naked siRNA at the time of immunization (to induce EAE) reduced the incidence of EAE disease by as much as 75% depending on the siRNA dose. It is possible that modification of the delivery method to one more appropriate for human routine clinical settings, such as those that employ cell-specific targeting as described above in the subsection on *Cancer*, might provide a better basis for clinical trials of RNAi compounds in autoimmune disorders. In addition, the use of a targeted cell delivery system, for example, using an epitope from the T-cell receptor, similar to the transferrin-directed complexes used in [170], might provide more specific elimination of disease-relevant T cells.

7.6.7.5 Neurodegenerative Disorders

Alzheimer disease is a neurodegenerative disorder characterized by an accumulation of β-amyloid (Aβ), a proteolytic product of the amyloid precursor protein (APP) [182]. Increase in β-secretase (BACE1) activity has been directly associated with the production and accumulation of Aβ [183–185]. Singer et al. [186] used lentiviral vectors expressing BACE1-targeted siRNAs delivered locally by intracranial injection into the hippocampi of APP transgenic mice (a model of Alzheimer disease). This treatment specifically reduced both the cleavage of APP into Aβ and neurodegeneration in this *in vivo* model. RNAi-mediated reduction of Aβ-reactive plaques was observed only in the hippocampus and not in other parts of the brain. Behavioral deficits were, nevertheless, also improved by this treatment. Another important issue in this study was that siRNA-targeted inhibition downregulated, rather than completely knocked out, the target gene; this may have been advantageous, in this case, because BACE1 has several potential substrates and the complete switching off of its activity could produce undesired or deleterious effects. In

the effective case of RNAi-mediated downregulation of a target gene, therefore, disease improvements might be observed by lowering the level of production of a relevant protein below some critical threshold level, without significant effect on normal functions.

Huntington's disease (HD) is a dominantly inherited neurodegenerative disorder associated with polyglutamine expansion in the huntingtin (htt) protein [187], for which, currently, there is no effective treatment. Wang et al. [188] used an siRNA compound directed against human mutant-htt, containing expanded polyglutamine tracts, delivered locally into the brains of newborn HD transgenic model mice by intraventricular injections. This treatment significantly increased the longevity of HD mice, resulted in improved motor function, and slowed HD-associated loss of body weight. Despite these successes, this method is currently problematic for human therapeutic applications; not only because of the delivery route used, but also due to the challenge of designing an siRNA sequence that is highly selective for the mutant form of htt, because reduced expression of the wild-type human gene could be deleterious.

7.6.7.6 Ocular Disorders

In age-related macular degeneration, vascular endothelial growth factor (VEGF) plays a crucial role in destructive vascularization. Downregulation of VEGF by antibody [189], or by siRNA [190], has been shown to reduce vascular invasion. Recently, Tolentino et al. [191] used intravitreal injection of VEGF-specific siRNA in a non-human primate model of laser-induced choroidal neovascularization (CNV). They demonstrated that VEGF-specific siRNA treatment is capable of inhibiting vascular growth and permeability in a dose-dependent manner. This study served as a preclinical "proof-of-principle," and phase I clinical studies of VEGF siRNA in patients with exudative age-related macular degeneration are currently in progress [192].

7.6.8 COMPARISON OF SIRNAS WITH OTHER PHARMACEUTICALS (TARGETED AND NONTARGETED TYPE), INCLUDING CLOSELY RELATED GENE SPECIFIC ANTISENSE-BASED DRUGS

Most drugs on the market today are small-molecule compounds, which can be systemically delivered in the form of pills. This is certainly the most convenient method. However, it might not be the most efficient method of drug delivery, due to the different specific physical-chemical nature of the drugs. Nevertheless, the consumer market is heavily affected by a demand for consumer convenience, and pharmacological companies have generally followed this trend with much success. There is a substantial number of drugs, however, which are not pills and could not be pills due to their physical-chemical, biological, and pharmacological properties. RNAi compounds will most likely belong to this class of drugs, at least in the near future, unless substantial efforts will be invested in the specific and robust protection of the extremely sensitive and reactive RNA molecules from the enzymes of the digestive tract. It is impractical, perhaps, to expect such efforts until the efficacy and safety of these drugs are proven in clinical trials, which will most likely be decided over the next 5–7 years.

Efficient delivery of a drug to its target organ(s), tissue(s), cell(s), and molecule(s) is an important requirement for the success of any therapeutic treatment. Any single improvement in targeted delivery, even of existing compounds, may significantly reduce the exposure of irrelevant cells and organs, which would result in less potential side effects and improved drug efficacy.

Many common drugs target proteins. The interaction of small molecules with proteins often treats or lessens the disease by correcting some biochemical aspect of a pathological pathway. RNAi drugs are completely different from these common drugs in that their immediate target is an RNA molecule, and not a protein. The effect on the "target protein" is a secondary one, by downregulation of the abundance or translation of the mRNA coding for this protein. Therefore, there may be a substantial delay in the desired effects of RNAi if the turnover rate of the target protein is low, or if the protein is localized in a different tissue than where it is expressed so that this protein and its mRNA are spatially separated. For example, a small drug directed at a protein present in the blood can be delivered directly into the bloodstream by a variety of methods. To achieve a similar effect, an RNAi compound must be delivered specifically to the organs and cells that produce this protein. If a particular serum protein has a very slow turnover rate, it might not even be feasible to obtain the desired effect in a reasonable period of time using RNAi. Another example of a potentially deceptive RNAi target is anucleated cells, such as erythrocytes, which are deficient in active mRNA and protein syntheses. In this case, to make a correction in these cells, RNAi compounds should be directed at their progenitors. Yet another difference is that RNAi drugs act by reducing the *amount* of the target protein, and not by inhibiting its activity as many small-molecule drugs do. Reducing the amount of a target protein might produce effects different from the inhibition of its activity, because the mere concentration of a particular protein in a cell or tissue could determine the regulation of other processes or biochemical pathways in the organism. All of these potentially problematic aspects that derive from differences between protein and RNA targeting should, therefore, be carefully considered when conceiving the targeted design of an RNAi drug against a specific protein.

A clear advantage of RNAi drugs is their common physical-chemical nature, unlike the disparate nature of the kingdom of small molecules. Therefore, advances made in any aspect of development of a specific RNAi compound (e.g., delivery, stability, and modification) will likely translate to improvements of other RNAi compounds directed against different targets. Other obvious advantages to RNAi drugs are ease of design and synthesis, high specificity, ease of target validation, and fast initial development and redevelopment [193]. It is much easier do design and test RNAi compounds against several targets or against several sites of the same target, a task not feasible for the common small drug. This property of RNAi drugs should significantly improve efficacy and resistance against mutations and natural diversity or polymorphism.

Most similar to RNAi compounds in their application and chemical nature are antisense compounds; one of which, Vitravene, reached the market as an FDA-approved drug in 1998 [194, 195]. Antisense oligonucleotides have been studied for their ability to knock down gene expression since 1978 [196, 197]. Later studies support that the mechanism of antisense inhibition acts either through the inhibition of translation or through RNase H-dependent degradation of mRNA [198].

Both technologies, RNAi and antisense, can successfully inhibit target gene expression; and both share many practical problems, such as delivery, stability, and potential off-target effects. Nevertheless, a significant difference between these two technologies is their relative efficiency of compound design. An efficient antisense oligonucleotide must be able to bind its target mRNA under the physiological conditions that exist inside a cell. However, mRNAs in cells have folded structures, with more than 90% of their sequence unavailable for hybridization with short oligonucleotides [199]. Therefore, not all possible antisense oligonucleotides would be able to hybridize to a target mRNA. Although the RNAi mechanism involves a specialized apparatus for RNA targeting and efficient hybridization of siRNA, antisense oligonucleotides do not have this help. Hence, the ability to efficiently hybridize to a specific mRNA directly determines the potential success or failure of an antisense experiment. As a result, where one out of every five randomly chosen double-stranded short RNA molecules is likely to be effective in RNAi, only about one out of every hundred antisense oligonucleotides would be expected to have some activity. As physical forces playing a role in the hybridization process are complex, a more reliable means to screen for efficient antisense oligonucleotides would be an empirical approach [200], which can be an expensive, labor, and time-consuming process. In addition, the concentrations of RNAi compounds required for inhibition are lower than those required for antisense oligonucleotides, which might result in less nonspecific toxicity. For an extensive description and detailed comparison of both technologies, see the comprehensive review by Achenbach et al. [201]. In general, and by many criteria, RNAi technology seems to provide a more convenient and powerful technology for therapeutic treatment. Nevertheless, therapeutic application of RNAi technology is still in its infancy; although therapeutic applications of antisense technology have been under development for decades and have achieved some substantial success, with one drug on the market and several promising drug candidates in advanced stages of clinical trials [150, 194]. In fact, many advances in antisense technology (e.g., modification and stabilization of compounds, delivery routes, aversion of side effects) have been, and will continue to be, applicable to the related field of RNAi technology. Hence, it is, perhaps, currently difficult to judge which technology may be superior, but the potential of both for delivering effective therapeutic applications will definitely continue to be explored in the future.

7.6.9 BIOTECH AND DRUG COMPANIES CURRENTLY INVESTED IN RNAI DRUG DISCOVERY AND DEVELOPMENT

Naturally, recognizing its great utility and success in multiple research applications and its high potential for therapy, numerous industrial companies and research institutes have taken an interest and joined the RNAi-therapy game. Over a dozen biotech companies are currently competing in the development of RNAi pharmaceuticals. There seem to be even more businesses exploiting the RNAi boom by providing different kinds of RNAi-related products and services to desirous research teams, such as the synthesis of RNAi compounds and libraries; the design, construction, and distribution of RNAi vectors; and customized transfection

reagents. (e.g., Invitrogen, Ambion, QIAGEN, Dharmacon). Changes are occurring fast on this playing field, as some companies have quickly been "taken out of the game" by others (e.g., Atugen was recently acquired by SR Pharma plc), and additional companies join in by changing their focus to RNAi technology (e.g., Genta). Several biotech companies have filed for FDA approval of clinical trials with RNAi compounds (Table 7.6-1).

Collectively, the companies invested in the RNAi drug business have over 40 RNAi compounds engaged in therapeutic projects, which cover a wide range of diseases, including cancers (10 compounds), infectious diseases (mostly viral, 11 compounds), neurological disorders (5 compounds), allergy and inflammation (2 compounds), diabetes, obesity, and others [202]. Some major players have been Sirna Therapeutics, Alnylam Pharmaceuticals, and Acuity Pharmaceuticals, which all compete in the development of RNAi drugs directed against age-related macular degeneration (AMD). This common choice of target disease does not seem to be coincidental, as (1) no cure is currently available for AMD, (2) the target gene product VEGF has been clearly implicated in the development of the disease, and (3) VEGF-specific siRNA compounds were found in prior studies to inhibit its expression and the growth and vascular permeability associated with the disease [189–191] (also, as discussed in Section 7.6.7). Most importantly, local delivery through topical application is feasible in this disease of the eye, assuring appropriate therapeutic concentrations of the compound and minimizing potential side effects. If there are no complications due to safety issues, in a few years we may see who will win the race to establish this new class of gene targeted medicines [203]. In the near future, the market for RNAi technology and related products will surely continue its rapid expansion [204], and more exciting news from biotech companies on advances in RNAi drug development will come into play.

7.6.10 CONCLUDING REMARKS

Extensive research and development efforts in RNAi technology during the last few years have resulted in enormous success in our ability to downregulate the expression of almost any gene in cell culture and in many different animal models. This success has created great enthusiasm and hope that the exploitation of this powerful technology will soon result in highly effective and safe new drugs, able to cure diseases, which were incurable or difficult to cure before. A significant concentration of research efforts in four key areas: target selection, targeted delivery, compound stability, and minimization of off-target effects should result in superior RNAi drugs. We shall see, probably within the next 5–7 years, whether expectations can be realized and deliver the first RNAi-based drug for human use on the market.

ACKNOWLEDGMENT

We thank Susan Francis and Vlad Malkov for their critical review of the manuscript and valuable discussion.

7.7.1 STATE OF THE ART OF NANOSIZED DELIVERY SYSTEMS

The earliest developments of drug delivery systems (DDS) date back to the 1950s where the first microencapsulated drugs were introduced. In the 1960s polymer-based slow release systems appeared, and as the first nanosized DDS with spherical shape properties, the liposomes were recognized as models to study membranes and as carriers of both hydrophilic and lipophilic molecules. Liposomes, small unilamellar phospholipid bilayer vesicles, undoubtedly represent the most extensively and advanced drug delivery vehicles. After a long period of research and development efforts, liposome-formulated drugs have now entered the clinics to treat cancer and systemic fungal infections, mainly because they are biologically inert and biocompatible and do not cause unwanted toxic or antigenic reactions [1–3]. For the delivery of genetic material (DNA, ribozymes, DNAzymes, aptamers, (antisense-) oligonucleotides, small interfering RNAs), the liposomes, in particular lipid–DNA complexes termed lipoplexes, compete with viral gene transfection systems, as will be outlined in the following sections. Nanoparticles, nanospheres, polymersomes, nanogels, micelles, dendrimers, and virosomes are other main types of nanocarrier systems used for drug delivery [4–7]. As shown in Figure 7.7-1, these drug delivery systems vary in their compositions, shapes, sizes, drug loading capacity, as well as their pharmacokinetic and organ or tissue targeting properties [8].

DDS are developed for drugs with nonideal properties that include (1) poor solubility, where a conventional pharmaceutic formulation is difficult to prepare as poorly water soluble drugs may precipitate in aqueous media. (2) Tissue damage caused by inadvertent extravasation of drugs, e.g., tissue necrosis caused by cytotoxic drugs. (3) Loss of drug activity after administration, e.g., enzymatic and fast metabolic degradation. (4) Unfavorable pharmacokinetic properties and poor biodistribution. (5) Lack of selectivity for target organs or tissues. Systemic drug distribution may cause toxic side effects, and low concentrations in target tissues may cause suboptimal therapeutic effects.

The formulation of pharmacologically active drug molecules in DDS can improve or abolish these unfavorable properties. However, there are also drawbacks in DDS development, such as system complexity, unwanted biologic effects, stability, costs of development and scale-up, as well as intellectual property issues. In the limited format of this review, it is not possible to cover all methods and references in the field. Hence, we concentrate this review on DDS for the delivery of peptides, DNA, plasmids, oligodeoxynucleotides, siRNA, and lipophilic nucleoside derivatives. Vaccine delivery systems will also be mentioned, and examples will be provided to demonstrate the general development trends.

7.7.2 COMPARISON OF VIRAL VS. NONVIRAL GENE DELIVERY SYSTEMS

Viral gene delivery has become an important therapeutic strategy for the development of novel treatment approaches. A deeper understanding of vector biology and the molecular mechanisms of disease together with remarkable advances in molecular biology and vector technology have considerably advanced the field of human

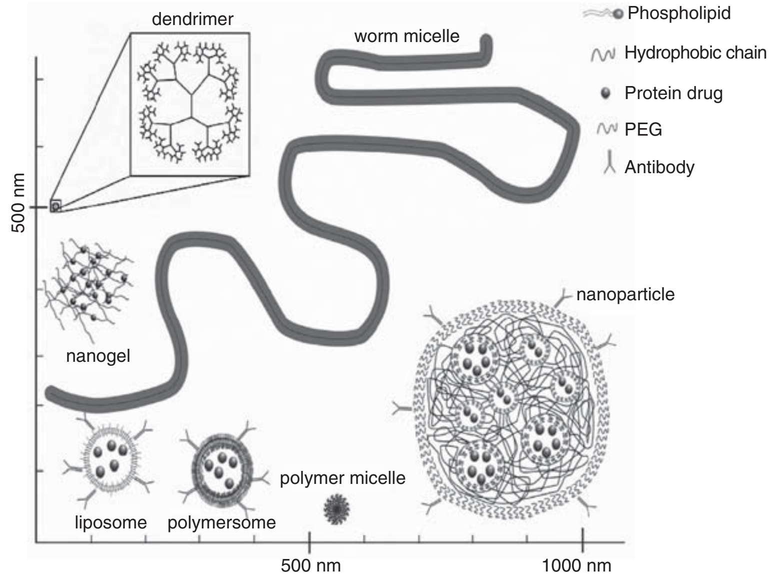

Figure 7.7-1. Nanocarriers for vascular drug delivery. Schematic representation of several main types of nanocarriers depicted in relative size scale with limited and oversimplified structural features. All nanocarriers can be surface-conjugated with targeting antibodies (or alternative affinity moieties) and PEG polymer providing stealth features. Dendrimers are the smallest of nanocarriers, in the maximum range of tens of nanometers. They possess multiple end groups suitable for a high extent of coupling targeting or active agents. Liposomes, composed of biologically derived phospholipids, are the most common form of nanocarriers with large aqueous loading potential; yet they are also the least stable of carriers. Polymersomes, one of three self-assembled polymeric nanocarriers, are the synthetic polymer analog of liposomes, possessing enhanced stability, dense PEG coating, and therefore prolonged circulation *in vivo*. Worm micelles are long, flexible cylindrical polymer micelles that possess one of the longest circulation times recorded *in vivo* with a yet unknown potential for therapeutic applications. Polymeric micelles are the smallest of the self-assembling polymer aggregate carriers and are the least stable self-assembler. Nanogels are composed of cross-linked polymers with drug entrapped into the ensuing matrix. Their circulation and potential therapeutic uses remain to be studied. Nanoparticles are solid polymer structures formed through processing rather than through self-assembly methods. They represent the largest of the carriers, have the greatest active protein loading capacity measured to date, and can protect encapsulated therapeutic enzymes from external proteolysis. (With permission from Ref. 8.)

gene therapy development. However, most viral gene delivery systems used to date have demonstrated limitations in practicality and safety, mainly due to low levels and short duration of recombinant transgene expression, induction of host immunogenicity to vector constituents, and suboptimal transgene expression to tissues or cells. A recent, additional cause for concern over using viral vectors is the phenomenon known as insertional mutagenesis, in which the chromosomal integration of viral gene material either interrupts the expression of a tumor suppressor gene or activates an oncogene, leading to the malignant transformation of cells.

Thus, safer, nonviral delivery approaches are needed and the latest advances indicate that efficient, long-term gene expression can be achieved by nonviral

means. In particular, integration of DNA can be targeted to specific genomic sites without harmful consequences, and it is possible to maintain transgenes as small episomal plasmids or artificial chromosomes. The application of these approaches to human gene therapy is progressively becoming a reality. Here, we briefly compare use, properties, advantages, and disadvantages of viral and nonviral gene delivery, the two main types of DDS that are used in gene therapy and vaccine approaches.

7.7.3 VIRAL SYSTEMS

The lack of efficient nontoxic gene delivery systems is still the major impediment to the successful application of gene therapy. Having evolved to deliver their genes to target cells, viruses are effective means of gene delivery and they can be manipulated to express therapeutic genes or to replicate specifically in certain cells.

The first viral vector systems were developed more than 25 years ago [9], and since then viral gene therapy strategies has been progressively developed [10]. A variety of virus vectors has been employed and modified to deliver genes to cells to provide either transient, such as adenovirus [11–13], poxviruses (vaccinia) [14], or herpes virus [15], or permanent, such as retroviruses (lentivirus) [16–18] and adeno-associated virus [19], transgene expression; each approach has its characteristic advantages and disadvantages.

7.7.3.1 Adenoviruses

Replication-defective adenoviruses are vectors of choice for delivering corrective genes into human cells. Major efforts are directed to design new generations of adenoviral vectors that feature reduced immunogenicity and improved targeting ability. Various targeting strategies have been attempted aiming at obtaining optimized and specific cellular transduction, including that of genetic manipulation of the viral capsid. Modification of the tropism-determining fiber protein and other capsid proteins has yielded vectors that are superior to the first-generation adenoviruses employed for gene therapy [11]. Adenoviral-based vectors are susceptible both to cytotoxic T-lymphocyte and humoral immune responses. In addition, leaky adenoviral genes also render transduced cells susceptible to host immune responses. These are the main reasons why adenoviral-based vectors are not suitable to correct genetic disorders, which require long-term expression of the transgene [20]. The production of adenoviral vectors for gene therapy applications still faces several challenges that limit the availability of high-quality material for clinical applications [21, 22].

7.7.3.2 Poxviruses

Poxviruses represent a heterogenous group of DNA viruses that have been used to express a multitude of foreign genes. Vaccinia virus is the prototypical recombinant poxvirus that can generate potent antibody and T-cell responses. Recombinant vaccinia viruses (rVVs) as nonreplicating viral vectors have been demonstrated for their great potential as vaccines, diminished cytopathic effects, high levels of protein expression, and strong immunogenicity, and they are relatively safe in

animals and in human patients. These properties have led to the use of rVVs as vaccines against HIV and cancer [14, 23].

7.7.3.3 Herpes Simplex Virus

Attenuated genetically engineered herpes simplex virus (HSV) vectors are potential vectors for several human therapy applications. These include delivery and expression of human genes to cells of the nervous systems, selective destruction of cancer cells, prophylaxis against infection with HSV or other infectious diseases, and targeted infection to specific tissues or organs [15].

7.7.3.4 Lentiviruses

Lentiviruses, members of the retroviral family, have the ability to infect cells at both mitotic and postmitotic stages of the cell cycle, thus opening the possibility to target nondividing cells and tissues. Human Immunodeficiency Virus (HIV)-based vectors have been used *in vitro* and *in vivo* in several situations; however, safety concerns still exist. Therefore, the development of vector systems based on primate as well as nonprimate lentiviruses is ongoing. Recent developments in the modification of the virus coat allow more targeted approaches and open new possibilities for the systemic delivery of therapeutic viruses [24]. However, the specific mechanisms used by different retroviruses to efficiently deliver their genes into cell nuclei remain largely unclear. Understanding these molecular mechanisms may reveal features to improve the efficacy of current retroviral vectors [25].

7.7.3.5 Adeno-Associated Virus

Vectors based on the adeno-associated virus (AAV) have attracted much attention as potent gene-delivery vehicles, mainly because of the persistence of this nonpathogenic virus in the host cell and its sustainable therapeutic gene expression. The principal historical limitation of this vector system, efficiency of recombinant AAV-mediated (rAAV) transduction, has recently observed a dramatic increase as the titer, purity, and production capacity of rAAV preparations have improved [26]. AAV vectors have been used in phase I clinical trials for the treatment of neurological disorders, such as Parkinson's and Canavan's diseases. Indeed, AAV-mediated gene transfer is a promising tool for the delivery of the therapeutic gene into the central and peripheral nervous systems. AAV-mediated gene transfer was also applied in phase I and II clinical trials for the treatment of cystic fibrosis and in phase I trials for the treatment of hemophilia B. In the context of cancer, the ability of attenuated viruses to replicate specifically in tumor cells has already yielded some impressive results in clinical trials, allowing the design of new therapeutic approaches, particularly when combined with other approved anticancer therapies. Despite the remark-able progress that has been reported, the design of further optimized vectors is still required. As it stands, AAV-mediated gene transfer has a limited capacity in accommodating foreign genes. In addition, some preclinical studies have shown that AAV-derived vectors can cause tumors in animals due to mutagenic random vector integration into the genome [27]. To circumvent this problem, a novel approach to AAV-mediated gene therapy based on gene targeting through homologous recombination has been introduced that allows efficient, high-fidelity, nonmutagenic gene repair in a host cell [28].

7.7.4 NONVIRAL SYSTEMS

Currently, the most severe limitations of the nonviral gene therapy systems are low transfection efficiency of gene material into the target cells, physico-chemical instability, and cytotoxicity. The major obstacles encountered in the transfer of foreign genetic material into the body include interactions with blood components and vascular endothelial cells and uptake by the mononuclear phagocyte system (MPS). The degradation of DNA by serum nucleases is another major obstruction for functional delivery to the target. In addition to targeting a specific cell type, an ideal nonviral vector (liposomes, lipoplexes, virosomes), once taken up by a target cell, must manifest an efficient endosomal escape, provide sufficient protection of DNA in the cytosol and help facilitate an easy passage of cytosolic DNA to the nucleus (Figure 7.7-2).

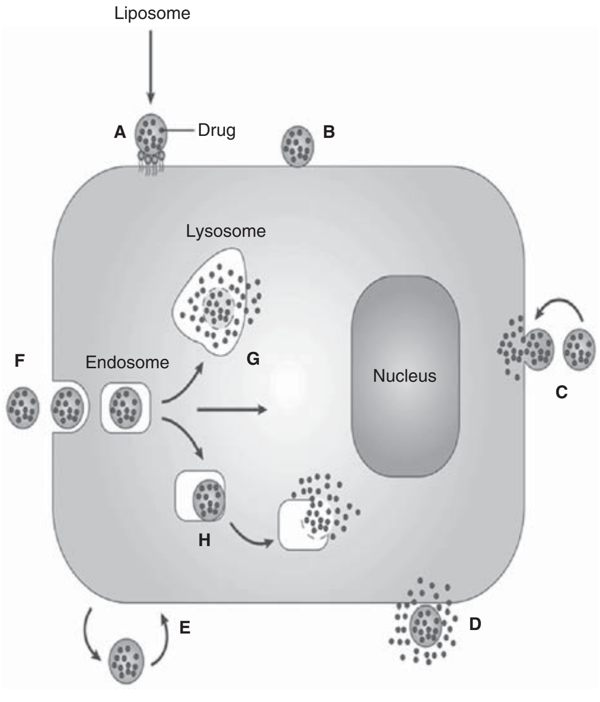

Figure 7.7-2. Liposome–cell interactions. Drug-loaded liposomes can specifically (**A**) or nonspecifically (**B**) adsorb onto the cell surface. Liposomes can also fuse with the cell membrane (**C**) and release their contents into the cell cytoplasm, or they can be destabilized by certain cell membrane components when adsorbed on the surface (**D**) so that the released drug can enter the cell via micro-pinocytosis. Liposome can undergo the direct or transfer-protein mediated exchange of lipid components with the cell membrane (**E**) or be taken up by specific or nonspecific endocytosis (**F**). In the case of endocytosis, a liposome can be delivered by the endosome into the lysosome (**G**), or en route to the lysosome, the liposome can provoke endosome destabilization (**H**), which results in drug liberation into the cytoplasm. (With permission from Ref. 29.)

7.7.4.1 Cationic Polymers, Lipoplexes

Cationic polymers have a great potential for DNA complexation and have shown to be useful as nonviral vectors for gene therapy applications. For the past 15–20 years liposomes composed of cationic lipids, termed lipoplexes, have routinely been used for the delivery of nucleic acids such as plasmids, oligodeoxynucleotides, and siRNA to cells in culture and *in vivo*. Many of these reagents are commercially available or can be formulated in the laboratory [30–32]. Most cationic lipid–DNA complexes form a multilayered structure with DNA sandwiched between the cationic lipids. Much more rarely, an inverted hexagonal structure with single DNA strands encapsulated in lipid tubules is observed [33]. Among other advantages, lipoplexes have the ability to transfer very large genes into cells. However, as the understanding of their mechanisms of action is still incomplete, their transfection efficiencies remain low compared with those of viruses. Particularly in cultured cells, toxicity remains a significant problem. In addition, these complexes are immunostimulatory, a fact that may either be harmful or beneficial. The development of cationic lipids that are safe to use, especially for *in vivo* applications, and possess enhanced transfection capabilities is an ongoing process. The lipoplexes are described in detail in Section 7.7.5.

7.7.4.2 NonLipidic Polycation Gene Delivery Systems

Of the many nonlipidic polycation gene delivery systems developed in the past decades, poly(L-lysine) (PLL) was the first polycation used for nonviral gene delivery [34]. Among a vast number of other positively charged polymers, polyethylenimine (PEI) has been widely used for nonviral transfection *in vitro* and *in vivo* and has an advantage over other polycations in that it combines strong DNA condensation capacity with an intrinsic endosomolytic activity [35–38].

Other synthetic and natural polycations developed as nonviral vectors are polyamidoamine dendrimers, the synthetic cationic polymer poly(2-dimethylamino)ethyl methacrylate (PDMAEMA) [39], and chitosan. Polyamidoamine (PAMAM) dendrimers represent a novel class of polycationic synthetic polymers that can be used for gene transfer [40, 41]. The three-dimensional spherical structure of dendrimers offers synthesis control of the molecule in terms of degree and generation of branching. The control of branching of the dendrimers during synthesis allows the production of polymer particles with a very high degree of monodispersity, which is a significant advantage over other polymers such as polylysine that generate highly polydisperse particles (see Figure 7.7-1). Low polydispersity can lead to reproducible gene delivery and a clinically reliable formulation. The cationic amino acid residues in the polymeric structure of PAMAM dendrimers can help in DNA condensation and endosome release. Dendrimers that protect oligonucleotides from serum nucleases have been used to enhance oligonucleotide delivery [42].

Chitosan, a natural-based polymer obtained by alkaline deacetylation of chitin, is nontoxic, biocompatible, and biodegradable. These properties make chitosan a promising candidate for conventional and novel drug delivery systems. Because of the high affinity of chitosan for cell membranes, it has been used as a coating agent for liposome formulations [43–45].

7.7.4.3 Other Methods

Various other methods, such as DNA electrotransfer, electroporation-based gene transfer, calcium phosphate nanoparticles, peptide nucleic acids, and cell penetrating peptides, round off the currently used methods in the field of nonviral gene delivery techniques.

DNA electrotransfer, the use of electric pulses to transfect various types of cells, is well known and regularly used *in vitro* for bacteria and eukaryotic cell transformation. Electric pulses can also be delivered *in vivo* either through the skin or with electrodes in direct contact with the target tissues. After injection of naked DNA in a tissue, appropriate local electric pulses can result in a very high expression of the transferred genes [46].

Electroporation has been applied in preclinical autoimmune and/or inflammatory diseases to deliver either cytokines and anti-inflammatory agents or immunoregulatory molecules. The method is also effective for the intratumoral delivery of therapeutic vectors, and it strongly boosts DNA vaccination against infectious agents or tumor antigens. Electroporation gene therapy has become a widely used method for nonviral gene delivery, including applications for intramuscular and intratumoral electro-gene transfer and for the transfection of dendritic and stem cells [47, 48]. The current challenges faced by both *in vitro* and *in vivo* applications comprise the enhancement of transfection efficiency, extention of the duration of gene expression, and increase of the survival rate for *in vitro* cell transfections.

Virus- or liposome-like-sized calcium phosphate nanoparticles of 20–200 nm mean diameter have been found to overcome many of the known limitations in delivering genes to the nucleus of specific cells. It has been demonstrated that calcium ions play an important role in endosomal escape, cytosolic stability, and enhanced nuclear uptake of DNA through nuclear pore complexes. The role of exogenous calcium ions to overcome the major obstacles encountered in the practical accomplishment of gene delivery suggests that calcium phosphate nanoparticles can be designated as a new generation of nonviral vectors [49].

Peptide nucleic acid (PNA) is a powerful new biomolecular tool with a wide range of important applications. PNA mimics the behavior of DNA and binds complementary nucleic acid strands and RNA sequences with high affinity and selectivity. The unique chemical, physical, and biological properties of PNA are exploited to produce powerful biomolecular tools, antisense and antigene agents, molecular probes, and biosensors [50–53].

Cell penetrating peptides (CPPs) have proven to be an efficient intracellular delivery system overcoming the lipophilic barrier of cell membranes [54]. CPPs can deliver a wide range of large cargo molecules such as proteins, peptides, oligonucleotides, and even small particles as liposomes to a variety of cell types and to different cellular compartments. The CPPs are basic, lysine-, or arginine- rich amphipathic peptides. The peptides originate from different sources, either as naturally occurring peptide sequences, virally derived (TAT, VP22), from transcription factors (pAntp), as chimeric (transportan) or as synthetic peptides (polyarginines) and others [55].

As depicted in Figure 7.7-3, CPPs can either form complexes with peptides, proteins, plasmids, oligonucleotides, or siRNA molecules or they can be covalently linked to these cargo molecules [54]. Larger structures such as liposomes have also

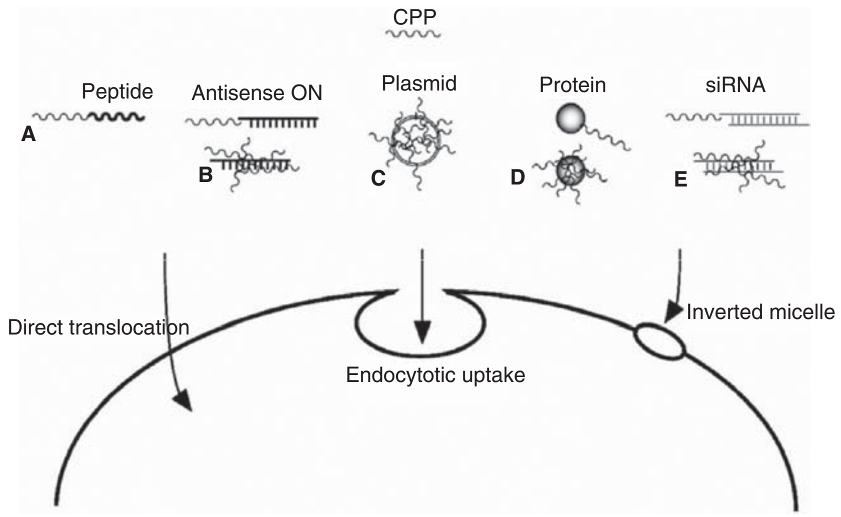

Figure 7.7-3. Cell penetrating peptides, CPPs. Suggested uptake mechanisms for CPPs and examples of delivered cargoes. (A) CPP and peptide in single amino acid chain. (B) Oligodeoxynucleotides either in complex or covalently linked. (C) Plasmid in complex by electrostatic interaction. (D) Protein either as fusion protein or in complex with CPP. (E) siRNA, covalently linked or as complex. (With permission from Ref. 54.)

been decorated with the TAT [56] or pAntp CPPs [57], demonstrating higher cell uptake rates *in vitro*.

Unfortunately, their usefulness as drug delivery systems is hampered by their ability to penetrate virtually any cell type both *in vitro* and *in vivo*. This feature makes CPP applications as target specific drug delivery systems complicated and their application as therapeutic drug carrier systems seems unlikely, unless their target cell specificity can be significantly improved.

7.7.4.4 Virosomes

Virosomes were developed from liposomes by combining liposomes with fusogenic viral envelope proteins. Almeida et al. [58] were the first to report on the generation of lipid vesicles containing viral spike proteins derived from influenza virus. Using preformed liposomes and hemagglutinin (HA) and neuraminidase (NA), purified from influenza virus, they succeeded to generate membrane vesicles with spike proteins protruding from the vesicle surface. Visualization of these vesicles by electron microscopy revealed that they very much resembled native influenza virus. Consequently, they were named virosomes. Reconstituted viral envelopes (virosomes, artificial viral envelopes) appear to be ideally suited as vaccine formulations for the delivery of protein antigens to the cytosol of antigen presenting cells (APCs), and thus for the introduction of antigenic peptides into the MHC class I presentation pathway. Cytotoxic T-cell activity can be induced by immunization of mice with an antigenic peptide or an entire protein encapsulated in virosomes. As shown schematically in Figure 7.7-4, the action of influenza virosomes is likely to involve both delivery of the enclosed antigen to the cytosol of antigen presenting

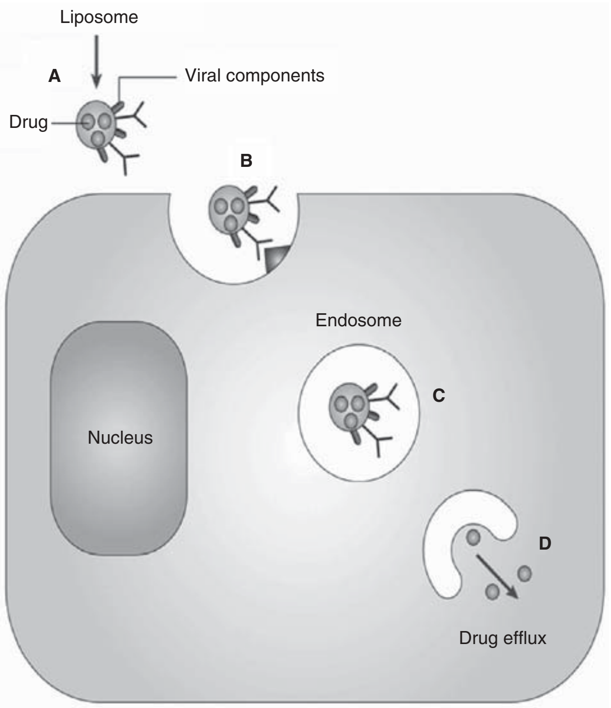

Figure 7.7-4. Virosome–cell interactions. Liposome modified with specific viral components (**A**) and loaded with a drug can specifically interact with cells (**B**), provoke endocytosis, and via the interaction of viral components with the inner membrane of the endosome (**C**), allow for drug efflux into the cell cytoplasm (**D**). (With permission from Ref. 29.)

cells and the powerful helper activity of the virosomal hemagglutinin. Although the immune responses elicited by DNA-virosomes are moderate, they are promising and warrant further research to ultimately develop effective DNA-based virosomal vaccines [59–61].

7.7.5 LIPOSOMES AND CATIONIC LIPOSOME-DNA COMPLEXES (LIPOPLEXES)

Liposomes have become known as one of the most versatile tools for the delivery of DNA, DNA-related, and many other therapeutic molecules [6, 7, 29]. Liposomes are spherical vesicles that consist of an aqueous compartment enclosed in a phospholipid bilayer. If multiple bilayers of lipids are formed around the primary core, the structures that are generated are known as multilamellar vesicles (MLVs). MLVs are formed spontaneously by reconstitution of lipid films in aqueous media. Small unilamellar vesicles (SUVs) of specific size (100–500 nm) are produced by high-pressure extrusion of MLVs through polycarbonate membranes. SUVs (25–90 nm) are also obtained by sonication of MLVs or larger SUVs, by detergent dialysis [62] and by many other, less important methods. Both hydrophilic and

hydrophobic drugs can be entrapped in the liposomes, and the choice of the lipid composition as well as the surface modification of the liposomes provides them with a high versatility such as long circulation half-life and sustained and targeted delivery (Figure 7.7-5) [29, 62].

Liposomes can be used as DNA drug delivery systems either by entrapping the DNA-based therapeutics inside the aqueous core or by complexing them to positively charged lipids (lipoplexes, see below). Liposomes offer significant advantages over viral delivery systems; for example, liposomes are generally nonimmunogenic because of the absence of proteinaceous components. As the phospholipid composition in the liposome bilayers can be varied, liposomal delivery systems are of high versatility and customized formulations can be easily engineered to obtain desired sizes, surface charge, composition, and morphology. Liposome encapsulated DNA molecules are protected from nuclease activity and thus improve their biological stability.

Long circulating ("stealth") liposomes are sterically stabilized liposomal formulations that include poly(ethylene glycol) (PEG)-conjugated lipids or other hydrophilic coating molecules. PEGylation prevents the opsonization and recognition of the liposomal vesicles by the MPS. PEGlyation has also been used in conjunction with other polymeric delivery systems such as poly(L-lysine) to achieve longer circulation half-lives.

Immunoliposomes are complex drug or gene delivery systems that can be used for cell targeting by the incorporation of functionalized antibodies attached to lipid bilayers. The "state-of-the-art" immunoliposomes are long circulating PEG-liposomes to which receptor specific molecules are attached, preferably at the distal tips of the PEG chains [62–65]. Immunoliposomes target specific receptors and facilitate receptor-mediated endocytosis for cell uptake (see Fig. 2). Immunoliposomes decorated with single-chain antibody fragments against the ED-B isoform of fibronectin were successfully used in targeted delivery of cytotoxic drugs into tumors *in vivo* [66]. Tissue-specific gene delivery using immunoliposomes has also been achieved by antitransferrin receptor immunoliposomes [67].

To release encapsulated material into the cytoplasm, pH-sensitive liposomes can be generated by the inclusion of dioleyl-phosphatidylethanolamine (DOPE) into liposomes composed of acidic lipids such as cholesterylhemisuccinate or oleic acid. At the neutral cellular pH 7, these lipids have the typical bilayer structure; however, upon endosomal compartmentalization, they undergo protonation and collapse into nonbilayer structures, thereby leading to the disruption and destabilization of the endosomal bilayer, which in turn helps in the rapid release of encapsulated molecules into the cytoplasm [7].

There is an important difference between liposome vesicles and cationic lipid–DNA complexes, the lipoplexes. Lipoplexes are cationic lipid–DNA complexes that are formed spontaneously in aqueous media upon mixing DNA and preformed liposome vesicles composed of cationic and neutral lipids [68]. From a physical point of view, lipoplexes are ordered, self-assembled, composite aggregates whose spatial geometry and phase behavior are controlled by the electrostatic interactions between the positively charged lipids and the negatively charged DNA molecules. Numerous studies have demonstrated the use of cationic liposome formulations for the delivery of different plasmid constructs in a wide range of cells, both *in vivo* and *in vitro*. Despite their cytotoxicity, their nonimmunogenic nature and the

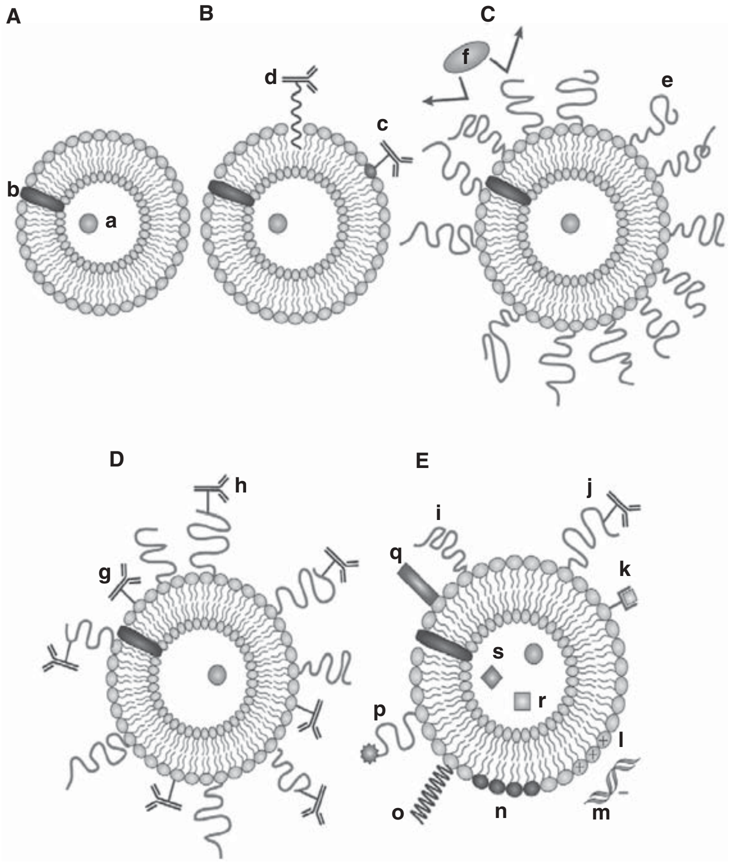

Figure 7.7-5. Evolution of liposomes. (**A**) Early traditional "plain" liposomes with water-soluble drug (**a**) entrapped into the aqueous liposome interior, and lipophilic drug (**b**) incorporated into the liposomal membrane. (**B**) Antibody-targeted immunoliposome with antibody covalently coupled (**c**) to the reactive phospholipids in the membrane, or hydrophobically anchored (**d**) into the liposomal membrane after preliminary modification with a hydrophobic moiety. (**C**) Long circulating liposome grafted with a protective polymer (**e**) such as PEG, which shields the liposome surface from the interaction with opsonizing proteins (**f**). (**D**) Long circulating immunoliposome simultaneously bearing both protective polymer and antibody, which can be attached to the liposome surface (**g**) or, preferably, to the distal end of the grafted polymeric chain (**h**). (**E**) New-generation liposome, the surface of which can be modified (separately or simultaneously) by different ways. Among these modifications are the attachment of protective polymer (**i**) or protective polymer and targeting ligand, such as antibody (**j**); the attachment/incorporation of a diagnostic label (**k**); the incorporation of positively charged lipids (**l**) allowing for the complexation with DNA yielding lipoplex structures (**m**); the incorporation of stimuli-sensitive lipids (**n**); the attachment of a stimuli-sensitive polymer (**o**); the attachment of a cell-penetrating peptide (**p**); and the incorporation of viral components (**q**). In addition to a drug, liposomes can be loaded with magnetic particles (**r**) for magnetic targeting and/or with colloidal gold, silver particles, or fluorescent molecules (**s**) for microscopic analysis. (Adapted with permission from Ref. 29.)

simplicity of production of these systems make them attractive tools for gene transfer. Currently, many gene therapy trials in progress employ nonviral liposomal vectors for transgene delivery.

Lipoplex formulations generally consist of mixtures of cationic and neutral (zwitterionic) lipids. Commonly used cationic lipids are 1,2-dioleoyl-3-trimethylammonium propane (DOTAP), N-[1-(2,3-dioleyloxy)propyl]-N,N,N-trimethylammonium chloride (DOTMA), 2,3-dioleoyloxy-N-[2-(sperminecarboxamido) ethyl]-N,N-dimethyl-1-propanaminium (DOSPA), dioctadecyl amido glycil spermine (DOGS), and 3,[N-(N1,N-dimethylethylenediamine)-carbamoyl] cholesterol (DC-chol) [69–71]. Commonly used neutral molecules, also known as helper or colipids, are DOPE and cholesterol. The cationic lipids in the liposomal formulation serve as a DNA complexation and DNA condensation agent during the formation of the lipoplex. The positive charge also helps in cellular association. The colipids facilitate membrane perturbation and fusion. Many proprietary reagents of cationic lipids such as Lipofectamine (Invitrogen, Carlsbad, CA), Effectene (Qiagen, Valencia, CA), and Tranfectam (Promega, Madison, WI) are commercially available. However, most of these transfection reagents can only be used for *in vitro* gene transfection applications. Despite the appreciable success of cationic lipids in gene transfer, toxicity is a main issue for both *in vitro* and *in vivo* applications. Inflammatory toxicity represents a typical toxicity associated with systemic administration of lipoplexes. Results obtained from *in vivo* studies indicate that lipoplex gene delivery systems mediate uptake of plasmid DNA by the liver, mainly by Kupffer cells, in which a large amount of cytokines is produced [72, 73]. Upon administration via the airways, cytokine-mediated pulmonary toxicity and TNF-α induction by cationic lipids in lung tissue have been reported [74]. Reduction in toxicity was observed by a modification of DOPE polyplexes with cetylated PEI, resulting in remarkable transgene efficiency with low cytotoxicity [72]. In another study, a sterically stabilized immunolipoplex composed of a p53 DNA–lipid complex to which PEG molecules and an antitransferrin receptor single-chain antibody fragment were attached resulted in improved delivery of the complex to tumor cells *in vivo* [75]. The negative factors of lipoplex-mediated gene transfer are low transfection efficiencies, which have been attributed to the heterogeneity and instability of the lipoplex formulations. Lipoplex size heterogeneity also adversely affects their quality control, scale-up, and long-term shelf stability, which are important issues for their pharmaceutical development. Compared with viral vectors, the transfection efficiencies of cationic liposomal vectors are significantly lower. Another drawback in the use of cationic lipids is the rapid inactivation of their cargo in the presence of serum [76].

As an alternative to cationic lipids, the potential of anionic lipids for DNA delivery has been investigated. However, in recent years, only a few studies using anionic liposomal DNA delivery vectors have been reported [77, 78]. These vectors have limited applications, mainly because of inefficient entrapment of DNA molecules within anionic liposomes and lack of toxicity data. Lacking progress of these systems may be attributed to the poor association between DNA molecules and anionic lipids, which is caused by electrostatic repulsion between these negatively charged species.

7.7.6 PEPTIDE AND OLIGONUCLEOTIDE LIPOSOME VACCINE FORMULATIONS

With the increasing availability of defined antigens such as highly purified proteins or synthetic peptides, more effective and safer vaccines are developed. As many antigens are often poorly immunogenic when administered alone, the development of suitable adjuvants, possessing the ability to potentiate the immunogenicity of a given antigen, preferably with little or no side effects, is required. Based on their principal mechanisms of action, adjuvants can be divided into two groups: (1) vaccine delivery systems and (2) immunostimulatory adjuvants. As described in this chapter, vaccine delivery systems are generally particulate delivery systems of size dimensions comparable with pathogens as bacteria and viruses (e.g., liposomes, microemulsions, immunostimulatory complexes, and other nano- or microparticle systems in the size range of 20–500 nm). Their function is mainly to target antigens to antigen-presenting cells (APCs; dendritic cells, macrophages) and to act as adjuvants. The rationale for the development of an optimal vaccine is to ensure that both antigen and adjuvant are delivered into the same population of APCs, thereby reducing systemic distribution and minimizing the potential to induce adverse reactions. Small unilamellar liposomes have an important potential as delivery systems for the coadministration of antigens and of immunostimulatory adjuvants, including synthetic oligodeoxynucleotides containing immunostimulatory deoxycytidylyl-deoxyguanosine dinucleotides (CpGs) or DNA encoding antigens [79–81]. Additionally, the efficiency of the liposomes can be improved by targeting them more effectively and specifically to the APCs by exploiting various scavengers and other receptors as their targets or by enhancing their cell uptake by modification with cell penetrating peptides as recently shown by us [57].

Using the lymphocytic choriomeningitis virus (LCMV) model system, we successfully prepared efficient peptide vaccines with liposomes as the carrier [82]. Liposome-encapsulated antigenic peptides were highly immunogenic when administered intradermally, and they elicited protective antiviral immunity. An optimized formulation contained immunostimulatory oligonucleotides leading to activation of dendritic cells and antitumor immunity in LCMV peptide transfected EL4 thymomas. In a follow-up study we could confirm the efficacy of such peptide–liposome vaccines in a hepatitis C virus model in HLA-A2.1 transgenic mice [83]. These findings clearly indicate that liposomal antigen delivery *in vivo* is a promising approach to induce efficient antiviral and antitumor immune responses with relevance for human applications.

A cautionary note to the potential dangers of all viral gene products, transgenes, viral proteins and peptides, and CpG DNA sequences in siRNA or plasmids formulated in DDS has to be given. Immune responses induced by these molecules may lead to problems such as transient gene expression, nonefficient readministration of the same vectors and to severe side effects in clinical trials [84]. Due to their particulate nature, the DDS are recognized as foreign in an organism that reacts with an immune response. However, the immunomodulating activities of the DDS depend largely on their composition, size, and homogeneity. Synthetic polymers can exhibit significant immunomodulating activity, whereas liposomes prepared with natural phospholipids and cholesterol are known to be less immunogenic [85].

7.7.7 LIPOSOMES AS CARRIERS OF LIPOPHILIC AND AMPHIPHILIC NUCLEOSIDE ANALOGS

Most applications of liposomes as therapeutic drug carrier systems are based on the encapsulation of water-soluble molecules within the trapped aqueous volume of the liposomes. Long circulating PEG-modified liposomes with cytotoxic antitumor drugs doxorubicine, paclitaxel, vincristine, and methotrexate are examples of clinically applied chemotherapeutic liposome formulations [86–88]. In contrast to the extensive exploitation of the trapped aqueous volume of the liposomes that serves as a nanocontainer for the water-soluble molecules, the phospholipid bilayer has not been given the same attention for its use as the carrier matrix for lipophilic drugs. Hence, the development of liposomal drug formulations with lipophilic drugs is less popular. This difference may have several reasons, the main probably consisting in the chemistry required to transform water-soluble molecules into lipophilic compounds that allow incorporation into the lipid bilayer core. The most favorable chemical modifications to obtain a molecule that intercalates in a stable fashion into the lipophilic moiety of a lipid bilayer consist in the attachment of long-chain fatty acyl or alkyl residues, for example saturated or unsaturated fatty acids, preferably palmitic or stearic acid and alkylamines, preferably hexadecyl- or octadecylamine to a suitable functional group of the hydrophilic part of the molecule. Some recent examples of lipophilic modifications of antitumor drugs and their formulation in liposomes are gemcitabine, 5-iodo-2′-deoxyuridine, methotrexate, paclitaxel, cytosine arabinoside, and a lipophilic topoisomerase inhibitor, DB67 [89–96].

Drugs that are highly lipophilic by their own nature, e.g., taxanes, epothilones, and cyclosporins, can only be used therapeutically by the addition of possibly toxic solubilizing agents (e.g., Cremophor EL) in complex pharmaceutical formulations [97–99]. One of several feasible means of obtaining nontoxic parenterally applicable formulations of such drugs is their incorporation into the bilayer matrix of phospholipid liposomes.

Nucleoside analogs are a major class of chemotherapeutic agents for the treatment of cancer and viral diseases. Natural endogenous nucleosides must be phosphorylated to corresponding 5′-triphosphates to be incorporated into the DNA or RNA synthesized within the cell. The first phosphorylation step, leading to the formation of nucleoside-5′-monophosphate, is commonly performed by a nucleoside kinase encoded by either the host cell or the virus infecting the host cell. Hence, cellular and virally encoded kinases play a vital role in the metabolism and replication of cells and viruses. Nucleoside analogs used for chemotherapy of cancer and viral infections are in essence prodrugs because they must be phosphorylated in the cytoplasm like the natural nucleosides to triphosphates before they can exert their activities. Thus, administration of phosphorylated nucleoside analogs would circumvent the enzymatic phosphorylation step, which transforms inactive nucleosides into active drugs. Phosphate groups possess an anionic charge at nearly all physiological pH values, making them very polar. This high polarity can be responsible for many deficiencies in terms of efficient drug delivery. Nucleotides are too hydrophilic to penetrate the lipid-rich cell membrane. In addition, blood and cell-surface phosphohydrolases rapidly metabolize the nucleotides to the corresponding nucleosides. Due to their polarity, nucleotides often exhibit a low

volume of distribution and are therefore efficiently cleared by renal elimination. In an attempt to overcome these shortcomings, various prodrugs or "pronucleotide" approaches have been devised and investigated for the *in vivo* delivery of pharmacologically active nucleotides. The general aim of these approaches has been to promote passive diffusion through cell membranes and to increase the bioavailability of phosphorylated nucleoside analogs [100, 101]. A simple solution for the delivery of nucleoside monophosphate analogs into cells consists in the chemical neutralization of the ionizable phosphate group via chemical derivatization for example by esterification, resulting in nucleotide phosphodi- and phosphotriester derivatives or by the synthesis of nucleotide phophorodiamidates, cyclic phosphoramidates, and phosphoramidate mono- and diesters. These compounds have a neutral charge and should be capable of entering cells via passive diffusion. To retain the advantage of nucleoside phosphotriesters with regard to their improved cellular uptake, a variety of biolabile moieties have been evaluated as potential protecting groups for nucleoside phosphotriesters.

We chose the approach of the chemical transformation of water-soluble nucleosides of known cytotoxic and antiviral properties into lipophilic drugs or prodrugs. Thus, we reversed the paradigm of transforming lipophilic molecules into hydrophilic derivatives [102]. The first cytotoxic nucleoside that we transformed into lipophilic derivatives was 1-β-D-arabino-furanosyl cytosine (ara-C) because its major clinical disadvantages are a very short plasma half-life and rapid degradation by deamination to the inactive metabolite 1-β-D-arabino-furanosyluracil (ara-U), a shortcoming that also impedes the oral application of ara-C. To reduce these limitations, a large number of 5′- and N^4-substituted ara-C derivatives have been synthesized and characterized in the past (reviewed in Ref. 103). We synthesized a new class of N^4-alkyl-ara-C derivatives with alkyl chain lengths ranging between 6 and 22 C-atoms, demonstrating a typical structure-activity correlation between the length of the alkyl side chains and their antitumor activity profile [104]. The most effective derivative, N^4-octadecyl-ara-C (NOAC), which is highly lipophilic and extremely resistant toward deamination exerted excellent antitumor activity after oral and parenteral therapy in several mouse tumor models and showed to have distinct pharmacological properties compared with ara-C [105].

Consequently, we further modified NOAC by the synthesis of a new generation of lipophilic/amphiphilic heterodinucleoside phosphate derivatives, termed "duplex drugs" that combine the clinically used antitumor drugs ara-C and 5-fluorodeoxyuridine (5-FdU) with NOAC yielding the heterodinucleoside phosphates arabinocytidylyl-N^4-octadecyl-1-β-D-arabino-furanosylcytosine (ara-C-NOAC) and 2′-deoxy-5-fluorouridylyl-N^4-octadecyl-1-β-D-arabinofuranosy-lcytosine (5-FdU-NOAC) (Figure 7.7-6) [106, 107]. Ethynylcytidine (1-(3-C-ethynyl-β-D-ribopentafuranosyl)-cytosine, ETC) is a novel nucleoside that was found to be highly cytotoxic [108–110]. Thus, by combination of ETC with NOAC, we obtained the lipophilic duplex drug ETC-NOAC (3′-C-ethynylcytidylyl-(5′ → 5′)-N^4-octadecyl-1-β-D-arabinofuranosylcytosine).

Due to the combination of the effects of both active molecules that can be released into the cytoplasm as monomers or as the corresponding monophosphates (MPs), the cytotoxic activity of the duplex drugs is expected to be more pronounced as compared with the monomeric drugs. Furthermore, it can be anticipated that the monophosphorylated nucleosides ara-CMP, 5-FdU-MP, and ETC-MP, respec-

tively, are directly released into the cell after enzymatic cleavage of the duplex drugs. Thus, monophosphorylated molecules would not have to pass the first phosphorylation step, which is known to be rate limiting [100, 101].

The lipophilic side chains allow a stable incorporation of these duplex drugs into liposomes, allowing the exploitation of the advantages liposome formulations are offering. Due to their high polarity, the nonderivatized heterodinucleoside phosphodiesters are less suited for liposomal formulations. In comparison with the nonpolar heterodinucleoside phosphotriesters that have good properties to be taken up by cells, but whose capacity to be cleaved enzymatically is limited, the cleavage of the natural phosphodiester bond of the duplex drugs is not constrained. A delayed intracellular release of nucleoside and nucleotide analogs from the duplex molecules provides a depot effect that may be therapeutically of advantage.

A structure-related disadvantage of the duplex drugs is that upon enzymatic cleavage of the phosphodiester bonds, a 1-to-1 ratio of nucleoside to nucleotide is obtained (see Figure 7.7-6). Thus, the desired 5′-phosphorylated nucleotide is only formed at maximally 50%. Additionally, one of the two nucleosides has to be transformed into a lipophilic derivative without loss of antitumor or antiviral activity. On the other hand, it was shown that the lipophilic derivatization of nucleosides can result in enhanced activity and modulation of cell specificity [106].

The disadvantage of obtaining only a 50% yield of 5′-phosphorylated nucleoside analogs, which results from the enzymatic cleavage of the duplex drugs, can be avoided by the synthesis of glycerol–lipid–heteronucleotides, the so-called “multiplex drugs.” Figure 7.7-7 shows an example of such a compound where the two cytotoxic nucleosides ara-C and 5-FdU are linked at their 5′-hydroxyl groups via a phosphodiester to the 1,3-hydroxy groups of glycerol. To introduce amphiphilic/

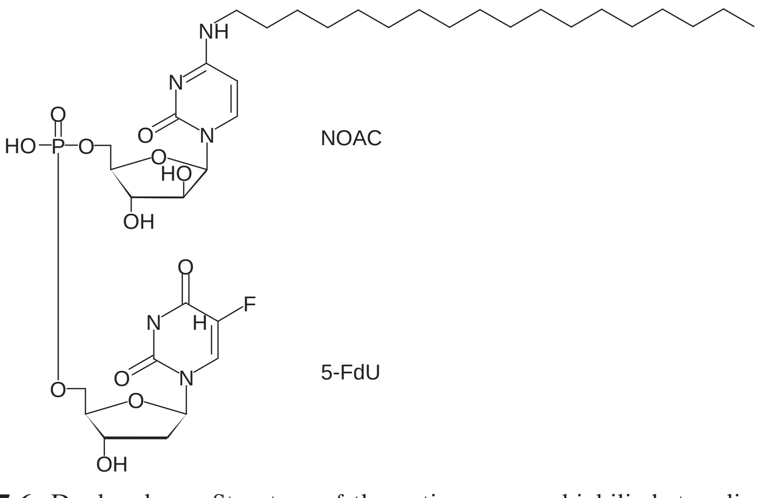

Figure 7.7-6. Duplex drugs. Structure of the anticancer amphiphilic heterodinucleosidyl phosphodiester (Duplex-drug) combining the hydrophilic 5-fluoro-deoxyuridine (5-FdU) with the lipophilic N^4-octadecylarabino-furanosylcytosine (NOAC). Upon enzymatic hydrolysis of the duplex drugs, different anticancer nucleotides and nucleosides are formed with additive or synergistic activities.

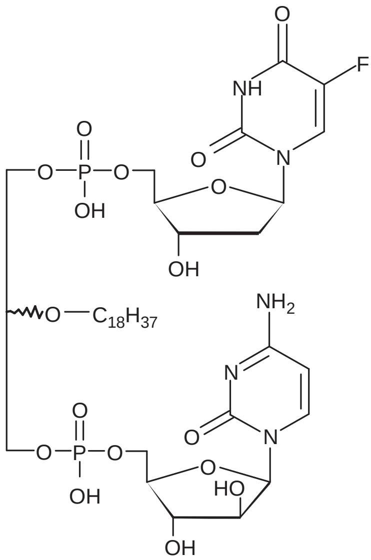

Figure 7.7-7. Multiplex drugs. Example of an amphiphilic glyceryllipid-heterodinucleotide (Multiplex drug). The two hydrophilic nucleoside-5′-monophosphates p5-FdU and paraC are esterified with the terminal hydroxyl residues of the lipophilic 2-octadecylglycerol. By the enzymatic cleavage, several different anticancer metabolites with additive or synergistic activities are obtained.

lipophilic properties, an octadecyl chain is coupled to the 2-hydroxy position of glycerol.

After metabolic degradation by phosphodiesterase, both nucleosides are released as 5′-nucleotides. In case of different hydrolysis kinetics, other active intermediate products may be formed. The structure of the glycerol–lipid–heteronucleotides provides a programmed release of differently active drugs that can penetrate a cell membrane when the cleavage takes place outside of a cell. These compounds may also be formulated in DDS, such as liposomes or micellar systems.

In vitro tests of the glycerol–lipid–heteronucleotides shown in Figure 7.7-7 revealed that these multiplex drugs inhibited colony formation of 5-FU sensitive and resistant human colon tumor cell lines and induced dose-dependent apoptosis in colon tumor cells as well as in mouse leukemia cells. No significant difference in the cytotoxicity could be observed between 5-FU sensitive and resistant cells, indicating that the multiplex drugs might be useful for the treatment of 5-FU resistant tumors [111, 112]. The effectiveness of the postulated mechanisms and advantages of the multiplex drugs will have to be elucidated in *in vivo* experiments.

We conclude that the chemical modification of water-soluble molecules by attachment of long alkyl chains and their stable incorporation into the bilayer membranes of small unilamellar liposomes represent a very promising example of taking advantage of the high loading capacity lipid bilayers offer for lipophilic drugs. The combination of chemical modifications of water-soluble drugs with their pharmaceutical formulation in liposomes is a valuable method for the development of novel pharmaceutical preparations not only for the treatment of tumors or infectious diseases, but also for many other disorders.

7.7.8 OUTLOOK AND FUTURE DIRECTIONS

The development of DDS is a challenging venture that combines research efforts of experts in various areas, including bioengineering, nanotechnology, biomaterials, pharmaceutics, biochemistry, and cell and molecular biology. Specific characteristics of pathological processes and cell or tissue types that are the subject of therapeutic interventions govern the path from target selection to the development of specific DDS formulations. The identification of novel cellular targets, for example, easily accessible vascular endothelial cells, in contrast to tumor cells or other less reachable tissues, will lead to optimized pharmaceutical drug delivery formulations and preparation technologies. Refinement of DDS to overcome unwanted properties such as toxicity, unspecific tissue distribution, and uncontrolled release of entrapped active molecules will be the major challenges in the field. Future DDS will mostly be based on DNA therapeutics such as DNA, ribozymes, DNAzymes, aptamers, (antisense-) oligonucleotides, small interfering RNAs, and their next-generation analogs and derivatives. The use of high-throughput systems for lead identification will yield many new therapeutic targets. Validation and optimization of these disease targets will provide a tremendous stimulus in developing newer potent molecules and their corresponding delivery systems. Further advances in the study of gene function and identification of single-nucleotide polymorphisms will not only help in fine-tuning DNA-based therapeutics but will also fulfill the ultimate goal of providing individualized therapies and medicines.

8.1.1 BACKGROUND

8.1.1.1 Neuropathic and Nociceptive Pain Mechanisms

Role of Growth Factors and Cytokines in These Pain Mechanisms (Peripheral). Pain is generally classified into two main categories: neuropathic and nociceptive (inflammatory) pain. Nociceptive pain is caused by the activation of primary afferent fibers known as nociceptors [1]. Primary nociceptive afferents (Aδ and C fibers) can become sensitized as a result of various factors such as tissue trauma,

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.
Copyright © 2007 John Wiley & Sons, Inc.

inflammation, and ischemia [2]. Peripheral injury (tissue damage) results in the synthesis and release of various inflammatory mediators that induce inflammation and edema as part of the healing process. These mediators include bradykinin, substance P, histamine, serotonin (5-HT), glutamate, acetylcholine (Ach), ATP, ions (H^+, K^+), cholecystokinin, nerve growth factor (NGF) [3], cytokines such as tumor necrosis factor α (TNFα), interleukin-1β (IL-1β) and interleukin-6 (IL-6), and eicosanoids (such as prostaglandin E_2, prostaglandin I_2, and leukotriene B_4), which excite and sensitize nociceptors as well as recruit additional nociceptors to enhance pain perception [1, 4]. Peptide neurotransmitters such as substance P (SP) and calcitonin gene-related peptide (CGRP) can be released from the nerve terminals of nociceptors into damaged tissues, a process that serves to augment the effects of inflammatory agents by causing vasodilation and increased capillary permeability. Bradykinin (released from blood vessels) and other chemical agents such as 5-HT released from platelets, histamine from mast cells, and eicosanoids from various cellular elements further contribute to sensitization of nociceptors, by either opening ion channels or activating second messenger systems [5].

The process of peripheral sensitization is manifested by a decrease in the activation threshold of nociceptors (allodynia) and an increase in the response of nociceptors to noxious stimulation (hyperalgesia) [6, 7]. In addition, peripheral sensitization may be enhanced due to the recruitment of "silent" nociceptors [6, 8], which are normally unresponsive to thermal or mechanical stimuli in healthy tissue. The release of various chemical mediators in the periphery also causes repetitive activity in primary afferent fibers. This barrage of input results in the central release of neurotransmitters and neuropeptides that act on brain cells or neurons in the central nervous system to increase their response to tissue stimulation. This phenomenon is known as central sensitization and results in the amplification and persistence of nociceptive signals that are eventually perceived as pain. It is theorized that central sensitization is the mechanism underlying pain referral and clinical signs of secondary hyperalgesia, which refers to the sensitization of noninflamed tissue surrounding the site of inflammation in the periphery [9–12].

Normally, as the injured tissue heals and inflammation subsides, the phenomena of peripheral and central sensitization dissipate [1]. However, under certain conditions, pain does not resolve with tissue healing and becomes chronic [1, 4]. It is thought that the transition from acute to chronic pain under these conditions may reflect damage or dysfunction of the peripheral and/or central nervous system, which results in abnormal processing of sensory input, and thus, this type of pain is called neuropathic pain [1, 13, 14]. The pathophysiology of neuropathic pain syndromes (such as postherpetic neuralgia, diabetic neuropathy, posttraumatic neuralgia etc.) is not completely understood, but it is considered to be complex and multifactorial [1, 13–15]. Neuropathic pain syndromes and peripheral nerve injury are generally accompanied by a cascade of inflammatory events ("neuroinflammatory cascade") mediated by a group of cytokines and other molecules, as mentioned above [4]. Cytokines such as TNFα and IL-1β, released at the site of inflammation, bind to their receptors on primary afferent fibers and activate and/or sensitize nociceptors, thus inducing and maintaining pain as well as a state of hyperalgesia [4]. Studies have shown that the expression of the receptors of these cytokines increases after peripheral nerve injury [16–18] and likely contributes to increased

neuronal excitability. Also, use of cytokine antagonists has been shown to reduce nociceptive behavior in rodents [19–21], suggesting a role for TNFα and IL-1β in mediating neuropathic-like pain. Similarly, neurotrophic factors such as NGF have also been shown to be involved in nociceptive and neuropathic pain conditions such as diabetic peripheral neuropathies.

This chapter will focus on NGF and TNFα and their role in the mechanisms of neuropathic and nociceptive pain.

8.1.1.2 Introduction to Nerve Growth Factor

Discovery of NGF. Rita Levi-Montalcini, an Italian scientist, discovered NGF in the early 1950s. Levi-Montalcini's research on the central nervous system and its peripheral targets led her to hypothesize that "the failure of neurons to thrive in the absence of peripheral target tissue was because of a degenerative process" [22]. Through her research collaboration with Victor Hamburger, a neuroembryologist, Levi-Montalcini gained further evidence that confirmed her hypothesis. Their work on chick embryos led them to hypothesize that "developing nerve cells depend on feedback signals that are in limited supply, and the neuronal targets provide a specific signal that is required for neuronal survival" [22, 23]. This "specific signal" was later identified to be "a diffusible agent that stimulated the growth and differentiation of nerve cells" and thus named the "nerve growth factor." The biological characterization (isolation and purification) of NGF was achieved through experiments performed by Levi-Montalcini in collaboration with Stanley Cohen, a biochemist who discovered the epidermal growth factor [22]. In 1986, both Rita Levi-Montalcini and Stanley Cohen received a Nobel Prize in medicine for their discovery of NGF [23].

NGF was the first neurotrophic factor to be characterized [24]. The structure of NGF comprises 2α, 2β, and 2γ subunits and one or two zinc ions [25]. The β subunit of the complex is released as a result of autocatalytic cleavage initiated by the loss of zinc ions. The biologically active form of NGF is NGF-β, which is a dimeric molecule (2β subunits) weighing 26.8 kDa, with each monomer consisting of 118 amino acids and three disulfide bridges [25, 26].

Role/Function of NGF. NGF is a neurotrophic protein molecule essential for the growth and survival of sympathetic and small-diameter afferent neurons (nociceptors) [27, 28] and is involved in neuronal function and plasticity [24]. NGF belongs to the neurotrophin family, which also includes the brain-derived neurotrophic factor (BDNF), glial-derived neurotrophic factor (GDNF), neurotrophin-3 (NT-3), and neurotrophin 4/5 (NT-4/5) [29, 30].

Sources of NGF. Neurons as well as non-neuronal cells such as mast cells, fibroblasts, eosinophils, T and B lymphocytes, and epithelial cells synthesize NGF [31, 32]. NGF and other neurotrophins can also be synthesized and secreted by sympathetic and sensory target organs [24]. High levels of NGF are present in the central nervous system (CNS) where it is known to play a crucial role in growth and plasticity [29]. During development, NGF is secreted by target tissues of sensory axons/neurons [24]. Also, during peripheral nerve injury, NGF synthesis is initiated in Schwann cells and fibroblasts within the injured nerve by cytokines

released in response to the injury (for survival and regeneration of the injured nerve) [24].

NGF Receptors. NGF exerts its biological effects by acting on two different receptors found on target cells: tyrosine kinase receptor A (TrkA; tropomyosin related kinase A) and p75 receptor [29]. The TrkA receptor is a tyrosine kinase consisting of intracellular, transmembrane, and extracellular domains, and NGF binding results in phosphorylation of key transduction-related proteins or ion channels causing downstream receptor modulation [29, 32]. The TrkA receptor has a very slow dissociation rate for NGF and is therefore called a high-affinity NGF receptor [33]. In the periphery, TrkA receptors are expressed on small-diameter sensory neurons, inflammatory cells, and sympathetic neurons [30, 34]. The p75 receptor is a member of the superfamily of TNF (tumor necrosis factor) receptor-related molecules that has extracellular and transmembrane domains. The p75 receptor can bind all neurotrophins [29]. The p75 receptor is known as the low-affinity NGF receptor because it has fast association and dissociation rates for NGF binding [33]. The binding of NGF to TrkA and p75 receptors results in the activation of downstream signal transduction pathways that mediate the physiological effects of NGF [35].

Downstream Signaling Pathways of NGF. NGF binding to the TrkA receptors causes receptor activation and dimerization, which results in transautophosphorylation and activation of intracellular signaling cascades like extracellular signal-regulated kinase (ERK), phosphatidylinositol 3-kinase (PI3K), and phospholipase Cγ (PLC-γ) pathways [24, 35]. The Src homologous and collagen-like (Shc) adaptor protein binds to the activated Trk receptor, and its phosphorylation results in an increase in the activities of PI3K and Akt (protein kinase B), which are involved in neuronal survival [35]. The Shc binding to TrkA receptors also increases the activities of Ras and ERK, which can influence transcriptional events such as induction of cyclic AMP-response element binding (CREB) transcription factor that is involved in neurite outgrowth, cell cycle, and synaptic plasticity [35]. It is thought that sustained activation of the ERK pathway requires the internalization of the NGF–TrkA receptor complex into membrane vesicles [24, 36]. The PLC-γ signaling cascade is initiated by direct PLC-γ binding to the activated Trk receptor and results in protein kinase C activation and the release of inositol phosphates and calcium [24, 35]. It has been suggested that activation of these signaling pathways may result in the modulation of ion channels such as the capsaicin receptor channel known as the TRPV1 or VR1 channel [35, 37]. The p75 receptor also activates signaling components such as Jun N-terminal kinase (JNK), nuclear factor-κB (NF-κB), and ceramide to mediate processes such as apoptosis or cell death [35].

NGF Tissue Levels. As compared with neurotransmitters, neurotrophic factors such as NGF exist in very low concentrations; therefore, their detection is very difficult [38]. The maximum peak level of NGF in the interstitial fluid of the brain of patients with severe head injury was found to be 1100 pg/mL [39]. A study using an enzyme-linked immunosorbent assay (ELISA) (measuring unbound β-NGF concentration) has shown that men have significantly higher serum NGF

concentration (40.8 ± 10.8 pg/mL) than women (8.2 ± 1.4 pg/mL in the follicular phase and 14.4 ± 2.9 pg/mL in the luteal phase) [40]. As differences in the NGF concentrations in both the follicular and the luteal phase of the menstrual cycle were reported to be statistically significant, it has been suggested that female sex hormones (and androgens) influence circulating NGF levels [40].

8.1.1.3 Introduction to Tumor Necrosis Factor α

Discovery of TNFα. In 1975, Carswell et al. published a study that showed that endotoxin treated serum of bacillus Calmette-Guerin (BCG)-infected mice induces the release of a substance that is selectively toxic for tumor/malignant cells [41]. They reported that this substance was as effective at causing necrosis of tumors as endotoxin itself and named it "the tumor necrosis factor" (TNF) [41]. TNF is now considered a part of a large and diverse group of polypeptides called cytokines, whose major role is to mediate interactions between the inflammatory and the immune system [42, 43]. There are two forms of TNF: TNFα and TNFβ. TNFα is synthesized as a prohormone, and its soluble form (17 kD, nonglycosylated protein) is released from the 26-kD transmembrane protein via specific proteolytic cleavage [44, 45]. TNFβ or lymphotoxin shares 28% sequence homology with TNFα [46].

Role/Function of TNFα. TNFα belongs to a family of cytokines that also includes interleukins, interferons, and transforming growth factors [42]. TNFα is involved in various processes such as inflammation, cytotoxicity, (apoptotic) cell death, metabolism (insulin resistance), thrombosis, and fibrinolysis [44, 47]. TNFα is also involved in exerting endocrine, paracrine, and autocrine control of inflammatory responses. It can activate macrophages [46], initiate a cascade of other cytokines (IL-1β, IL-6, and IL-8) and growth factors (NGF), and can recruit circulating inflammatory cells to the local site of inflammation to induce edema [47, 48]. TNFα-induced inflammatory response also involves the release of arachidonic acid, which results in the production of pro-inflammatory mediators such as prostaglandins and leukotrienes [49]. TNFα plays a major role in the pathogenesis of septic shock syndrome that results from the body's reaction to a bacterial, viral, or parasitic infection [49]. In the CNS, TNFα has both neurotoxic and neuroprotective effects [50, 51]. Recent research has suggested that TNFα (and other cytokines) link the immune and nervous system and may be involved in the generation of pain and hyperalgesia [52]. It has also been suggested that cytokines like TNFα can induce the production of NGF in both the peripheral and the central nervous system [53].

Sources of TNFα. Various stimuli such as endotoxins, superantigens, osmotic stress, injury, inflammation, and radiation can cause the release of TNFα [48]. TNFα is produced mainly by monocytes and/or macrophages and T cells [45, 48]. However, small amounts of TNFα can be released by various other cell types [44, 52]. For instance, Schwann cells can produce TNFα after injury. Like several other cytokines, TNFα can induce its own production as well [52].

TNFα Receptors. TNFα exerts its effect through two high-affinity, cell-surface receptors: p55 and p75 receptors [42, 52]. Both TNF receptors are expressed in the

CNS [42]. Both receptors are glycoproteins and have a single-membrane spanning hydrophobic segment [49]. At least one of these two TNF receptors is present on virtually all cells, explaining the pleiotropic nature of TNFα [44, 45]. It has been shown that tissues including kidney, liver, adipose, and muscle tissue express the p55 receptor [46]. Most of the effects of TNFα are mediating via its binding and activation of the p55 receptor. Some processes such as cytotoxicity and thymocyte proliferation are also associated with the p75 receptor [49]. The binding of TNFα to its receptors results in the activation of a multitude of complex signaling pathways. TNFβ also binds to the same receptors as TNFα and mediates similar biological actions [49].

Downstream Signaling Pathways of TNFα. The binding of TNFα to its receptors results in the activation of multiple signal transduction pathways, kinases, and transcription factors that activate several cellular genes [45]. These signaling pathways include those that activate transcription factors (such as NF-κB and AP1), protein kinases (such as mitogen activated protein kinase or MAPK, JNK, p38), and proteases [44]. The binding of TNFα to the p55 receptor results in the activation of phospholipase C (PLC) and production of diacylglycerol (DAG), which then activates a calcium-independent protein kinase C (PKC) isotype [49]. Through an unknown pathway, PKC then activates Jun and Fos proteins that are components of AP-1 transcription factor [49, 54] and therefore results in the induction of AP-1 responsive genes [54]. DAG can also activate a C type phospholipase known as SMase, which hydrolyzes sphingomyelin (SM) to ceramide, a second messenger for processes such as apoptosis. In addition, p55 receptor activation can result in the phosphorylation of phospholipase A_2 (PLA_2), which triggers the release of arachidonic acid (AA) and production of eicosanoids involved in the process of inflammation [49]. PLA_2 activation is also thought to be involved in TNFα-induced cytotoxicity. TNFα can also activate transcription factors such as NF-κB and JNK. Several adaptor proteins that initiate these pathways and link TNF receptors to their downstream targets have been identified. One such protein is called the death domain protein, which is involved in the process of apoptosis [44, 51]. Another adaptor protein is part of the TNF receptor associated factors (TRAFs) family, which consists of six distinct proteins, but only TRAF2, TRAF5, and TRAF6 are thought to mediate NF-κB and JNK activation [44]. Another molecule required for TNFα mediated NF-κB activation is known as the receptor interacting protein (RIP) [44]. NF-κB activation results in the synthesis of new proteins, some of which are involved in cell death, whereas others result in cell proliferation. Therefore, depending on the cell cycle, TNFα can either initiate apoptosis (programmed cell death) or be protective [51].

TNFα Tissue Levels. Cytokines are produced on demand, and they only travel over short distances. It is thought that *in vivo* concentrations of cytokines are in the range of a few picograms to nanograms per milliliter [52]. In a study conducted on baboons, infusion of a lethal dose of *Escherichia coli* increased plasma TNFα concentration to a peak level of 20,500 ± 9890 pg/mL within 90 minutes [55]. Similarly, it has been reported that in human volunteers, a bolus injection of endotoxin results in a burst increase in TNFα levels (peak level: 358 ± 166 pg/mL) followed by a rapid decline to undetectable levels [45, 56].

8.1.1.4 Clinical Significance

Currently available surgical techniques and powerful analgesics such as opioids are relatively ineffective for the treatment of painful neuropathies or, in the case of opioid analgesics, have other limitations such as adverse side effects [4]. Therefore, researchers have targeted other cellular and molecular mechanisms and mediators that are thought to be involved in neuropathic and inflammatory pain conditions in an effort to develop new drugs and therapeutic strategies. One such molecule is the nerve growth factor.

NGF. NGF levels change during some neurodegenerative disease states and other pathological conditions [57, 58]. NGF levels have been increased exogenously in experiments investigating diabetic peripheral neuropathies. There is a loss of dorsal root ganglion neurons and degeneration of Schwann cells and small-diameter sensory neuronal fibers during diabetic peripheral neuropathies [59]. Experimentally, it has been shown that induction of diabetes with streptozotocin causes a decrease in NGF levels in the sensory neurons and target tissues of rats [60, 61] and that human diabetic patients have low NGF levels in the skin [62]. Also, studies have shown that NGF uptake and retrograde transport mechanisms are impaired in animal models of diabetes [63, 64]. Therefore, it was thought that NGF replacement therapy might have a beneficial effect on the treatment of this condition due to its involvement in the promotion of neuronal growth and survival as well as its ability to prevent neuronal damage to small-diameter sensory and autonomic neurons [65].

Initial animal studies showed that increasing NGF levels in experimental models of peripheral neuropathy had beneficial effects (prevented the decrease in SP and CGRP levels in dorsal root ganglion neurons and prevented the loss of sensitivity to thermal noxious stimuli, i.e., prevented the onset of symptoms associated with polyneuropathy) [65–67]. This led to phase I (0.03–1-μg/kg human NGF) and II (0.1- or 0.3-μg/kg human NGF three times a week for 6 months) clinical trials that involved subcutaneous administration of human NGF into healthy human volunteers and diabetic patients suffering from polyneuropathy [68, 69]. Although symptoms of polyneuropathy were decreased by NGF treatment, these trials also revealed that human NGF administration results in serious dose-limiting, pain-related systemic side effects such as hyperalgesia at the site of injection, diffuse myalgias or arthralgias, and leg cramps (more frequent and severe with higher doses) [68, 69]. The positive results from phase II clinical trials resulted in a phase III clinical trial (0.1-μg/kg human NGF three times a week for 48 weeks) that also reported pain-related side effects in response to human NGF administration but failed to show the efficacy of human NGF in treating diabetic polyneuropathy [70]. Although initially NGF seemed to be an ideal therapeutic agent for the treatment of diabetic neuropathy, the failure of these subsequent clinical trials has served to highlight the potentially important role altered NGF levels may play in the development of chronic joint and muscle pain.

NGF is also considered to be a novel therapeutic target for the treatment of other types of neuropathic pain. Studies conducted on animal models of neuropathic pain suggest that there might be a relationship between neuropathic pain and NGF [71–74]. Procedures used to induce neuropathic pain such as sciatic nerve

constriction [73] or spinal nerve ligation [75] result in pain behaviors such as allodynia and mechanical and thermal hyperalgesia [71, 73, 74] and lead to increases in the levels of NGF [75, 76]. Administration of NGF antiserum has been shown to inhibit mechanical and thermal hyperalgesia caused by elevated endogenous NGF levels [72, 77], which suggests that NGF is a mediator of mechanical sensitivity. Also, neuropathic patients with chronic hyperalgesia and allodynia have increased levels of NGF in the area of peripheral neuropathy [78]. However, some studies conducted on animal models of nerve constriction injury have reported contradictory results. For example, exogenous NGF administration (chronic infusion of 10 μL of 0.5-mg/mL NGF) has been shown to abolish behavioral hyperalgesia (decrease in mechanical threshold) caused by chronic constriction injury of the rat sciatic nerve [79]. Also, a study has shown that intrathecal rat NGF infusion restores the antiallodynic and antihyperalgesic effects of morphine in a rat model of sciatic nerve constriction injury [80]. Overall, these studies suggest that there might be a correlation between NGF levels in the periphery and pain behaviors such as mechanical allodynia and thermal hyperalgesia that are hallmarks of neuropathic pain.

Tissue inflammation is known to result in an increase in the production and release of NGF [32, 81–83]. Studies have shown that inflammatory mediators such as interleukin-1 (IL-1), IL-4, IL-5, tumor necrosis factor-α, and interferon-γ induce NGF release. In turn, NGF can augment neurogenic inflammation by promoting the release of inflammatory mediators from basophils, mast cells, macrophages, and T and B lymphocytes [32, 34]. Various inflammatory diseases such as rheumatoid arthritis [84], multiple sclerosis [31], and systemic lupus erythematosus [31, 81] lead to upregulation of NGF synthesis. Anti-NGF antibodies have been shown to significantly reduce inflammatory hypersensitivity caused by high levels of NGF [85]. Therefore, NGF is considered to be a key mediator in the production of inflammatory pain. It has been suggested that NGF influences inflammatory responses by affecting immune cell function, altering neuropeptide (SP and CGRP) levels in sensory fibers [1, 31, 32, 86], or sensitizing nerve terminals through receptor phosphorylation [34]. Therefore, elevated endogenous levels of NGF seem to be associated with neuropathic and inflammatory pain. However, the use of anti-NGF antibodies for the treatment of these conditions is still under research, as some studies have produced contradictory results.

TNFα. Another novel therapeutic target that has been identified is TNFα. TNFα (and IL-1) plays a major role in the pathogenesis of inflammatory diseases such as arthritis [47]. It has been shown that there is an increased expression of TNFα producing cells in the synovial tissue samples of osteoarthritis patients [87] and that TNFα levels have also been detected in the synovial fluid and synovium of rheumatoid arthritis patients [47, 88]. It is thought that TNFα (acting synergistically with IL-1) increases the synthesis of matrix degrading proteins like interstitial collagenase and stromelysin [49, 89] and causes tissue (cartilage) destruction observed in rheumatoid arthritis, osteoarthritis, and other joint diseases [46, 51, 88]. Injections of TNFα have been shown to accelerate the onset or increase the severity of collagen-induced arthritis in rats and mice [90, 91]. The use of anti-TNFα antibodies or other TNFα inhibitors has been shown to treat collagen-induced arthritis in mice [92, 93]. Also, a study has shown that anti-TNFα antibodies

can reduce inflammation (foot swelling) and joint destruction even when used after disease onset [94].

The positive results of these animal studies led to clinical trials with monoclonal antibodies of TNFα [95–97]. An open label trial was conducted with chimeric (75% human and 25% murine) monoclonal anti-TNFα antibody cA2 (infliximab) to test its safety and efficacy in the treatment of rheumatoid arthritis [97, 98]. Infliximab was infused two to four times over 2 weeks at a total dose of 20-mg/kg body weight in 20 patients with rheumatoid arthritis unresponsive to disease-modifying anti-rheumatic drugs (DMARD) therapy. It was found that this treatment led to a rapid improvement in patient symptoms; i.e., patients had decreased number of swollen/tender joints, decreased degree of pain, and stiffness in the joints. Also, there was a decrease in the laboratory measurements of inflammatory activity [erythrocyte sedimentation rate and C-reactive proteins (CRP)]. The maximum clinical response (change from baseline) was achieved within the first month of treatment and lasted for 8–22 weeks. The infusions were reported to be safe as they were well tolerated and did not cause any adverse effects. It was reported that TNFα monoclonal antibody treatment might be useful for long-term therapy (for, e.g., for controlling chronic diseases) as seven patients that were retreated (given repeated infusions) after a relapse also showed significant improvement [96].

Another TNFα monoclonal antibody known as etanercept (a fusion protein of human IgG and two p75 TNF receptors) [98] that is a competitive inhibitor of TNF's cell-surface receptor has been developed. Clinical studies have shown that etanercept therapy results in significant clinical benefits and is well tolerated and safe for long-term use [99–101]. Etanercept is given subcutaneously (25 mg) twice weekly for the treatment of rheumatoid arthritis [98]. It is also used in the treatment of psoriatic arthritis, and a recent clinical trial has reported that in addition to decreasing joint pain and fatigue, etanercept also decreases symptoms of depression associated with this chronic disease [102].

Recently, a fully human monoclonal TNFα antibody called adalimumab (a humanized IgG_1) [98] has also been developed for the treatment of rheumatoid arthritis. Double-blind, placebo-controlled clinical trials have shown that the addition of adalimumab to methotrexate therapy resulted in significant, long-term improvement (slowed progression of structural joint damage and a reduction in signs and symptoms) in rheumatoid arthritis patients [103, 104]. Therefore, adalimumab has been approved for treating rheumatoid arthritis as a monotherapy and in combination with methotrexate [98]. Adalimumab is administered subcutaneously every 2 weeks (45 mg) [98]. Currently, all three of these TNFα inhibitors are being used in the treatment of various inflammatory conditions, such as rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and Crohn's disease.

8.1.1.5 NGF and Experimental Muscle Pain

Animal Research. Studies in adult rats [83, 105] have shown that NGF administration leads to hyperalgesia and sensitization of cutaneous nociceptive neurons [6, 82, 106–108]. Local or systemically administered mouse or human NGF resulted in two phases of hyperalgesia in response to thermal and mechanical stimuli in adult male and female rats: an early phase starting 30 minutes after NGF administration and a late, but longer lasting phase starting several hours after NGF

administration and lasting for several days [30, 105–107, 109]. Thermal hyperalgesia occurred during both phases but mechanical hyperalgesia only during the late phase. Local, but not systemic, administration of NGF resulted in hyperalgesia that was limited to the site of injection. Interestingly, injection of human NGF has not been reported to result in any overt pain behavior in these animals [30]. It was subsequently demonstrated that human NGF applied directly to the receptive fields of cutaneous afferent fibers decreased the thermal or heat threshold without changing the mechanical or cold threshold [30, 107]. These results suggest that the first phase of thermal hyperalgesia is due to the peripheral effects of NGF, whereas the second phase of thermal and mechanical hyperalgesia are likely a result of central mechanisms.

Human Research. In healthy men and women, single intravenous or subcutaneous doses of human NGF (0.03 to 1 μg/kg) produced mild-to-moderate muscle pain, especially pain in the masseter muscle that increased with chewing, beginning 1–1.5 hours postinjection [69]. Beginning at 60–90 minutes after human NGF administration, subjects reported muscle pain that increased at 4 to 6 hours and then slowly decreased over 2 to 8 days. Female subjects reported greater muscle pain as compared with male subjects, and the effect was found to be dose-dependent, which suggests that human NGF may have sex-dependent effects [69]. Subcutaneous injection of human NGF resulted in hyperalgesia to touch and heat at the site of the injection (in addition to mild, diffuse myalgias), which lasted for 7 weeks and was found to be dose-dependent [69]. This study demonstrated that human NGF administration results in diffuse muscle pain (including pain in the orofacial region) that peaks hours after injection and increases with muscle use. Another study conducted by Dyck et al. [110] had reported that healthy human subjects injected with intradermal injection of human NGF in the forearm (1 or 3 μg) developed pressure allodynia and heat-pain hyperalgesia within 3 hours on the NGF-injected side. The authors suggested that local tissue mechanisms might be responsible for the rapid onset of these processes [110].

8.1.1.6 TNFα and Experimental Joint Pain

Animal Research. In 1992, Cunha et al. conducted a study in rats to determine the hyperalgesic effects of various cytokines including TNFα [111]. They found that TNFα played a crucial role in the development of inflammatory hyperalgesia and blockade of TNFα activity completely abolished the inflammatory response. They reported that TNFα-induced hyperalgesia occurs through both prostaglandin and sympathetically mediated pathways [111]. Another study conducted on male rats has shown that repeated intraplantar injections of TNFα into the rat paw (2.5 pg daily for 30 days) caused persistent mechanical hypersensitivity in nociceptors that lasted for at least 30 days after the treatment was stopped [112]. The authors reported that hypersensitivity was not induced when indomethacin and atenolol were injected with TNFα, suggesting that TNFα-induced mechanical hypersensitivity was mediated via the release of eicosanoids and sympathomimetic mediators, as suggested by the Cunha et al. study [112]. Various other studies have also shown that intraplantar injections of TNFα can induce mechanical allodynia and hyperalgesic effects in rats [52, 111, 113, 114].

Researchers have also used an *in vitro* rat skin model to determine the effects of TNFα on heat-induced release of CGRP (neuropeptide) from nociceptors [115]. They found that, in contrast to the excitatory effects of TNFα *in vivo*, it did not induce any CGRP release at 32°C; however, TNFα produced a transient (short-term) and dose-dependent heat sensitization. Thus, the authors speculated that, in addition to their role in mediating long-term sensitization in various chronic inflammatory conditions [52, 116], cytokines such as TNFα might also play a role in the acute phase of inflammation, i.e., cause heat sensitization through receptor-associated mechanisms (phosphorylation of ion channels) [115] rather than through signaling pathways. A recent study has also suggested that TNFα-induced rapid thermal and mechanical sensitization processes (after peripheral administration) are probably due to a direct effect on afferent fibers [117].

TNFα is also thought to be one of the mediators involved in formalin-induced orofacial nociception in behavioral rat models [118] and carrageenan (CG)-induced inflammation in mice [119, 120]. A study has shown that intraarticular injections of TNFα could cause an intense incapacitation response in carrageenan-primed rat knee joints that lasts for more than 8 hours [121]. The treatment of knee joints with anti-TNFα antibodies (intraarticular injection) significantly inhibited CG-induced incapacitation response, which suggests that TNFα is a mediator of CG-induced inflammatory incapacitation and is involved in maintaining nociceptive responses over the long term [121]. Another study has shown that induction of arthritis in mice (streptococcal cell wall arthritis model) caused the release of TNFα, which resulted in significant knee joint swelling [122]. The use of anti-TNFα treatment markedly reduced the joint swelling, which suggests a role for TNFα in this arthritis model [122]. The contribution of TNFα to inflammatory pain has been assessed in another experimentally induced model of arthritis (complete Freund's adjuvant or CFA) [123]. It was found that CFA-induced joint inflammation in rats was associated with increased expression of both TNFα receptors in the dorsal root ganglion cells. Also, the number of macrophages was correlated with the development of hyperalgesia, which suggests that TNFα induces inflammatory hyperalgesia through its direct actions on neuronal receptors as well as by increasing the expression of macrophages [123].

The effects of subcutaneously injected TNFα on the mechanical sensitivity and activity of C fibers have also been tested in anesthetized rats [124]. It was found that the 5-ng dose of TNFα decreased the mechanical thresholds of ~67% of the C fibers, and this sensitization began within 30 minutes of the injection and lasted for at least 2 hours. Also, the authors reported that TNFα caused significant plasma protein extravasation that was dose-dependent [124]. Therefore, these studies suggest that TNFα released after tissue injury or disease is involved in the generation of increased pain sensitivity and inflammation, which is observed in patients suffering from inflammatory diseases. Further evidence for TNFα's role in pain conditions comes from studies that have shown strong correlations among tissue levels of TNFα, pain, and hyperalgesia [52, 118, 125–127].

Human Research. Animal research has provided strong evidence for the role of TNFα in mediating inflammatory pain sensitivity and tissue destruction associated with chronic inflammatory conditions, and the successful use of anti-TNFα antibodies in animals has led to their use in human subjects. Various clinical trials

have shown positive results (as discussed) and led to the approval of these agents for use in the treatment of conditions like rheumatoid arthritis.

TNFα has also been thought to be involved in the pathogenesis of other conditions such as migraine headaches, multiple sclerosis, and depression. Recently, a study was conducted to determine the role of TNFα in a migraine. It was found that migraine patients had significantly higher plasma TNFα levels during an attack as compared with headache-free periods, which suggests a potential role for TNFα [178]. Similarly, serum TNFα levels have been reported to be significantly higher in patients suffering from depression and multiple sclerosis than in healthy controls [129]. Also, it has been reported that TNFα may be important in the pathogenesis of temporomandibular disorders (TMDs) and the measurement of TNFα levels in the synovial aspirate may be useful for the diagnosis of temporomandibular joint (TMJ)-related pain conditions [130–133].

8.1.2 CASE STUDIES

8.1.2.1 Case Study I: Effect of Intramuscular Injection of NGF in Humans

To investigate the effects of intramuscular injection of NGF on muscle pain, a study was conducted on 12 male volunteers with a mean age of 24.8 years. A baseline measurement of pressure pain threshold (PPT) and pressure tolerance threshold (PTOL) was conducted with a pressure algometer for both the masseter and the temporalis muscles. PPT is a measure of mechanical allodynia and refers to the lowest pressure that the subjects perceived to be painful. PTOL is considered to be a measure of mechanical hyperalgesia and refers to the maximum pressure that the subjects could tolerate. Each subject received two injections (buffered isotonic saline control and ~0.1-μg/kg recombinant human NGF; injection volume = 0.2 mL), one in each masseter muscle. The side and sequence of injections was randomized and blinded. After the first injection, the subjects were asked to rate the pain experienced on an electronic visual analog scale (VAS) of 1 (no pain) to 10 (worst imaginable pain). The pain scores were used to determine the pain intensity felt by the subjects. Fifteen minutes after the first injection, the second injection was made in the contralateral masseter muscle and the pain score measurement was repeated. Subjects were also asked to fill out a pain questionnaire and rate their pain intensity on a 0–10 numerical rating scale (NRS) during activities involving jaw movements such as chewing, yawning, and talking. Both PPT and PTOL measurements were repeated 1, 7, 14, 21, and 28 days after the injections [134].

The results showed that intramuscular injection of NGF did not evoke any significant pain in the masseter muscle, as the VAS scores after the NGF injection were not significantly different from the low VAS scores reported after the control saline injection. There was no significant difference in the baseline PPT and PTOL values in either temporalis or masseter muscles. The NGF injection caused a decrease in the PPT values (as compared with the baseline) in the masseter muscle, with significantly lower PPTs at 1 and 7 days after injection (Figure 8.1-1). The saline injection also caused a significant decrease in PPTs 1 day after injection; however, the PPT values increased significantly above baseline after 14 and 21 days. At 1 day after injection, the mean PPT value in the NGF-injected muscles was significantly lower than that in the saline-injected muscles (Figure 8.1-1). The PPT

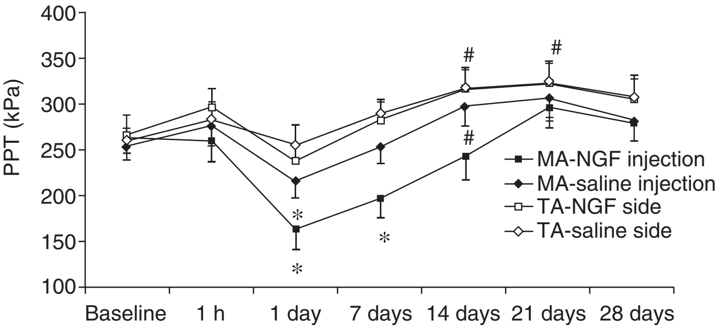

Figure 8.1-1. PPT measured in four test muscles for 28 days. NGF or isotonic saline was injected into the masseter (MA) muscle. Temporalis (TA) muscle PPTs were also assessed bilaterally on the side of NGF and saline injection. Each point indicates mean ± SEM (n = 12). The symbol (*) indicates significantly lower and (#) significantly higher compared with baseline (Dunnett: $p < 0.05$). (Reproduced from Ref. 134, with the permission of the International Association for the Study of Pain.)

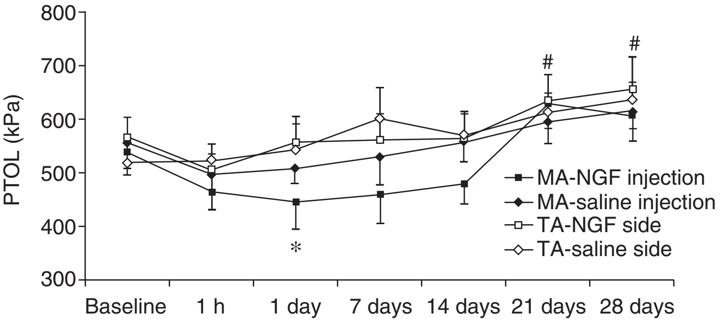

Figure 8.1-2. Pressure pain tolerances (PTOL) measured on four test muscles over 28 days. NGF or isotonic saline was injected into the masseter (MA) muscle. Temporalis (TA) muscle PPTs were also assessed bilaterally on the side of NGF and saline injection. Each point indicates mean ± SEM (n = 12). The symbol (*) indicates significantly lower and (#) significantly higher compared with baseline ($p < 0.05$). (Reproduced from Ref. 134, with the permission of the International Association for the Study of Pain.)

values in both temporalis muscles increased after (control saline or NGF) injections in the masseter muscles. The NGF injection also caused a decrease in the PTOL values, with significantly lower PTOL values at 1 day (compared with baseline) (Figure 8.1-2). However, at 21 days, the mean PTOL value in NGF-injected muscles increased significantly above the baseline value. The control saline injection did not cause any significant change in the PTOL values. The PPT values of the temporalis muscle ipsilateral to saline-injected masseter muscle were significantly higher at 21 and 28 days after injection. However, there was no significant change in the PPTs of the temporalis muscle ipsilateral to the NGF-injected masseter muscle. Subjects reported pain upon chewing and yawning in the NGF-injected masseter muscle, whereas activities such as talking, swallowing, and smiling did not evoke pain in the NGF-injected masseter muscle (Figure 8.1-3) [134].

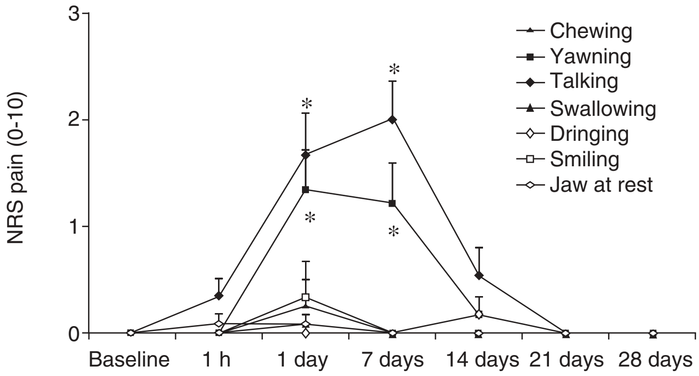

Figure 8.1-3. Perceived pain intensity measured on a 0–10 NRS in response to various jaw functions before and after injection of NGF into the masseter muscle. Each point indicates mean ± SEM ($n = 12$). The symbol (*) indicates significantly higher NRS pain scores compared with baseline (Dunnett: $p < 0.05$). (Reproduced from Ref. 134, with the permission of the International Association for the Study of Pain.)

The results of this study suggested that intramuscular injection of NGF did not evoke any significant pain but caused mechanical sensitization at the site of injection in the masseter muscle that lasted for at least 7 days and resulted in TMD-like symptoms. A significant reduction in the PPT and PTOL values in the NGF-injected muscles indicated that NGF can cause mechanical allodynia and hyperalgesia. Also, a significant number of subjects reported pain during oral functions such as chewing and yawning, which is also a characteristic symptom of TMD. The authors suggested that intramuscular administration of NGF into the masseter muscle could be used to model TMD-like pain and sensitization and to further study the pathophysiology of TMD. In addition, the authors commented that it was not clear whether NGF was causing mechanical sensitization through a peripheral or central mechanism [134]. Therefore, the mechanisms responsible for NGF-induced sensitization need to be further investigated.

8.1.2.2 Case Study II: NGF Effects on Masticatory Muscle Nociceptors

An animal study was undertaken to determine whether NGF significantly alters the masseter muscle afferent fiber mechanical threshold as part of the mechanism whereby it decreases PPTs in human subjects. In this study, *in vivo* single afferent neuron recordings were conducted on anesthetized, adult female Sprague–Dawley rats ($n = 17$). A recording electrode was lowered into the trigeminal ganglion to record orthodromic action potentials of afferent fibers activated by applying mechanical force to the masseter muscle. A blunt mechanical search stimulus was used to find afferent fibers in the rat masseter muscle. An antidromic collision technique [135] was used to confirm the projection of a fiber to the central nervous system (Figure 8.1-4). The mechanical threshold (MT) of each masseter muscle afferent fiber was assessed with an electronic von Frey (VF) hair (Figure 8.1-5). For each fiber, a baseline MT recording was conducted every minute for 10 minutes. Each primary afferent fiber was assigned to one of the following two groups: vehicle

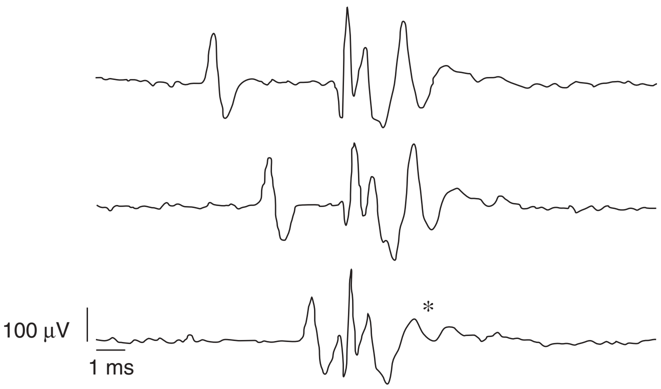

Figure 8.1-4. An example of a collision between an orthodromic (activated by mechanical stimulation of the masseter muscle) and an antidromic (activated by electrical stimulation of the caudal brain stem) is illustrated. *Collision resulted in the disappearance of the antidromic spike. This method was used to confirm the projection of the masseter afferent fiber from the masseter muscle to the caudal brain stem, a region believed to be responsible for the integration of muscle pain input.

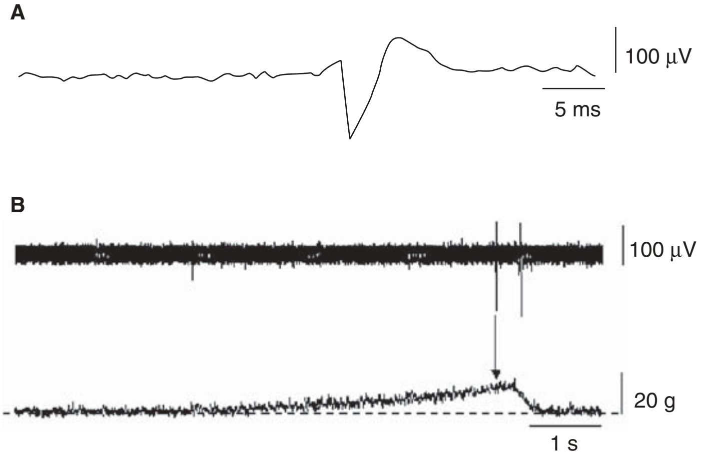

Figure 8.1-5. (**A**) The shape of a single action potential is shown. (**B**) The top trace shows the action potentials recorded from the trigeminal ganglion. The bottom trace shows an increase in the force applied with an electronic von Frey (VF) hair on the masseter muscle until the fiber started firing action potentials. The threshold of the fiber (7.71 g) was determined by subtracting the baseline from the minimum force required to activate the fiber.

control (10 μL of phosphate-buffered isotonic saline and albumin, n = 10) or 25-μg/mL human NGF (1 μg/kg, respectively, 10 μL, n = 7) dissolved in phosphate-buffered isotonic saline and albumin. After the baseline recording, an injection was made into the masseter muscle and the evoked response was recorded for 10 minutes. Sixty minutes after the injection, 10 consecutive MT recordings were conducted at 1-minute intervals. These recordings were repeated every hour for a total of 3 hours. Also, the effect of NGF on plasma protein extravasation in the masseter muscle was determined.

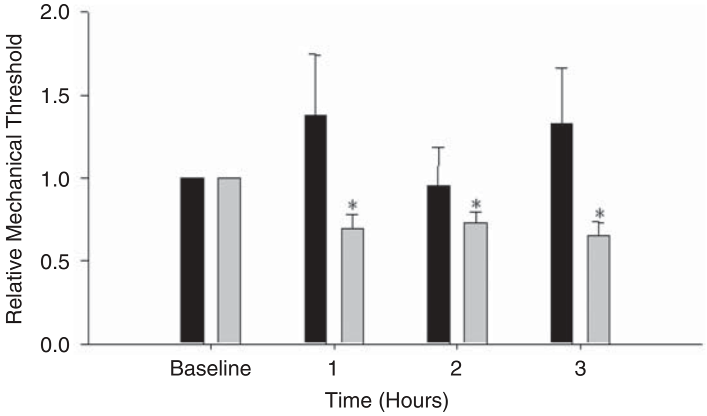

Figure 8.1-6. The vertical bar graph illustrates the mean relative mechanical threshold of afferent fibers at various time points after a 10-µL injection of phosphate-buffered saline control (black bars, $n = 10$) or 25-µg/mL human NGF (gray bars, $n = 7$) into the masseter muscle. The error bars represent the standard error of the mean. *$p < 0.05$: ANOVA and post hoc Holm–Sidak method compared with the baseline relative mechanical threshold.

Intramuscular injection of human NGF into the rat masseter muscle failed to evoke afferent discharge; however, it decreased the MT of masseter afferent fibers compared with the baseline (Figure 8.1-6). There was a significant decrease in the MT 1 hour postinjection (as compared with the baseline), which lasted for 3 hours. The postinjection MT of saline-injected fibers was not significantly different from the baseline. There was no significant difference between the level of plasma protein extravasation between control saline and human NGF groups.

The injection of human NGF caused mechanical sensitization that lasted for at least 3 hours; however, there was no indication that human NGF produced these effects indirectly through local muscle inflammation. The peripheral effects of NGF are likely mediated through a receptor mechanism, for example, TrkA receptor mediated pathways [136]. It is possible that nonspecific mechanisms, such as foreign protein reactions, decreased degradation of human NGF by rat proteases, slowed clearance from the muscle, modulation of intracellular calcium concentration (calcium uptake) [137, 138], actions on bradykinin receptors [139], capsaicin receptors [37, 140], or sodium channels [141, 142] might contribute to the effect of human NGF in rats.

The results of this study suggested that intramuscular injection of human NGF at a concentration equivalent to that which resulted in mechanical sensitization in humans [134] caused a significant decrease in the mechanical threshold of rat masseter muscle afferent fibers. Therefore, the method of injecting human NGF into the rat masseter muscle could be used to study peripheral mechanisms associated with the development of NGF-induced masseter muscle sensitization in humans.

8.2.1 TYPES OF GROWTH FACTORS, CYTOKINES, AND CHEMOKINES

Growth factors refer to a large class of proteins capable of stimulating cellular proliferation and differentiation. Examples of growth factors include cytokines and hormones that bind to specific receptors on the surface of their target cells.

Cytokines are a subclass of growth factors. Cytokines are primarily secreted from leukocytes. Cytokines that are secreted from lymphocytes are called lymphokines and those secreted by monocytes or macrophages are called monokines. Growth factors are often used interchangeably with cytokines. Traditionally,

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.
Copyright © 2007 John Wiley & Sons, Inc.

cytokines are associated with hematopoietic cells and the immune system, including lymphocytes, spleen, thymus, and lymph nodes. However, some of the same signaling proteins are also being used by other cells and tissues. Growth factors imply positive effects on cell division, but cytokines are neutral in terms of their functions. Some cytokines promote cell growth or proliferation, such as granulocyte colony stimulating factor (GCSF) and granulocyte macrophage colony stimulating factor (GM-CSF). Other cytokines exhibit inhibitory effects on these processes, such as Fas ligand as "death" signal causing target cells to undergo programmed cell death or apoptosis.

Chemokines are a family of pro-inflammatory activation-inducible cytokines or small protein signals secreted by cells. Chemokines induce directed chemotaxis in nearby responsive cells and therefore the name *chemo*tactic cyto*kines*. Four types of chemokines exist: (1) C chemokine: the first and the third conserved cysteine residues in the mature protein are missing; (2) CC chemokine: the first two conserved cysteine residues are adjacent in the mature protein; (3) CXC chemokine: one amino acid residue separates the first two conserved cysteine residues in the mature protein; and (4) CX3C chemokine: three amino acid residues separate the first two conserved cysteine residues in the mature protein.

Table 8.2-1 lists examples of the major types of growth factors, cytokines, and chemokines. This list is not intended to be complete. New members of growth factors, cytokines, and chemokines are discovered continuously.

8.2.2 FUNCTIONS OF GROWTH FACTORS, CYTOKINES, AND CHEMOKINES

Growth factors bind to receptors on the cell surface and subsequently activate cellular proliferation or differentiation. Many growth factors stimulate cellular division in numerous cell type, whereas others are specific to particular cell types. They often promote cell differentiation and maturation, whereas varies between growth factors. For example, bone morphogenic proteins stimulate bone cell differentiation, whereas vascular endothelial growth factors stimulate blood vessel differentiation.

Cytokines stimulate the humoral and cellular immune responses and activate phagocytic cells. Each cytokine binds to a specific cell-surface receptor, initiates intracellular signaling cascades, and alters cellular functions. The functional consequences may include upregulation or downregulation of gene expression, resulting in the production of other cytokines; increases in the number of surface receptors for other molecules; or the suppression of their own effects by feedback inhibition. The major functions of cytokines could be classified into three categories: (1) autocrine: cytokine acts on the cells that secrete it; (2) paracrine: cytokine action is restricted to the immediate vicinities of cytokine's secretion; and (3) endocrine: cytokine diffuses to distant regions of the body to affect different tissues. However, cytokines exhibit considerable "redundancy" because many cytokines share similar functions. Cytokines are also pleiotropic factors because they act on many different cell types. The reasons for these effects of cytokines are that a certain type of cell may express receptors for more than one cytokine and different cells may express receptors for the same cytokine.

TABLE 8.2-1. Types of Growth Factors, Cytokines, and Chemokines

Type	Representative growth factors, cytokines, and chemokines
Adipose-derived cytokine	Leptin
Angiogenic cytokine	VEGFa, VEGFb
C chemokine	XCL1 (Lymphotactin), XCL2 (SCM-1β)
CC chemokine	CCL1 (I-309), CCL2 (MCP-1), CCL3 (MIP-1α), CCL4 (MIP-1β), CCL5 (RANTES), CCL6 (C10), CCL7 (MIP-3), CCL8 (MCP-2), CCL9 (MIP-1γ), CCL10 (MRP-2), CCL11 (Eotaxin), CCL12 (MCP-5), CCL13 (MCP-4), CCL14 (HCC-1), CCL15 (MIP-5), CCL16 (HCC-4), CCL17 (TARC), CCL18 (MIP-4), CCL19 (MIP-3β), CCL20 (MIP-3α), CCL21 (Exodus-2), CCL22 (MDC), CCL23 (MIP-3), CCL24 (Eotaxin-2), CCL25 (TECK), CCL26 (Eotaxin-3), CCL27 (CTACK), CCL28 (MEC)
CXC chemokine	CXCL1 (GRO-α), CXCL2 (GRO-β/MIP-2), CXCL3 (GRO-γ), CXCL4 (PF-4), CXCL5 (ENA-78/LIX), CXCL6 (GCP-2), CXCL7 (NAP-2), CXCL8 (IL-8), CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC), CXCL12 (SDF-1α/1β), CXCL13 (BCA-1), CXCL14 (BRAK), CXCL15 (Lungkine), CXCL16 (small inducible cytokine B6)
CX3C chemokine	CX3CL1 (Fractalkine)
Hematopoietic growth factor	IL-20, M-CSF, SCF, SCGF-α, SCGF-β
Immunoregulatory lymphokine	IL-2, IL-9, IL-10, IL-13, IL-15
Interferon	INF-α, INF-β, INF-γ, INF-λ
Lectin	GALECTIN-1, GLECTIN-3
Neurotrophic factor	ART, BDNF, CNTF, GDNF, MK, NTN/NRTN, β-NGF, NNT-1, NT-3, NT-4, PSP, PTN
Osteoinductive cytokine	BMP-2
Other growth factor	EGF, EG-VEGF, Flt3 ligand, G-CSF, GM-CSF, HGF, IGF-1, IGF-II, IL-3, IL-5, IL-7, IL-25 (SF20), KGF/FGF-7, OSM, PDGF, TGFA, TPO
Pleiotropic cytokine	CT-1, IL-4, IL-6
Pro-inflammatory cytokine	IL-1α, IL-1β, IL-8, IL-17, IL-19, TNF-α, TNF-β, MIP-1α, MIP-1β, MIP-1γ, MIP-2, MIP-3, MIP-3α, MIP-3β, MIP-4, MIP-5
TGF superfamily	TGF-α, TGF-β1 to TGF-β4, GDF-1 to GDF-15, BMP-1 to BMP-15
TNF superfamily	TNFSF1 (TNF-β), TNFSF2 (TNF-α), TNFSF3 (TNFC/p33), TNFSF4 (TXGP1/gp34), TNFSF5 (CD40L/gp39), TNFSF6 (FasL), TNFSF7 (CD70), TNFSF8 (CD30L), TNFSF9 (CD137L), TNFSF10 (TRAIL/Apo2L), TNFSF11 (RANKL), TNFSF12 (TWEAK/Apo3L), TNFSF13 (APRIL/TALL2), TNFSF13B (THANK/TNFSF20), TNFSF14 (LIGHT), TNFSF15 (TL1/VEG1), TNFSF18 (AITRL/TL6)

Chemokines induce directed chemotaxis in nearby responsive cells. They are released from various cells in response to bacteria and viruses infection and in response to agents that cause physical damage such as silica or urate crystals. The main functions of chemokines are chemoattractants for leukocytes. They help to recruit monocytes, neutrophils, and other effector cells from the blood to the sites of infection or damage. They serve to guide cells involved in innate immunity and in the adaptive immune system. Some chemokines have other roles in the development of lymphocytes, migration, and the growth of new blood vessels.

Table 8.2-2 lists examples of the major functions of growth factors, cytokines, and chemokines. This list is not intended to be complete. New functions of growth factors, cytokines, and chemokines are discovered rapidly.

TABLE 8.2-2. Major Functions of Growth Factors, Cytokines, and Chemokines

No.	Abbreviation	Full Name	Major Function
1	AITRL	Activation-inducible TNF receptor ligand	Regulates T-cell proliferation and survival; promotes the interaction between T lymphocytes and endothelial cells
2	Apo-SAA	Apo-serum amyloid A protein	Circulates with high-density lipoproteins; increased by inflammatory stimulus
3	APRIL	A proliferating-inducing ligand	Stimulates proliferation of various tumor cell lines and B and T cells
4	ART	Artemin	Supports the survival of peripheral ganglia
5	4-1BBL		Provides a co-stimulatory signal for T cell activation and expansion
6	BAFF	B cell activating factor	Stimulates B and T cell function
7	BCA-1	B cell attracting chemokine	Behaves as a potent chemoattractant for B lymphocytes; induces a weak chemotactic response in T cells and macrophages
8	BD-1, -2, -3	β-Defensins	Provides antimicrobial activity; behaves as chemoattractant for immature dendritic cells and memory cells
9	BDNF	Brain-derived neurotrophic factor	Supports neuron proliferation and survival
10	BMP	Bone morphogenetic protein	Modulates cell proliferation, differentiation, matrix synthesis, apoptosis; initiates, promotes, and regulates the development, growth, and remodeling of bone and cartilage
11	BMP-2	Bone morphogenetic protein-2	Induces bone and cartilage formation; plays an important role in cardiac morphogenesis

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
12	BMP-13	Bone morphogenetic protein-13	Regulates articular cartilage; repairs oteochondral defects
13	BMP-14	Bone morphogenetic protein- 14	Plays a role in long bones during embryonic development and postnatally in articular cartilage
14	BRAK	Breast and kidney-expressed chemokine	Behaves as a highly selective monocyte chemoattractant
15	C10	CCL6	Behaves as a chemoattractant B cells, CD4+ T cells, monocytes, and NK cells; exhibits suppressive activity on colony formation
16	CT-1	Cardiotrophin-1	Induces myocyte hypertrophy; enhances the survival of cardiomyocyte and different neuronal populations
17	CD40L	CD40-Ligand	Plays an important role in B cell proliferation and differentiation, and immunoglobulin class switching
18	CNTF	Ciliary neurotrophic factor	Provides a vital role in the survival of neural cells
19	CTACK	Cutaneous T cell-attracting chemokine	Attracts CLA+ T cells and directs them into the skin
20	CXCL16		Attracts lymphocyte subsets during inflammation; facilitates certain immune response
21	EGF	Epidermal growth factor	Stimulates proliferation of epidermal and epithelial cells; inhibits gastric secretion; involves in wound healing
22	EG-VEGF	Endocrine-gland-derived vascular endothelial growth factor	Induces proliferation and migration fenestration in capillary endothelial cells
23	EMAP-II	Endothelial-monocyte activating polypeptide II	Inhibits endothelial cell proliferation, vasculogenesis, neovessel formation; inhibits angiogenesis of vascular beds; suppresses tumor growth; induces apoptosis and myeloperoxidase activity from neutrophils
24	ENA-78	Epithelial neutrophil activating peptide 78	Binds to CXCR2 receptor
25	Eotaxin	CCL11	Binds to CCR3 receptor; chemoattracts eosinophils; plays a key role in the regulation of eosinophil recruitment in asthmatic lung and allergic reactions
26	Eotaxin-2	CCL24	Binds to CCR3 receptor; chemoattracts cells expressing CCR3 including eosinophils,

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
			basophils, Th2 T cells, mast cells; inhibits the proliferation of multipotential hematopoietic progenitor cells
27	Eotaxin-3	CCL26	Similar to Eotaxin and Eotaxin-2
28	Exodus-2	CCL21	Binds to CCR7 receptor; chemoattracts T and B lymphocytes; inhibits hematopoiesis
29	FasL	Fas ligand	Binds to Fas receptor; induces apoptosis of Fas-containing cells; kills T cells; activates B cells leading to downregulation of immune response
30	FGF family	Fibroblast growth factor family	Promotes cell proliferation and differentiation
31	Flt3L	Flt3-ligand	Binds to cells expressing tyrosine kinase receptor Flt3; regulates proliferation of early hematopoietic cells
32	FS	Follistatin	Binds to TGF-β ligands; inhibits their access to their signaling receptors
33	Fractalkine	CX3CL1	chemoattracts monocytes, microglia cells, and NK cells
34	Galectin-1	S-LAC lectin-1	Binds to β-galactoside moieties; interacts with CD3, CD4, and CD45; induces apoptosis of activated T cells and T leukemia cells; inhibits the protein phosphatase activity of CD45
35	Galectin-3	Galactose-specific lectin-3	Binds to β-galactoside moieties; regulates embryogenesis, inflammatory responses, cell progression, and metastasis
36	gAcrp30	Globular domain of adipocyte complement-related protein of 30 kDa	Binds to AdipoR1 and AdipoR2 receptors; decreases hyperglycemia and reverses insulin resistance; promotes fat loss
37	GCP-2	Granulocyte chemotactic protein-2	Attracts neutrophils; exhibits anti-angiogenic activity
38	G-CSF	Granulocyte colony-stimulating factor	Stimulates the development of committed progenitor cells to neutrophils; enhances the functional activities of the mature end-cell; facilitates hematopoietic recovery after bone marrow transplantation or chemotherapy
39	GDF-11	Growth/differentiation factor-11	Suppresses neurogenesis through a myostatin-like pathway

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
40	GDNF	Glial cell line-derived neurotrophic factor	Promotes dopamine uptake, survival and differentiation of midbrain neurons; improves bradykinesia, rigidity, and postural instability
41	GM-CSF	Granulocyte/macrophage colony-stimulating factor	Stimulates the development of neutrophils and macrophages; promotes proliferation and development of early erythroid megakaryocytic and eosinophilic progenitor cells; inhibits neutrophil migration; enhances the functional activities of the mature end-cells; increases the recovery rate of hematopoietic cells after bone marrow transplantation
42	GRO	Growth regulated protein/ melanoma growth stimulatory activity family (MGSA)	Chemoattracts and activates neutrophils and basophils
43	HCC-1	Hemafiltrate CC chemokine-1	Chemoattracts blood monocytes
44	HGF	Hepatocyte growth factor	Induces cell proliferation, motility, morphogenesis; inhibits cell growth; enhances neuron survival; helps liver regeneration
45	I-309	CCL1	Chemoattracts monocytes and Th2-differentiated T cells
46	IFN-α	Interferon alpha	Induces nonspecific resistance against viral infections; regulates expression of MHC class I antigens; affects cell proliferation; modulates immune responses; treats viral infection and neoplasia
47	IFN-γ	Interferon gamma	Increases the surface expression of class I MHC antigens to T-helper (CD4+) cells; regulates the antigen-specific phases of the immune responses; stimulates lymphoid cell functions
48	IFN-λs	Interferon-lambdas	Induces antiviral defense
49	IGF-I/II	Insulin-like growth factor I and II	Stimulates the proliferation and survival of various cell types similar to insulin but with higher growth-promoting activity
50	IL-1α	Interleukin-1 alpha	Stimulates thymocyte proliferation by inducing IL-2 release; promotes B cell maturation and proliferation; exhibits mitogenic FGF-like activity; stimulates the release of prostaglandin and collagenase from synovial calls

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
51	IL-1β	Interleukin-1 beta	Similar to IL-1α. IL-α is a mainly cell-associated cytokine, but IL-β is a secreted cytokine
52	IL-2	Interleukin-2	Stimulates growth and differentiation of B cells, NK cells, lymphokine-activated killer cells, monocytes, macrophages, and oligodendrocytes; enhances the immune system of patients for the treatment of cancer and infectious diseases
53	IL-3	Interleukin-3	Promotes the survival, differentiation, and proliferation of committed progenitor cells of the megakaryocyte, granulocyte-macrophage, erythroid, eosinophil, basophil, and mast cell lineages; enhances thrombopoiesis, phagocytes, and antibody-mediated cellular cytotoxicity; activates monocytes
54	IL-4	Interleukin-4	Regulates diverse T and B cell responses, including cell proliferation, survival, and gene expression; regulates the differentiation of native CD4+ T cells into helper Th2 cells; regulates immunoglobulin class switching to the IgG1 and IgE isotypes
55	IL-5	Interleukin-5	Stimulates the proliferation and activation of eosinophils; induces cell-mediated immunity against parasitic infections and some tumors
56	IL-6	Interleukin-6	Regulates immunes and inflammatory responses; stimulates B cell differentiation and antibody production; induces expression of hepatic acute-phase proteins; regulates bone metabolism
57	IL-7	Interleukin-7	Affects early B and T cells mainly; costimulates mature T cells with other factors
58	IL-8	Interleukin-8	Chemoattracts and activates neutrophils
59	IL-9	Interleukin-9	Enhances the proliferation of T lymphocytes, mass cells, erythroid precursor cells, and megakaryoblastic leukemia cells

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
60	IL-10	Interleukin-10	Inhibits the expression of pro-inflammatory cytokines such as IL-1 and TNF-α; enhances humoral immune responses and attenuates cell-mediated immune responses
61	IL-11	Interleukin-11	Regulates hematopoiesis by stimulating growth of myeloid, erythroid, and megakaryocyte progenitor cells; regulates bone metabolism; inhibits production of pro-inflammatory cytokines; protects against gastromucosal injury
62	IL-12	Interleukin-12	Induces IFN-γ expression by NK and T cells; promotes the growth and activity of activated NK, CD4+, and CD8+ cells; induces the development of INF-γ-producing Th1 cells
63	IL-13	Interleukin-13	Plays a role in the expulsion of gastrointestinal parasites; exhibits anti-inflammatory effects on monocytes and macrophages; inhibits pro-inflammatory cytokine expression; enhances B cell proliferation; increases IgE production by inducing isotype switching
64	IL-15	Interleukin-15	Stimulates the proliferation of T lymphocytes; relates to rheumatoid arthritis, inflammatory bowel diseases
65	IL-16	Interleukin-16	Induces chemotaxis of CD4+ T cells and monocytes and eosinophils; induces expression of IL-2R and MHC class II proteins on CD4+ T cells
66	IL-17A	Interleukin-17A	Induces production of pro-inflammatory and hematopoietic molecules
67	IL-17B	Interleukin-17B	Stimulates the release of TNF-α and IL-1β from cells of monocyte lineage
68	IL-17D	Interleukin-17D	Stimulates the production of IL-6, IL-8, and GM-CSF; inhibits hemopoiesis of myeloid progenitor cells
69	IL-17E	Interleukin-17E	Stimulates the secretion of IL-8; induces activation of NFκB in cells expressing IL-17BR receptor

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
70	IL-17F	Interleukin-17F	Stimulates proliferation and activation of T cells and PBMCs; regulates cartilage matrix turnover; inhibits angiogenesis
71	IL-19	Interleukin-19	Upregulates IL-6 and TNF-α; induces apoptosis through TNF-α
72	IL-20	Interleukin-20	Stimulates colony formation by CD34+ multipotential progenitors; induces inflammatory skin diseases
73	IL-22	Interleukin-22	Inhibits IL-4 production by Th2 cells; induces acute-phase reactants in the liver and pancreas
74	IP-10	γ-interferon inducible protein 10	Chemoattracts Th1 lymphocytes and monocytes; inhibits cytokine-stimulated hematopoietic progenitor cell proliferation; behaves angiostatic and mitogenic for vascular smooth muscle cells
75	I-TAC	Interferon inducible T-cell alpha chemokine	Chemoattracts IL-2-activated T cells
76	JF	CCL2/MCP-1	Chemoattracts and activates monocytes, activated T cells, basophils, NK cells, and immune dendritic cells
77	KC	CXCL1/GROα	Chemoattracts and activates neutrophils and basophils
78	KGF	Keratinocyte growth factor	Regulates keratinocyte growth
79	LAG-1	Lymphocyte activation gene-1 protein	Chemoattracts monocytes; exhibits activity in HIV suppressive factor
80	LD78β	CCL3L1	Exhibits activity in HIV suppression assays
81	LEC	Liver-expressed chemokine (CCL16)	Chemoattracts monocytes and lymphocytes
82	Leptin	Obesity protein	Suppresses appetite; increases thermogenesis; reduces body weight, food consumption, and plasma glucose levels
83	LIGHT	TNFSF14	Activates MFlB; costimulates the activation of lymphocytes; induces apoptosis in some tumors
84	Lymphotactin	XCL-1	Chemoattracts lymphocytes
85	M-CSF	Macrophage colony-stimulating factor	Regulates cell proliferation, differentiation, and survival of blood monocytes, tissue macrophages, and their

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
			progenitor cells; modulates dermal thickness and male and female fertility; treats infection, malignancies, and atherosclerosis; facilitates hematopoietic recovery after bone marrow transplantation
86	MCPs	Monocyte chemoattractant proteins	Chemoattracts and activates monocytes, activated T cells, basophils, NK cells, and immune dendritic cells
87	MDC	Macrophage-derived chemokine (CCL22)	Chemoattracts monocytes, NK cells, and dendritic cells; exhibits HIV suppressive activity
88	MEC	Mucosae-associated epithelial chemokine (CCL28)	Chemoattracts resting CD4 and CD8 T cells and eosinophils
89	MK	Midkine	Chemoattracts embryonic neurons, neutrophils, and macrophages; exhibits angiogenic, growth, and survival activities during tumorgenesis
90	MIG	Monokine-induced by interferon-γ (CXCL9)	Chemoattracts Th1 lymphocytes; inhibits tumor growth, angiogenesis, and colony formation of hematopoietic progenitors
91	MIP-1α/1β	Macrophage inflammatory protein-1 alpha/-1 beta	Regulates the trafficking and activation state of inflammatory cells such as macrophages, lymphocytes, and NK cells; chemoattracts B cells, eosinophils, and dendritic cells
92	MIP-1γ	Macrophage inflammatory protein-1 gamma	Chemoattracts neutrophils; inhibits colony formation of bone marrow myeloid immature progenitors
93	MIP-2	Macrophage inflammatory protein-2 (CXCL2/GROβ)	Chemoattracts and activates neutrophils and basophils
94	vMIP-2	Viral macrophage inflammatory protein-2	Chemokine analog of human herpes virus; exhibits antagonistic activity toward several chemokine receptors
95	MIP-3	Macrophage inflammatory protein-3 (CCL23)	Chemoattracts monocytes and resting T lymphocytes; inhibits colony formation of bone marrow myeloid immature progenitors

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
96	MIP-3α	Macrophage inflammatory protein-3 alpha (CCL20)	Chemoattracts lymphocytes and dendritic cells; promotes the adhesion of memory CCD4+ T cells; inhibits colony formation of bone marrow myeloid immature progenitors
97	MIP-3β	Macrophage inflammatory protein-3 beta (CCL19)	Chemoattracts T and B lymphocytes and myeloid progenitor cells
98	MIP-4	Macrophage inflammatory protein-4 (CCL18)	Chemoattracts lymphocytes; exhibits activity on CD4+ and CD8+ T cells
99	MIP-5	Macrophage inflammatory protein-5 (CCL15)	Chemoattracts T cells and monocytes
100	Myostatin	GDF-8	Inhibits skeletal muscle growth; interacts with Activin type I and II receptors; suppresses myoblast proliferation by arresting cell cycle in G1 phase
101	Myostatin propeptide		Binds to and inhibits myostatin; increases skeletal muscle growth
102	NAP-2	Neutrophil activating protein-2 (CXCL7)	Chemoattracts and activates neutrophils
103	NTN	Neurturin	Promotes neuron development and survival
104	β-NGF	Beta-nerve growth factor	Promotes neuron development and preservation
105	NNT-1	Novel neurotrophin-1/ B-cell stimulating factor-3 (BSF-3)	Binds to and activates glycoprotein 130 and leukemia inhibitory factor receptor member β; induces tyrosine phosphorylation of these receptors
106	Noggin		Binds to ligands of TGF-β family and regulates their activity by interfering their access to signaling receptors
107	NP-1	Neutrophil peptide-1	Exhibits antimicrobial activity and chemotactic activity on dendritic cells
108	NT-3	Neurotrophin-3	Promotes the growth and survival of nerve and glial cells
109	NT-4	Neurotrophin-4	Promotes the survival of peripheral sensory sympathetic neurons
110	OSM	Oncostatin M	Regulates neurogenesis, osteogenesis, and hematopoiesis; stimulates the proliferation of fibroblast, smooth muscle cells, and Kaposi's sarcoma cells; inhibits some tumor cells; promotes cytokine release from

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
			endothelial cells; enhances the expression of low-density lipoprotein receptor in hematoma cells
111	OPG	Osteoprotegerin	Binds to sRANKL; inhibits osteoclastogenesis by interrupting the signaling between stromal cells and osteoclastic progenitor cells and leads to excess accumulation of bone and cartilage
112	PDGF	Platelet-derived growth factor (AA, BB, AB forms)	Acts as mitogens for cells like smooth muscle cells, connective tissue cells, bone and cartilage cells, and blood cells; relates to hyperplasia, chemotaxis, embryonic neuron development, and respiratory tubule epithelial cell development
113	PSP	Persephin	Promotes the survival of ventral mid-brain dopaminergic neurons and motor neurons after sciatic nerve oxotomy; promotes ureteric bud branching
114	PF-4	Platelet factor 4 (CXCL4)	Chemoattracts neutrophils and monocytes; inhibits angiogenesis
115	PTN	Pleiotrophin	Functions in neurogenesis, cell migration, secondary organogenetic induction, and mesoderm-epithelial interaction
116	PTHrP	Parathyroid hormone-related protein	Regulates extracellular concentrations of calcium and phosphorous
117	RANKL	Receptor activator of NFκB ligand	Regulates specific immunity and bone turnover; binds to RANK receptor; stimulates naïve T cell proliferation; promotes survival of RANK +T cells; regulates T cell-dependent immune response; binds to OPG; inhibits osteoclastogenesis and leads to excess accumulation of bone and cartilage
118	RANK	Receptor-activator of NF- kappa B	Binds to RANKL
119	RANTES	Regulated upon activation normal T cell express sequence	Chemoattracts monocytes, memory T cells (CD4+/CD45R+), basophils, and eosinophils; inhibits some strains of HIV-1, HIV-2, and simian immunodeficiency virus (SIV)

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
120	RELMα	Resistin-like molecule alpha	Tissue-specific cytokine; physiological roles unknown
121	RELMβ	Resistin-like molecule beta	Tissue-specific cytokine; physiological roles unknown
122	Resistin	Adipose tissue-specific secretory factor	Tissue-specific cytokine; physiological roles unknown
123	SCF	Stem cell factor	Essential for the survival, proliferation, and differentiation of hematopoietic cells committed to the melanocyte and germ cell lineages
124	SCGFα/β	Stem cell growth factor alpha/beta	Supports the growth of primitive hematopoietic cells; promotes proliferation of erythroid or myeloid progenitor cells
125	SDF-1α/β	Stromal cell derived factor-1 alpha/beta (CXCL12)	Chemoattracts T and B cells; induces migration of CD34+ stem cells; exhibits HIV suppressive activity in cells expressing CXCR4 receptor
126	SF20	IL-25	Binds to the surface of cells expressing TSA-1 (Thymic shared Ag-1) receptor; stimulates the proliferation of FDCP2 cells and lymphoid cells
127	Shh	Sonic Hedgehog	Regulates developmental processes
128	TACI	Transmembrane activator and CAML interactor (TNFRSF13B)	Binds to APRIL and BAFF; stimulates the activation of NFκB and AP-1; mediates calcineurin-dependent activation of NF-AT; stimulates B and T cell function
129	TARC	Thymus and activation regulated chemokine (CCL17)	Chemoattracts T cells
130	TECK	Thymus expressed-chemokine (CCL25)	Chemoattracts activated macrophages, thymocytes, and dendritic cells
131	TGF-α	Transforming growth factor-alpha	Stimulates the proliferation of epidermal and endothelial cells; induces transformation and anchorage independence in cultured cells
132	TGF-β1	Differentiation inhibiting factor and cartilage-inducing factor	Regulates cell proliferation, growth, differentiation, motility, synthesis and deposition of extracellular matrix, embryogenesis, tissue remodeling, and wound healing
133	TGF-β2	Glioblastoma-derived T cell suppressor factor	Regulates cell proliferation, growth, differentiation, motility, synthesis and deposition of extracellular matrix, embryogenesis, tissue remodeling, and wound healing

TABLE 8.2-2. *Continued*

No.	Abbreviation	Full Name	Major Function
134	TGF-β3		Regulates cell proliferation, growth, differentiation, motility, synthesis and deposition of extracellular matrix, embryogenesis, tissue remodeling, and wound healing
135	TNF-α	Tumor necrosis factor alpha	Inhibits tumor cells; mediates immune response against bacterial infection; induces septic shock, autoimmune diseases, rheumatoid arthritis, inflammation, and diabetes
136	TNF-β	Tumor necrosis factor beta	Mediator of inflammatory and immune response; similar to TNF-α
137	TPO	Thrombopoietin	Stimulates megakaryocyte proliferation and maturation
138	TRAIL	TNF-related apoptosis-inducing ligand (Apo2L)	Activates rapid apoptosis in tumor cells
139	TWEAK	TNF-related weak inducer of apoptosis	Induces NFκB activation and chemokine secretion; promotes endothelial cell proliferation and migration
140	VEGF	Vascular endothelial growth factor	Stimulates endothelial cell proliferation and migration; promotes angiogenesis and vascular permeability

8.2.3 SOME DRUGS INVOLVING GROWTH FACTORS, CYTOKINES, AND CHEMOKINES

It was estimated that the revenue potential involving growth factors, cytokines, and chemokines could reach at least tens of billions of U.S. dollars. The research based on these proteins is changing the treatment of various diseases such as inflammation and infectious and neoplastic diseases. Current product development is focused on autoimmunity, allergy, cancer, infection, transplantation, and wound healing. A number of the first-generation cytokine-based drugs, including IFN-1β and TNF-α, are being replaced by next-generation drugs developed from studies using more refined approaches, causing the knowledge of growth factors/cytokines/chemokine networks to become more clarified. The increased market potential of approved drugs targeting growth factors, cytokines, chemokines, and their receptors has encouraged major biotechnology and pharmaceutical companies to devote their pipelines to the development of new therapeutics.

Table 8.2-3 lists a few examples of the therapeutic targets currently under development targeting growth factors, cytokines, and chemokines.

TABLE 8.2-3. Representative Drugs Involving Growth Factors, Cytokines, and Chemokines

Type	Representative Drug	Company
TNF superfamily	HGS-ETR1 (agonistic human monoclonal antibody to TRAIL receptor 1)	Human Genome Sciences
	HGS-ETR2 (agonistic human monoclonal antibody to TRAIL receptor 2)	Human Genome Sciences
	HGS-TR2J (agonistic human monoclonal antibody to TRAIL receptor 2)	Human Genome Sciences
Growth factor	Neupogen (Filgrastim, r-metHuG-CSF)	Amgen
	Neulasta (Pegfilgrastim, PEG-r-metHuG-CSF)	Amgen
	Nutropin [somatropin (rDNA origin) for injection]	Amgen
	Growth hormone	GENENTECH
	Kepivance (a recombinant form of human keratinocyte growth factor)	Amgen
Pro-inflammatory cytokine	Enbrel (etanercept) (TNF blocker)	Amgen
	Kineret (a recombinant form of a naturally occurring protein that regulates interleukin-1)	Amgen
C chemokine	CCR5 mAb	Human Genome Sciences
Angiogenic cytokine	Avastin (bevacizumab) (anti-VEGF antibody)	GENENTECH
Interferon	INTRON A (recombinant interferon α-2b)	Schering-Plough Corp.
	Albuferon (albumin-interferon α)	Human Genome Sciences

8.2.4 FORMULATIONS OF GROWTH FACTORS, CYTOKINES, AND CHEMOKINES

The formulations for growth factors, cytokines, and chemokines include low concentrations of nontoxic detergents, such as Tween 80, and osmotic agents, such as sorbitol. Additional agents are also included for providing optimum pH for their activity. Some salts are usually included in the formulations. A number of formulations for growth factors, cytokines, and chemokines exist. These formulations are based on saline, liposome, conjugation, and coadministration. The goals of developing optimum formulations are designed to protect the activities of these proteins and to effectively deliver the biologics to the targets.

Table 8.2-4 lists a few examples of the formulations for growth factors, cytokines, and chemokines (please refer to Refs. 1–12 for more details).

TABLE 8.2-4. Formulation of Growth Factors, Cytokines, and Chemokines

Formulation	Growth factor and cytokine	Reference
Saline	G-CSF	[*1*]
	IL-2	[*2*]
Liposome	G-CSF/ProGelz interleukin-2	[*1*]
	GM-CSF and TNF-alpha	[*2*]
	VEGF/PLGA	[*3*]
Conjugation	PEGfilgrastim, MonoPEGylated INF-alpha2b	[*4*]
	bio-bFGF/OX26-SA	[*5*]
	Fc-EPO (NDS) fusion protein	[*6*]
	(99m)Tc-IL-8	[*7*]
	PEG-rHuMGDF	[*8*]
	PEGlylated INF	[*9*]
Coadministration	IL-2/INF-alpha/histamine	[*10*]
	TNF-alpha/Doxil	[*11*]
	TNF-alpha/MTX	[*12*]

8.2.5 DELIVERY OF GROWTH FACTORS, CYTOKINES, AND CHEMOKINES

A number of routes for the delivery of growth factors, cytokines, and chemokines have been studied in detail. Those routes include: (1) oral administration; (2) intravenous injection; (3) intraperitoneal injection; (4) intramuscular injection; and (5) subcutaneous injection. Most of the delivery methods for these compounds are accomplished through injection because of their protein nature.

The U.S. FDA recently approved the first inhaled version of insulin (Exubera) for adults with type 1 or type 2 diabetes. Pfizer and Aventis developed Exubera, in collaboration with Nektar Therapeutics (formerly Inhale Therapeutics, a company that specializes in finding delivery solutions for oral, injectable, and pulmonary drug administration). It weighs about 4 ounces and is about the size of an eyeglass case when closed. It is portable, but not necessarily discrete. Exubera is a short-acting powder form of insulin that can be taken before meals. Inhaled insulin enters the bloodstream more rapidly than that delivered by subcutaneous injection. However, most people with diabetes still need to get long-acting insulin via an injection. Some side effects are associated with the inhaled insulin, including coughing, shortness of breath, sore throat, and dry mouth. It is also possible that overdose for smokers may be developed because smokers get more of the inhaled insulin entering their bloodstream than nonsmokers. Much still needs to be done to effectively deliver growth factors, cytokines, and chemokines to the patients.

Table 8.2-5 lists a few examples of the delivery for growth factors, cytokines, and chemokines (please refer to Refs 2, 3, 5, 9, 10, 13–17 for more details).

8.2.6 PHARMACOKINETICS OF GROWTH FACTORS, CYTOKINES, AND CHEMOKINES

Numerous published papers exist dealing with the pharmacokinetics of growth factors, cytokines, and chemokines. Those studies were performed using cells,

TABLE 8.2-5. Routes of Administration of Growth Factors, Cytokines, and Chemokines

Route of delivery	Growth factor and cytokine	Reference
Oral administration	TLF	[*13*]
Intravenous injection	VEGF	[*3*]
	BFGF	[*5*]
	IL-2	[*2*]
	Apo2L/TRAIL	[*14*]
	IL-1	[*15*]
Intraperitoneal injection	INF-gamma	[*16*]
Intramuscular injection	INFs	[*9*]
Subcutaneous injection	VEGF	[*3*]
	IL-2/IFN-alpha	[*10*]
	G-CSF analog	[*17*]
	INFs	[*9*]

tissues, animals, and patients. The experiments tested the various formulations and delivery methods mentioned above.

Table 8.2-6 is a summary of the selected studies on the formulation, delivery, and pharmacokinetics for growth factors, cytokines, and chemokines (Please refer to Refs. 1–18 for more details).

8.2.7 POTENTIAL APPLICATIONS OF TRISTETRAPROLIN FAMILY PROTEINS IN INFLAMMATION-RELATED DISEASES BY CAUSING CYTOKINE mRNA INSTABILITY

Tristetraprolin (TTP) and related proteins are well-established factors that destabilize cytokine mRNAs [*19*, *20*]. TTP is the best-understood member of a small family of tandem CCCH zinc finger proteins. Similar zinc finger sequences are found in numerous species in the GenBank database ranging from human to yeast and plants (including human, cow, mouse, rat, sheep, chimpanzee, dog, horse, pig, *Xenopus*, carp, zebrafish, *Drosophila*, *C. elegans*, baker's yeast, fission yeast, oyster, rice, and *Arabidopsis*.) In humans, three members of this family have been characterized: TTP (ZFP36, TIS11, G0S24, and NUP475), ZFP36L1 (TIS11B, cMG1, ERF1, BRF1, and Berg36), and ZFP36L2 (TIS11D, ERF2, and BRF2) [*19*]. They are encoded by different genes and their patterns of cell- and tissue-specific expression and agonist-stimulated expression are quite different. However, they share certain properties: All have highly conserved tandem zinc finger domains, in which each C8xC5xC3xH zinc finger is preceded by the sequence R/KYKTEL, and the two fingers are separated by 18 amino acids [*19*]; all are nuclear-cytoplasmic shuttling proteins [*21*, *22*]; and all are capable of binding AREs within single-stranded RNA [*23–29*] and promoting the deadenylation and subsequent destruction of those transcripts, both in transfection studies and in cell-free experiments [*26–28*, *30*].

TTP is an extraordinarily low-abundance, inducible, stable cytosolic, and hyperphosphorylated mRNA binding protein [*24*, *25*, *31–33*]. TTP mRNA and protein

TABLE 8.2-6. Summary of the Formulation, Delivery, and Pharmacokinetics for Growth Factors, Cytokines, and Chemokines

Drug	Experimental system	Formulation	Delivery	Pharmacokinetics	Reference
Apo2L/TRAIL	Mice model of human colon carcinoma	Apo2L/ TRAIL	Intravenous injection	Intact [125I]-Apo2L/TRAIL was detectable in the solid tumor at all time points and was the only tissue in which radioactivity transiently increased over time. Apo2L/TRAIL was stable in the circulation, localized to human solid xenograft tumors, and was primarily eliminated through the kidney	[*14*]
Epo	Mice myeloma cells	Fc-Epo(NDS) fusion protein		Fc-Epo(NDS) was secreted almost exclusively as a dimer, was relatively stable to the removal of N-linked oligosaccharides, had much improved pharmacokinetic properties, and had a significantly improved effect on RBC production	[*6*]
bFGF	Rat	bFGF, bio-bFGF, and bio-bFGF/OX26-SA conjugation to a blood-brain barrier peptide drug delivery vector	Intravenous injection	The brain uptake of the [^{125}I]-bio-bFGF/OX26-SA was increased five-fold, although the uptake of the conjugate by peripheral tissues was decreased relative to the unconjugated bio-bFGF. Conjugation of bio-bFGF to a BBB drug delivery vector (1) caused only a minor decrease in affinity for the bFGF receptor,	[*5*]

TABLE 8.2-6. *Continued*

Drug	Experimental system	Formulation	Delivery	Pharmacokinetics	Reference
				(2) decreased the peripheral organ uptake of the bFGF, and (3) increased the brain uptake of the neurotrophin	
G-CSF	Mice	ProGelz (PG) (17% poloxamer-407 and 5% hydroxypropyl methylcellulose) vs. saline	One injection in PG vs. multiple injections in saline	PG increased bioavailability (>1.5-fold), the time required to achieve the maximum concentration (Tmax) (six fold), and prolonged elimination (Tbeta) half-life (>three fold). Mobilized HPC was transported more rapidly to the spleen than that to the blood (289-fold vs. eight-fold increase)	[*1*]
GM-CSF & TNF-α	Normal and tumor-bearing mice	Liposomal cytokine vs. soluble cytokines		Liposome-entrapped GM-CSF and TNF-α was more efficacious immunomodulators than the soluble cytokines: (1) the entrapped cytokine displayed high stability; (2) release of TNF-α, but not of GM-CSF, from the liposomes was required for their biological activity in vitro; (3) plasma half-lives and the area under the curve of the entrapped cytokines were 10–20 times greater than those of the soluble cytokines; (4) the toxicity of liposomal TNF-α was 1/3–1/7 that of soluble TNF-α; (5) liposomal GM-CSF led to a 2–4-fold increase	[*18*]

				vs. soluble GM-CSF in the number of peritoneal and spleen leukocytes and of GM colony-forming cells in the spleen; and (6) liposomal GM-CSF markedly enhanced the level of blood granulocytes	
G-CSF analog	Monkeys		Subcutaneous injection	The analog enhanced stability and resulted in greater systemic exposure, probably because of improved absorption from the subcutaneous compartment	[*17*]
IFN-α2b	Rat	MonoPEGylated IFN-α2b vs. native IFN-α		PEGylation markedly enhanced both the resistance to tryptic degradation and the thermal stability of IFN-alpha2b. The serum half-life of 40K PEG-IFN was 330-fold longer, while plasma residence time was increased 708 times compared with native IFN. The PEG2,40K conjugate of IFN-α2b has higher stability than the native cytokine	[*4*]
IFN-γ	Mice		Intraperitoneal and intravenous injection	IFN-γ pretreatment for 24h resulted in retardation of plasma elimination of the drug with a concomitant increase of its tissue levels in liver, kidney, and intestine. A more pronounced effect might be elicited by IFN-γ for common substrates of P-gp and CYP3A	[*16*]
IFNs		Pegylated interferon	Intramuscular, muscular, intravenous, and subcutaneous injection	The decline in serum concentrations of IFNs was rapid after intravenous administration. The volume of distribution was approximately 20–60% of body weight. Terminal elimination half-lives ranged from	[*9*]

TABLE 8.2-6. *Continued*

Drug	Experimental system	Formulation	Delivery	Pharmacokinetics	Reference
				4 to 16 hrs, 1 to 2 hrs, and 25 to 35 min for alpha, beta, and gamma, respectively. Intramuscular and subcutaneous administration of interferons alpha and beta resulted in protracted but fairly good absorption >80% for interferon alpha to 70% for interferon gamma. Pegylated interferon safety and pharmacodynamic profiles were comparable. Pegylated interferon demonstrated delayed clearance compared with non-pegylated interferon. The severity of adverse effects was dose-dependent. Most patients treated had influenza-like syndrome within 2 to 8 hrs of drug administration. Other effects such as fatigue, lethargy, and anorexia were usually dose-limiting. Neuropsychiatric reactions might also become dose-limiting. Interferon induced the formation of serum neutralizing antibodies in approximately 10–20% of treated patients	
IL-1α	Phase I trial		Intravenous injection	IL-1 had measurable effects on tumor blood flow and caused a significant decrease in blood flow. This decrease was temporally associated	[*15*]

				with a significant leukopenia and an increased expression of the adhesion integrin CD11b on the circulating cell surface. IL-1 caused decreased tumor blood flow in vivo in human cancer patients, an effect that was temporally related to cytokine-induced peripheral blood cellular changes	
IL-2, IFN-α	Patients with stage IV melanoma	IL-2 2.4 MIU/m2, IFN-alpha 3 MIU, histamine as an adjunct	Subcutanous injections	Histamine, IL-2, and IFN-α treatment was safe, well-tolerated, and tumor responses were observed	[*10*]
IL-2	Mice	Liposomal IL-2 vs. soluble IL-2	Intravenous injection	Liposomal IL-2 exhibited a superior immunomodulatory activity and more efficiently stimulated spleen cell proliferation and lymphokine-activated killer (LAK) cell activation in vitro, fastened the circulation time, and increased in the leukocyte levels in blood, spleen, and peritoneal exudates	[*2*]
IL-8	Neutropenic rabbits	IL-8 was coupled with (99 m)Tc		(99 m)Tc-IL-8 was localized in the abscess, mainly bound to peripheral neutrophils. Accumulation in the abscess was a highly specific, neutrophil-driven process. Total fraction that accumulated in the inflamed tissue was extremely high	[*7*]
MGDF	Monkey bone marrow-derived mononuclear cell	Pegylated MGDF (PEG-rHuMGDF)	Infusion	The study confirmed predictions from PK/PD modeling of PEG-rHuMGDF (pegylated recombinant human megakaryocyte growth and development factor) that	[*8*]

TABLE 8.2-6. *Continued*

Drug	Experimental system	Formulation	Delivery	Pharmacokinetics	Reference
				thrombocytopenia is preventable after AuBMT	
TLF	Patients with advanced solid tumors		Oral administration	Significant levels of talactoferrin were undetectable in circulation, but a statistically significant increase in circulating IL-18 occured, a pharmacodynamic indicator of talactoferrin activity	[*13*]
TNF-α	Melanoma-bearing mice	Co-administered Doxil	Coinjection	Systemic application of clinically tolerable doses of TNF might improve drug distribution and tumor response	[*11*]
TNF-α	Patients with RA	Adalimumab (a human anti-TNF α monoclonal antibody) added to continuing MTX therapy	Coadministration of adalimumab and MTX	Adalimumab exhibited linear pharmacokinetics. Among patients with active RA who had not had an adequate response to MTX, addition of adalimumab to MTX achieved long-term improvement compared with placebo plus MTX	[*12*]
VEGF	Rat	Poly(lactic-co-glycolic) acid microspheres vs. protein solutions	Subcutaneous vinjection of microspheres vs. intravenous injection of solutions	VEGF in microspheres administered subcutaneously was detected with low plasma concentrations and high subcutaneous concentrations over a period of 7 weeks. VEGF in solution administered intravenously was rapidly cleared with high plasma concentrations as expressed by rapid absorption and elimination	[*3*]

are detected in a number of tissues including spleen, thymus, lymph node, lung, liver, and intestine, consistent with its proposed antiinflammatory role [*31*, *34*]. The expression levels of TTP mRNA and protein in mammalian cells are increased in response to several kinds of stimuli, including insulin and other growth factors, and stimulators of innate immunity, such as the endotoxin lipopolysaccharide (LPS) [*31*, *34*]. TTP is an mRNA-binding protein with high binding specificity for the so-called class II AREs within the 3′-untranslated mRNAs [*23–27*, *29*, *30*, *35*, *36*]. TTP and its related proteins can bind to the 3′-untranslated AREs of certain clinically important mRNAs, such as those coding for TNFα [*24–27*], GM-CSF [*30*], IL-3 [*36*], cyclooxygenase-2 [*37*, *38*], and plasminogen activator inhibitor type 2 [*39*]. This specific binding of TTP to the AREs results in the destabilization of the mRNAs in transfected human embryonic kidney (HEK) 293 cells [*26*, *27*]. In animals, TTP deficiency causes a profound inflammatory syndrome with cachexia, dermatitis, erosive arthritis, autoimmunity, and myeloid hyperplasia, apparently because of excessive production of TNFα and GM-CSF, both of whose mRNAs are direct targets of TTP and are stabilized in cells from the knockout (KO) mice [*27*, *30*, *40*]. For these reasons, TTP can be thought of as an anti-inflammatory or arthritis-suppressor protein [*25*, *40*, *41*]. Therefore, TTP and related proteins are potential therapeutic agents for inflammation-related diseases.

9.1 INTRODUCTION

During the past decade, the incorporation of noncoded amino acids into proteins has emerged as a novel and promising approach in protein science. In its infancy, the approach of protein engineering was essentially restricted to the possibility to chemically modify, in a rather unspecific fashion, particular amino acid side chains in proteins [1]. More recently, the advent of recombinant DNA technology allowed the site-specific alteration of a given polypeptide chain at a glance, thus, greatly expanding the tools available for studying the molecular mechanisms of protein folding, stability, and function [2]. Nevertheless, a quantitative description of the physical and chemical basis that makes a polypeptide chain efficiently fold into a stable and functionally active conformation is still elusive [3]. This mainly originates from the fact that nature combined, in a yet unknown manner, different properties (i.e., hydrophobicity, conformational propensity, polarizability, and hydrogen bonding capability) into the 20 standard protein amino acids, thus making it difficult, if not impossible, to univocally relate the change in protein stability or function to the variation of physico-chemical properties caused by amino acid exchange(s). In this view, incorporation of noncoded amino acids with tailored side chains, allowing investigators to finely tune the structure at a protein site, would facilitate to dissect the effects of a given mutation in terms of one or a few physico-chemical properties, thus, greatly expanding the scope of physical-organic chemistry in the study of proteins [4].

Incorporation of noncoded amino acids has been widely exploited in the study of bioactive peptides [5]. However, the results of these studies provide only a qualitative picture of the mechanism of the ligand–receptor interaction, and thus, they are of limited predictive power, as also documented by the explosion in the last few years of serendipity-based approaches in peptide design and drug discovery [6]. These difficulties stem primarily from the fact that introduction of single or multiple amino acid exchanges into a short peptide is expected not only to alter the interaction energy at the binding site(s) of the receptor, but also to affect (in a yet unpredictable way) fundamental properties of the free ligand, including electrostatic potential, hydration energy, and conformational entropy. Contrary to short peptides (5–20 amino acids), longer polypeptide chains (>50 amino acids) are generally characterized by a well-defined and stable three-dimensional (3D) structure, thus serving as macromolecular scaffolds, by keeping the global properties of the molecule rather constant and allowing the changes in binding free energy to be related in a more predictable way to the local variations of the physico-chemical properties at the mutation site(s). Hence, the incorporation of noncoded amino acids into proteins represents a further, (almost) obligatory extension of the studies aimed at elucidating the relationships existing among the structure, stability, and function in proteins (i.e., protein engineering).

In this view, several different strategies have been pursued to incorporate noncoded amino acids, including peptide synthesis [7] native chemical ligation [8, 9], enzyme-catalyzed semisynthesis [10, 11], biosynthetic incorporation *via* auxotrophic bacterial strain expression [12, 13], and nonsense suppression methodologies in cell-free [4] or whole-cell [14] expression systems. Both native chemical ligation and enzymatic semi-synthesis require careful tailoring of the experimental procedures, whereas biosynthetic incorporation methods are not site-specific and are

restricted to those cases when the structure of the noncoded amino acid (e.g., p-fluorephenylalanine, selenomethionine, and 7-zatryptophan) is similar to that of the natural counterpart to be replaced. On the other hand, despite significant advancements during the last decade [15–17], genetic methods are still limited by exceedingly low amounts of the resulting mutant protein, usually micrograms, that impair a thorough structural and functional characterization. However, stepwise solid-phase chemical synthesis remains the easiest and fastest approach to site-specifically incorporate in high yields any noncoded amino acid into even long (50–80 amino acids) polypeptide chains approaching the size of real proteins [18].

Relevant applications from our laboratory, regarding protein engineering with noncoded amino acids as a tool in the study of protein folding and function, will be presented. In particular, we will discuss the use of noncoded amino acids in structure-activity relationship (SAR) studies of hirudin binding to thrombin, as well as the incorporation of noncoded analogs of tryptophan and tyrosine (i.e., 7-azatryptophan and 3-nitrotyrosine) as spectroscopic probes for studying the hirudin–thrombin interaction.

9.2 HIRUDIN–THROMBIN INTERACTION

Thrombin is a serine protease of the chymotrypsin family that plays a key role at the interface among coagulation, infammation, and cell growth [19], and it exerts either procoagulant or anticoagulant functions in hemostasis [20]. The procoagulant role entails conversion of fibrinogen into fibrin and platelets activation, whereas the anticoagulant role regards the activation of protein C [21]. The most effective modulator of thrombin function in solution is Na^+, which triggers the transition of the enzyme from an anticoagulant (*slow*) form to a procoagulant (*fast*) form [22–24]. The Na^+-bound (*fast*) form displays procoagulant properties, because it cleaves more specifically fibrinogen and the protease-activated receptor (PAR), whereas the Na^+-free (*slow*) form is anticoagulant because it retains the normal activity toward protein C but cannot promote acceptable hydrolysis of procoagulant substrates [23, 24]. The importance of Na^+ on thrombin function is outlined by the fact that under physiological conditions the two forms are almost equally populated and that natural thrombin variants with compromised Na^+ binding result in bleeding phenotypes [24]. In this view, molecules capable of affecting the equilibrium between these two forms can have great potential therapeutic impact on the treatment of coagulative disorders [25].

Among natural anticoagulants, hirudin is the most potent and specific inhibitor of thrombin, with a dissociation constant in the 20–200-fM range [26, 27]. Due to its important pharmacological implications, the hirudin–thrombin pair has been the object of thorough structural and biochemical investigations. With respect to this, structural studies conducted on hirudin in the free [28–30] and thrombin-bound state [31] indicate that this inhibitor is composed of a compact N-terminal region, encompassing residues 1–47 and cross-linked by three disulfide bridges, and a flexible negatively charged C-terminal tail that binds to the fibrinogen-recognition site (exosite I) on thrombin. The N-terminal domain covers the active site of thrombin and through its first three amino acids extensively penetrates into the specificity

pockets of the enzyme (see Figure 9-1). Notably, the N-terminal tripeptide makes about half of the total contacts observed for the binding of the core domain 1–47 to thrombin (PDB code 4htc.pdb) [31] and accounts for ~30% of the total free energy of binding [33]. By limited proteolysis of full-length hirudin, we could produce the peptide fragment corresponding to the N-terminal domain 1–47 of hirudin HM2 [27]. Although far less active (at least 2×10^5-fold) than intact hirudin, this fragment (like the parent hirudin molecule) binds ~30-fold more tightly to the *fast* form of thrombin than to the *slow* form [34], which suggests that the structural determinants for this behavior are stored in the N-terminal domain. Hence, mutational studies on hirudin fragment 1–47 can be useful not only to investigate the physico-chemical determinants responsible for the extraordinary

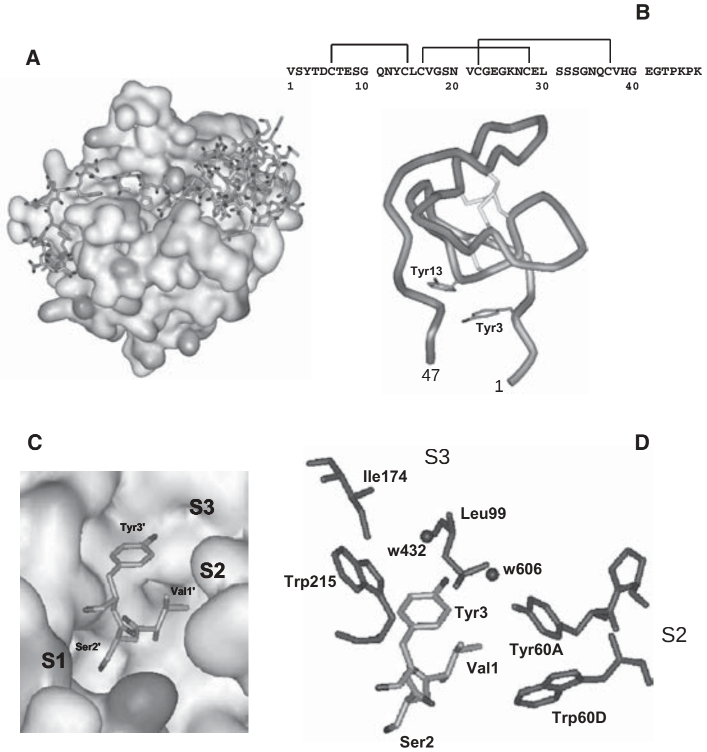

Figure 9-1. (**A**) Schematic representation of the interaction of full-length hirudin (stick) with thrombin (van der Waals surface), based on the crystal structure of the hirudin–thrombin complex [31]. (**B**) Amino acid sequence [32] and schematic representation of the solution structure [30] of the N-terminal fragment 1–47 of hirudin HM2 from *Hirudinaria manillensis*. Disulfide bonds are indicated by plain lines. (**C–D**) Structural details of the interaction of the N-terminal tripeptide of hirudin with thrombin. Val1′ of hirudin contacts the S2 site of thrombin, shaped by Tyr60a and Trp60d; Ser2′ covers, but does not penetrate, the S1 site, containing Asp189 at the bottom; Tyr3′ fills the apolar S3 site, formed by Trp215, Leu99, and Ile174. Structural water molecules at the hirudin–thrombin interface in the S2–S3 sites are also indicated. The ribbon drawing was generated using the program WebLab ViewerPro vs. 4.0 (Molecular Simulations Inc., 2000).

affinity and specificity of hirudin for thrombin, but also to probe the structural properties of the enzyme in the *slow* or *fast* forms.

9.3 SELECTION OF AMINO ACID REPLACEMENTS

9.3.1 Val1

Nuclear magnetic resonance (NMR) studies indicate that Val1 is almost fully exposed to solvent and highly flexible in the free hirudin [29, 30, 35]. Conversely, in the thrombin-bound state, Val1 is completely buried into the active site of the enzyme and fixed into a single side-chain conformation [31]. In particular, the α-NH_2 group of Val1 forms a hydrogen bond with the Oγ of the catalytic Ser195, whereas its side chain makes numerous hydrophobic contacts with Tyr60A and Trp60D, shaping the S2 of the enzyme (Figure 9-1). This loop, absent in other homologous trypsin-like proteases, defines the S2 specificity site on thrombin and narrows the access to the active site such that only small-sized apolar residues are allowed.

Considering the structural properties of hirudin in the free and bound state and the steric requirements at the S2 site of thrombin, we shaved the Val1 side chain with Ala or replaced it with *tert*-butylglycine (*t*Bug) (Figure 9-2). In fact, both Val and *t*Bug have comparable side-chain volume [36] and strong β-forming propensities [37], with minimum energy points at $\phi/\psi = -90°, 100°$ for Val and $\phi/\psi = -130°,$

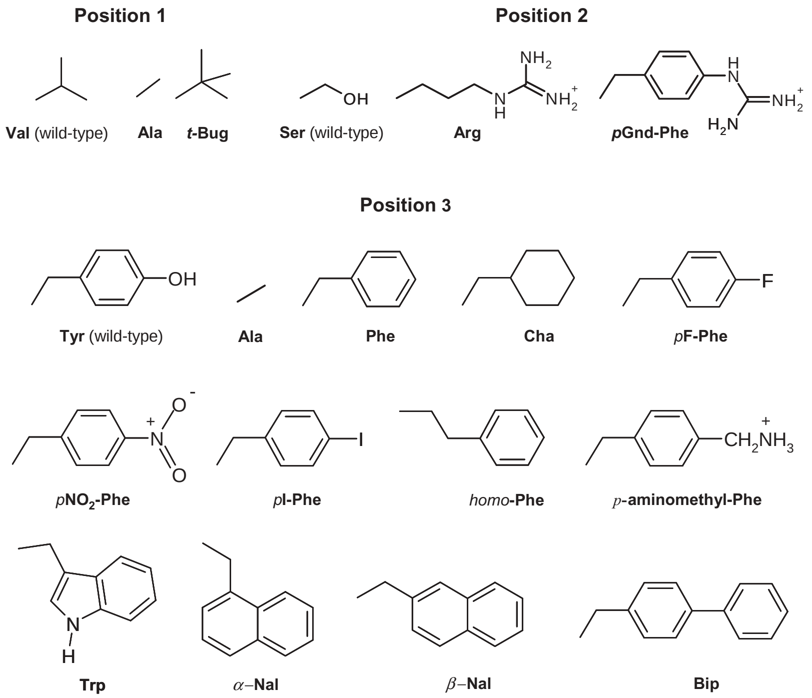

Figure 9-2. Amino acid replacements introduced into the hirudin fragment 1–47.

140° for *t*Bug [37]. On the other hand, the addition of a methyl group to the Cβ of valine is expected to restrict the backbone conformations available to *t*Bug to about one third of those allowed to Val [37].

9.3.2 Ser2

Analysis of the 3D structure of hirudin thrombin complex reveals that position 2 of hirudin is located at the entrance to, but does not enter, the primary specificity (S1) site [31]. Hence, the occupancy of the S1 site is not strictly required for binding. To evaluate the effects of perturbation of Asp189, located at the bottom of the S1 site, on the affinity of hirduin fragment 1–47 to thrombin, we have replaced Ser2 with Arg and its more rigid analog, *p*-guanidophenylalanine (*p*Gnd-Phe).

9.3.3 Tyr3

Contrary to the high conformational flexibility observed for the first two residues of hirudin, Tyr3 has a well-defined conformation in both the free and the bound state [29–31]. In the hirudin–thrombin complex, the side chain of Tyr3 projects into the apolar binding site of thrombin (the S3 site), which is formed by a large hydrophobic cavity comprising residues Trp215, Leu99, and Ile174 [31]. The importance of position 3 is confirmed by the fact that Tyr3 is highly conserved through the hirudin family [38]. To probe the S3 site of thrombin, we introduced at position 3 of hirudin 1–47 relatively large structural and chemical diversity by systematically replacing Tyr3 with natural and non-natural amino acids having different side-chain volume, hydrophobicity, electronic, and conformational properties (Figure 9-2).

9.4 STRUCTURE-ACTIVITY RELATIONSHIPS

Chemical synthesis of peptide analogs of the N-terminal domain 1–47 of hirudin was carried out by a combination of manual and automated solid-phase synthesis using the synthetic strategy previously described [34, 39]. The crude peptides with the Cys-residues in the reduced state were allowed to fold (2 mg/mL) under air-oxidizing conditions in bicarbonate buffer, pH 8.3, in the presence of 100-μM β-mercaptoethanol [39]. As an example, the reversed phase (RP)–high-performance liquid chromatography (HPLC) analyses of the crude synthetic analog Tyr3*homo*-Phe in the reduced and disulfide-oxidized state are reported in Figure 9-3. The chemical identity of the disulfide folded peptides was established by N-terminal sequence analysis and electrospray ionization (ESI)–time-of-flight (TOF) mass spectrometry, and for some synthetic peptides, the exact topology of disulfide bonds was established by enzymatic fingerprint analysis [39]. All peptides were purified by preparative RP–HPLC, lyophilized, and used for subsequent conformational and functional characterization. The results of conformational characterization, conducted by far- and near-Ultraviolet (UV) circular dichroism (CD) indicated that amino acid exchanges do not appreciably affect the conformation of hirudin fragment 1–47, allowing us to interpret the differences in affinity to thrombin exclusively on the basis of the variation of the physico-chemical properties at

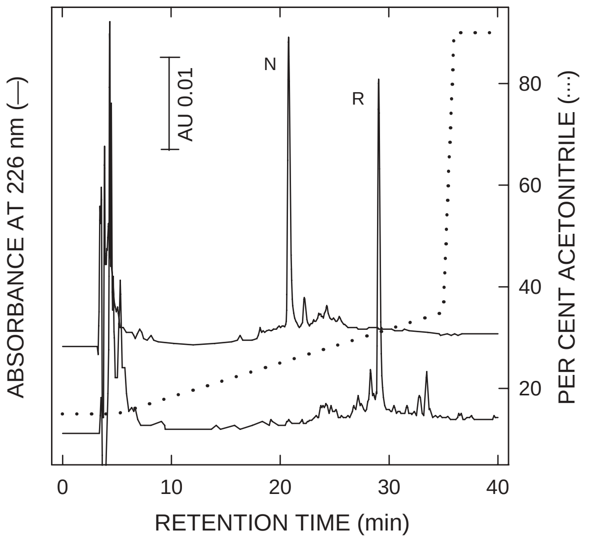

Figure 9-3. RP–HPLC analysis of the crude synthetic analog Tyr3*homo*-Phe in the reduced (*lower trace*) and disulfide oxidized state (*upper trace*). The chromatographic separations were conducted on a Vydac C18 analytical column (4.6 × 250 mm, 5 μm) eluted with a linear acetonitrile-0,05% TFA (. . . .) gradient, at a flow rate of 0.8 mL/min.

the mutation site. The inhibitory potency of the synthetic analogs toward the procoagulant *(fast)* and anticoagulant *(slow)* form of thrombin was determined by measuring at 405 nm the release of *p*-nitroaniline from the synthetic substrate D-Phe-Pro-Arg-*p*-NA, under temperature (25°C) and salt conditions in which the enzyme predominantly (>90%) exists in the *fast* (0.2-M NaCl) or in the *slow* (0.2-M choline chloride ChCl) form [22, 23] (Table 9-1).

9.4.1 Val1 → X

Shaving of Val1 with Ala (Val1Ala) reduces affinity for the *fast* and *slow* form of thrombin by 15- and 3-fold, respectively. On the other hand, replacement of Val1 with *tert*-butylglycine (*t*Bug) enhances the affinity of fragment 1–47 for the fast form of thrombin by about 3-fold, with a gain in the free energy of binding (ΔG_b) of 0.65 kcal/mol. This result is unprecedented, considering that almost all mutations at this position reported so far dramatically decrease binding [33, 41].

Model building studies indicate that *t*Bug fits snugly into the S2 subsite of the enzyme without steric hindrance and buries approximately the same amount of apolar surface as Val1 upon binding to thrombin. Likely, the enhanced binding of V1tBug is due to the higher symmetry of the *tert*-butyl group of *t*Bug over the isopropyl side chain of Val. In the case of *t*Bug, three energetically equivalent side-chain rotamers of *t*Bug can bind thrombin into the functionally active conformation, leading to a reduction of the entropy change of binding compared with Val ($\Delta S_{b,\mathrm{Val}\rightarrow t\mathrm{Bug}}$), which binds thrombin in only one totamer (i.e., the *trans* rotamer). An estimate of $\Delta S_{b,\mathrm{Val}\rightarrow t\mathrm{Bug}}$ can be obtained from the equation $\Delta S_{b,\mathrm{Val}\rightarrow t\mathrm{Bug}} = R \cdot \ln(\gamma_{b,t\mathrm{Bug}}/\gamma_{b,\mathrm{Val}}) = R \cdot \ln(3/1)$ [42], where $\gamma_{b,t\mathrm{Bug}}$ and $\gamma_{b,\mathrm{Val}}$ are the number of functionally active conformations allowed to *t*Bug and Val in the hirudin–thrombin

complex, respectively. Thus, a relative stabilization of $\Delta G_{\text{Val}\rightarrow\text{tBug}} = -T\cdot\Delta S_{\text{Val}\rightarrow t\text{Bug}} = -0.65$ kcal/mol at 298K is expected for the Val1*t*Bug analog over the natural species, in excellent agreement with the experimental value ($\Delta G_{\text{Val}\rightarrow\text{tBug}} = -0.63$ kcal/mol) reported in Table 9-1. Our results suggest that proper introduction of symmetric groups into amino acid side chains can significantly improve binding by increasing the entropy of the ligand in the bound state, thus reducing the overall change in ΔS_b. With this respect, amino acid substitutions like valine → *tert*-butylglycine or leucine → *tert*-butylalanine represent safe mutations, enabling us to improve binding with minimal steric requirements.

9.4.2 Ser2 → X

Replacement of Ser2 with Arg or its more rigid analog *p*Gnd-Phe induces a strong enhancement of the affinity of fragment 1–47 for thrombin (see Table 9-1), which is partly anticipated by modeling studies showing that the Arg side chain can be electrostatically coupled to Asp189, positioned at the bottom of the S1 site. Notably, perturbation of Asp189 enhances the affinity of hirudin preferentially for the *slow* form of the thrombin (see below).

9.4.3 Tyr3 → X: Effect of Side-Chain Volume and Hydrophobicity

The effects of coarse variations in the side-chain volume at position 3 on the binding to the *fast* or *slow* form were investigated by replacing Tyr3 with a smaller amino acid, like Ala, and with much larger residues, like Trp, α- and β-naphthylalanine (αNal and βNal), and biphenylalanine (Bip) (see Figure 9-2) [34, 43]. Thrombin dinding data, reported in Table 9-1, indicate that shaving of Tyr3 at Cβ reduces affinity almost exclusively for the *fast* form of thrombin, whereas enlargement of the side-chain volume at position 3 enhances binding in all cases, but preferentially to the procoagulant *fast* form of the enzyme. The lower affinity of Tyr3Ala can be reasonably explained either by the lower hydrophobicity of Ala or by the loss of numerous van der Waals contacts with the S3 site of the enzyme. Modeling of the Tyr3Ala–thrombin complex reveals that shaving of the Tyr3 side chain creates a cavity of about 150 Å^3 at the inhibitor–enzyme interface within the S3 region, which allows penetration of water at the binding interface, with a resulting destabilization of the hirudin–thrombin complex. Increasing the side-chain volume at position 3 also increases the hydrophobic effect, due to the burial of larger apolar surface upon binding. Strikingly, replacement of Ala with Bip enhances the affinity of hirudin 1–47 for thrombin by more than 1.3×10^4 times.

Clearly, thrombin binding data indicate that hydrophobicity is a major driving force for interaction. However, in the following we show that, beyond hydrophobicity, both side-chain orientation and electronic effects also play an important role in binding.

9.4.4 Tyr3 → X: Orientation Effects

As shown in Table 9-2, Trp is less hydrophobic than αNal. Nevertheless, the corresponding 1–47 analogs Tyr3Trp and Tyr3αNal display very similar inhibitory activity. Conversely, although αNal and βNal have the same hydrophobicity value,

[1] All measurements were carried out at 25°C in 5-mM Tris, pH 8.0, containing 0.1% PEG in the presence of 200-mM NaCl for the *fast* form or 200-mM ChCl when the *slow* form was being studied.

[2] $\Delta\Delta G_b$ is the difference in the free energy change of binding to thrombin between the synthetic analog (ΔG_b^*) and the natural fragment (ΔG_b^{wt}): $\Delta\Delta G_b = \Delta G_b^* - \Delta G_b^{wt}$. A negative value of $\Delta\Delta G_b$ indicates that the mutated species binds more tightly to thrombin than the natural fragment. Errors are ±0.1 kcal/mol or less.

[3] ΔG_c is the free energy of coupling to thrombin measured as $\Delta G_c = \Delta G_{b,\text{fast}} - \Delta G_{b,\text{slow}}$ [40]. The value of ΔG_c is negative if the inhibitor binds to the *fast* form with higher affinity than to the *slow* form. Binding data for the triple mutated species BugArgNal and recombinant hirudin HM2 variant from *Hirudinaria manillensis* are also reported.

Tyr3βNal is sixfold more potent than Tyr3αNal. Model building studies and accessible surface area (ASA) calculations provide reasonable explanation for these results. In fact, both Trp and αNal have similar side-chain orientation and bury approximately the same amount of apolar surface area upon complex formation. In addition, the side-chain of the residue in position 3 points toward the S2 site of thrombin in both Tyr3Trp and Tyr3αNal. Conversely, the βNal isomer in the analog Tyr3βNal buries a larger amount of apolar surface area upon binding, and it favor-

TABLE 9-2. Physico-Chemical Properties of Amino Acid Side Chains at Position 3 of Hirudin Fragment 1–47

Side Chain at Position 3	Volume (Å^3)[1]	logP (π)[2]	F[3]	R[3]	μ[4] (Debye)

[1] Side-chain molecular volumes are referred to the volume within van der Waals surface and are calculated for the corresponding organic compounds taken as suitable models for the amino acid side chains (e.g., *p*-cresol for Tyr, toluene for Phe).
[2] LogP values are those of the corresponding model compounds determined experimentally at 25°C and reported by Sangster [44]. When available, the hydrophobic substituent constants, π, of amino acid side chains are given in parenthesis [36].
[3] *F* and *R* are the field (*F*) and resonance (*R*) contribution to the Hammett electronic substituent constant, σ_p, according to Hansch et al. [45]. Electron-withdrawing groups possess positive F and *R* values, whereas electron-releasing groups have negative *R* values.
[4] μ is the electric dipole moment of organic model compounds of the amino acid side chains determined at 25°C in benzene [46].
[5] The μ value of Tyr was corrected for the absence of resonance effects. A positive sign of μ stands for a negative endpointing away from the phenyl ring, toward the *para*-X substituent.
Abbreviation: n.a., not available.
Note: A detailed description of the procedures employed to get estimates of side-chain physico-chemical properties is reported in Ref 43.

ably interacts with in the S3 site (see Figure 9-1D). Further support to the importance of orientation effects to the binding of hirudin to thrombin comes from the low affinity of the analog of hirudin 1–47 in which Tyr3 was replaced by *homo*-Phe. Although *homo*-Phe is much more hydrophobic than Tyr and Phe (Table 9-2), the analog Tyr3*homo*Phe is less potent than the wild-type species and Tyr3Phe analogs by 4- and 40-fold, respectively (Table 9-1). Due to steric clashes, the side chain of *homo*-Phe cannot favorably interact with the apolar S3 site, but more likely it points

toward Tyr60A and Trp60D in the S2 site, leaving an uncompensated cavity at the S3 site.

An important aspect emerging from our work is that the intrinsic aversion of nonpolar groups for water is the dominant driving force for ligand binding only when the removal of these groups from the aqueous solvent leads to favorable specific interactions with the receptor binding-site(s), which suggest that ligand–receptor association is strongly influenced by both hydrophobic and shape-dependent packing effects.

9.4.5 Tyr3 → X: Electronic Effects

Aromatic–aromatic interactions have been identified as important factors for protein stability and binding [47]. Indeed, edge-to-face interaction between two aromatic side chains allows the δ^+ hydrogen atoms of the edge of one aromatic ring to approach the δ^- π-electron cloud of the other ring, favorably contributing to protein stability and binding by 0.6–1.3 kcal/mol [48]. Analysis of the 3D structure of the hirudin–thrombin complex reveals that the δ^+ hydrogens on the edge of the Tyr3 ring can favorably interact in a T-shaped conformation with the δ^- π-electron cloud of the aromatic ring of Trp215 at the S3 site on thrombin (see Figure 9-1D). To probe the importance of aromatic–aromatic interactions in the hirudin–thrombin system, we replaced Tyr3 with Phe and its saturated analog, cyclohexylalanine (Cha). Compared with Tyr or Phe, Cha is similar in size but significantly more hydrophobic (Table 9-2). Hence, if hydrophobicity were the dominant driving force for binding, Tyr3Cha would be expected to be a more potent inhibitor than the wild-type and Tyr3Phe derivatives. Conversely, the Tyr3 → Phe exchange improves affinity for thrombin by 10-fold, whereas saturation of the aromatic ring of Phe (by Phe → Cha substitution) reduces binding by a similar amount. These findings clearly indicate that the enhanced affinity of Tyr3Phe and wild-type species over Tyr3Cha is primarily due to the stabilizing interaction with Trp215, which is possible only for the aromatic side chain of Phe or Tyr and not for its saturated analog, Cha, thus demonstrating that, beyond hydrophobicity, electronic effects, and specifically aromatic–aromatic interactions, can markedly modulate binding.

With the aim to strengthen aromatic–aromatic interactions, we systematically replaced Tyr3 with noncoded amino acids retaining the aromatic nucleus of Tyr, as well as similar size and hydrophobicity, but possessing electron-withdrawing substituents on the aromatic ring (i.e., *p*-fluoro-, *p*-iodo-, *p*-nitro-Phe, *p*-aminomethyl-Phe; see Table 9-2). The presence of electron-attracting groups in the *para*-position of Phe3 was expected to enhance binding by making the hydrogens of the aromatic nucleus at position 3 more electron-deficient, thus reinforcing the aromatic electrostatic interaction with the π-electron cloud of Trp215. Contrary to expectations, electron-withdrawing substituents failed to improve thrombin binding. Conversely, their presence resulted in a significant reduction in the affinity by 4 (i.e., Tyr3*p*F-Phe) to 46-fold (i.e., Tyr3pNO$_2$-Phe) in respect to that of Tyr3Phe (Table 9-1). Rather surprisingly, the presence of *p*-aminomethyl-Phe (*p*AM-Phe), carrying a net positive charge at position 3 (pK_a 9.36), reduced affinity for the *fast* form of thrombin by only threefold and did not affect the binding strength to the *slow* form. Notably, the charged amino-group of *p*AM-Phe is shielded from water and buried into the apolar S3 site. Both theoretical and experimental work estimated an energy

cost of 9–10 kcal/mol to bury a charge in the protein interion [49, 50]. In our case, the difference of hydrophobicity (see Table 9-2) between *p*-aminomethyl-Phe and Tyr or Phe would yield an unfavourable increase of ΔG_b to thrombin by 3.8 and 4.8 kcal/mol, respectively. Therefore, the low energetic penalty of 0.72 and 0.03 kcal/mol experimentally derived for the binding of Tyr3*p*AM-Phe to the *fast* or *slow* form of the enzyme would lead us to reconsider the apolar properties of the S3 site or, more reasonably, to invoke specific interactions of the charged amino group within the S3 site (see below) that would compensate for its unfavorable desolvation properties.

Given the apolar character of the S3 site, traditionally referred to as the "aryl binding site" of thrombin [51], we first attempted to relate the affinity of the synthetic analogs of hirudin fragment 1–47 for the fast form of thrombin to the hydrophobicity value of the amino acid side chain at position 3. The contribution of hydrophobicity to the free energy change of binding (ΔG_b) was estimated using the approach of Eisenberg and McLachlan [52], which assumes that desolvation free energy change of binding, $\Delta G_{desolv} = G_{desolv}(\text{complex}) - [G_{desolv}(\text{thrombin}) + G_{desolv}(\text{hirudin})] = -\Sigma_i \Delta\sigma_i \times \Delta \text{ASA}_i$, is related to the amount of polar and apolar surface area of both ligand and receptor that becomes buried upon complex formation [53]. $\Delta\text{ASA}_\text{i}$ is the change in the ASA for the atom-type *i* upon binding of hirudin to thrombin, and $\Delta\sigma_\text{i}$ (i.e., the atomic solvation parameter) is the solvation free energy change per unit area of atom type *i* that becomes buried upon binding. Desolvation free energy change of binding for a mutated hirudin analog (M) was calculated relatively to that of the wild-type fragment 1–47 (WT) as $\Delta\Delta G_{desolv} = \Delta G_{desolv}(\text{M}) - \Delta G_{desolv}(\text{WT})$.

Data reported in Figure 9-4A clearly indicate that the experimental free energy change of ΔG_b is linearly related to the variation of desolvation free energy (ΔG_{desolv}), which is calculated on theoretical grounds. Only two data points strongly deviate from the regression line, namely Tyr3*p*I-Phe and Tyr3*p*AM-Phe. In particular, these analogs were found to bind thrombin much more tightly than predicted by desolvation free energy calculations. Structural analysis of the corresponding complexes with thrombin reveals that both the iodine atom of *p*I-Phe and the charged nitrogen of *p*AM-Phe can productively interact with the aromatic nucleus of Trp215 at the S3 site, thus compensating (or overwhelming) their unfavorable desolvation free energy of binding. In the case of the Tyr3*p*I-Phe analog, the favorable interaction of iodine with Trp215 is predominantly driven by dispersive forces related to the high polarizability of iodine. In this regard, I_2 forms stable complexes with benzene [54]. On the other hand, the surprisingly high affinity of the Tyr3*p*AM-Phe analog can be rationalized by taking into account a specific charge–π interaction between the protonated amino group of *p*-aminomethyl-Phe and the π-electrons of Trp215. Since the seminal work of Burley and Petsko [47] on "weakly polar interactions," a great deal of experimental evidences have been accumulated over the years, leading to the conclusion that "nonconventional" hydrogen bonds of the type X–H . . . π and cation–π interactions can play a key role in protein structure and stability, as well as in ligand recognition [55]. With respect to this, theoretical calculations indicate that, among many other possible combinations of cations and aromatics, the interaction of NH_4^+ (or K^+) with indole provides the most favorable interaction energy [56]. These predictions have been confirmed by a comprehensive structural analysis of X–H . . . π hydrogen bonding in proteins, in which the indolyl

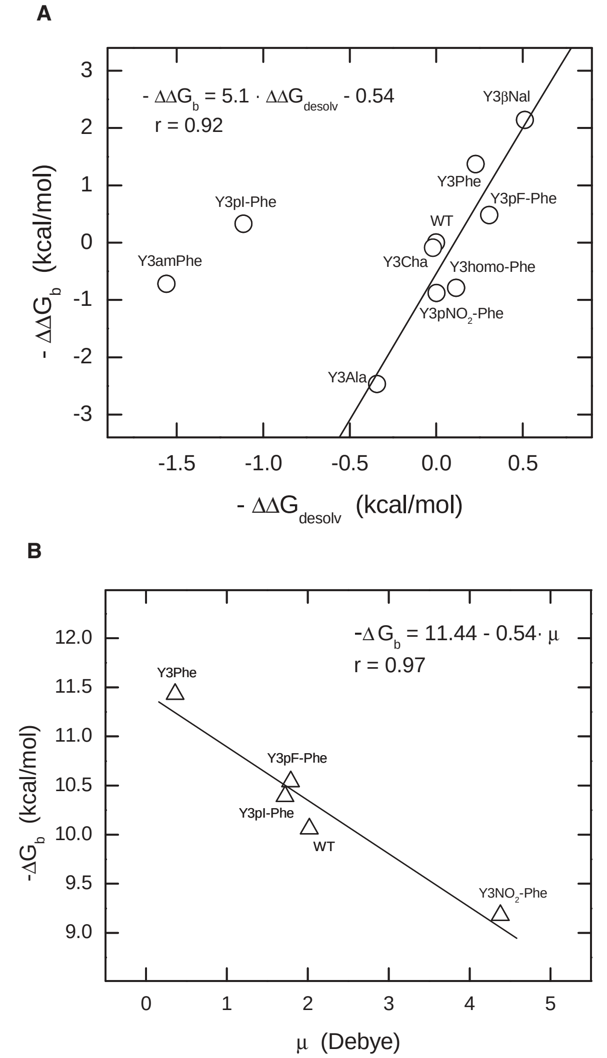

Figure 9-4. (**A**) Plot of the experimental free energy change of binding to the *fast* form of thrombin ($-\Delta\Delta G_b$) for the synthetic analogs of fragment 1–47 mutated at position 3 as a function of free energy change of desolvation ($\Delta\Delta G_{desolv}$) upon hirudin–thrombin interaction. (**B**) Plot of ΔG_b *versus* the electric dipole moment μ of the amino acid side chain at position 3. A positive sign of μ stands for a negative endpoint away from the phenyl ring toward the *para*-X substituent. For details, see Ref 43. **r** is the correlation coefficient of the linear fitting.

nucleus of Trp was found by far to be the most frequent π-acceptor of hydrogen and Lys-Trp to be the most represented donor–acceptor pair [57].

To better understand the physical nature of these forces driving the hirudin–thrombin interaction, we plotted the experimental ΔG_b of hirudin analogs *versus* the electric dipole moment, μ, of the *para*-X substituted (X = –H, –F, –I, –OH and $-NO_2$) amino acid side chain at position 3 (see Table 9-2). The data shown in Figure 9-4B indicate that the affinity of hirudin fragment 1–47 for thrombin is inversely

related to the value of μ, which suggests that hirudin–thrombin interaction is destabilized by the presence of a partial negative charge at the *para*-position of the phenyl ring, as in the case of *p*NO2-Phe, where the two oxygen atoms are strongly electron-dense. A reasonable explanation for these results may be found in the specific electrostatic interactions with the electronic π-system of Trp215, which for *p*-aminomethyl-Phe are attractive, whereas for *p*NO2-Phe are repulsive.

Taken together, our results indicate that the relative change in the affinity of hirudin 1–47 analogs can be accounted for by the apolar character of the ligand quite well, but on the other hand, they also emphasize the importance of "hidden interactions," mainly of electrostatic nature, in strengthening hirudin–thrombin binding. If a reasonable estimate of the hydrophobic effect can be obtained by calculating the free energy change due to desolvation of apolar surfaces that become buried upon ligand–receptor association, electrostatic effects are much more difficult to evaluate and predict, because they are mediated by weakly polar interactions, whose strength is strongly dependent on the electron density and polarizability, as well as on the orientation and distance of the interacting groups, such that even subtle perturbations in the ligand or receptor structure may dramatically alter binding. In this perspective, the possibility to introduce at a given protein site noncoded amino acids with larger structural and chemical diversity will improve our understanding of the mechanisms dictating molecular recognitions in proteins.

9.5 CUMULATIVE AMINO ACID SUBSTITUTIONS IN HIRUDIN YIELD A HIGHLY POTENT THROMBIN INHIBITOR

Hirudin offers numerous advantages over the existing anticoagulants heparins and cumarins [58, 59], and its use in clinical practice has been recently introduced. However, hirudin administration necessitates careful dose-titration, and bleeding effects are not rare [60]. These problems stem primarily from the intrinsic instability of the highly flexible C-terminal tail of full-length hirudin to degradation by endogenous proteases, generating truncated N-terminal fragments that, however, are dramatically less potent as thrombin inhibitors than the intact molecule [39, 61].

To minimize the hirudin sequence binding to thrombin and to improve its therapeutic profile, several N-terminal fragments of hirudin have been prepared as potential anticoagulants. Their use would provide a more predictable effect *in vivo* compared with intact hirudin, due to their stability to denaturants and proteolytic attack and lower immunogenicity [61]. Moreover, N-terminal core fragments targeting solely the active site of thrombin are expected to have a safer therapeutic profile, in keeping with the notion that active-site reversible inhibitors of thrombin display a better antithrombotic/hemorrhagic balance than bivalent inhibitors [62–64]. However, a major limitation of these fragments resides in their poor affinity for thrombin (K_d = 30–400 nM), compared with hirudin (K_d = 0.2–1.0 pM) [27, 33, 61].

To possibly obtain a mini-hirudin retaining the highly potent antithrombin activity of full length hirudin, but lacking the susceptibility to proteolysis, we selected the best-performing amino acid exchanges tested in our previous work (i.e., Val1*t*Bug,

Ser2Arg, and Tyr3βNal) [34] and combined them in the same analog, denoted as BugArgNal [65], which was synthesized in high yields by standard Fmoc chemistry. The introduction of only three mutations at the N-terminal end of hirudin fragment 1–47 yields a molecule that inhibits the *fast* or *slow* form by 2670- and 6820-fold more effectively than the natural counterpart and that binds exclusively at the active site of thrombin with an affinity ($K_{d,fast}$ = 15 pM, $K_{d,slow}$ = 220 pM) comparable with that of full-length hirudin ($K_{d,fast}$ = 0.2 pM, $K_{d,slow}$ = 5.5 pM). Strikingly, BugArgNal induced a change in the coagulative parameters (i.e., thrombin time, prothrombin time, and activated partial thromboplastin time) comparable with that evoked by intact hirudin (unpublished data). BugArgNal is also highly stable to low pH and resistant to the action of numerous proteases, including trypsin, chymotrypsin, thermolysin, and pepsin, and like full-lemgth hirudin, it displays almost absolute selectivity for thrombin over other closely related, physiologically important serine proteases, including plasmin, factor Xa, and tissue plasminogen activator, up to the highest concentration of inhibitor tested (10 μM). Only a slight inhibition was observed for factor Xa, with an estimated K_d value higher than 8 μM.

The issue of protease selectivity is crucial in the design of novel thrombin inhibitors, because inhibition of other physiologically relevant serine-proteases (e.g., tissue plasminogen activator and plasmin) can impair their clinical use [66–68]. The results reported in this study demonstrate that the presence of an Arg-residue at the N-terminal end of hirudin fragment 1–47 strongly improves binding, while retaining the extraordinary selectivity of the natural product. This is in contrast with the results obtained for low-molecular-weight inhibitors, where it is paradigmatic that the introduction of a positive charge at P1-position improves binding, but strongly reduces selectivity [66–68], because the positive charge of the inhibitor interacts in the S1 site of thrombin with Asp189, which is highly conserved among the endogenous enzymes prevalent in the vascular system. Likely, in the case of BugArgNal, many weak favorable contacts operate at the inhibitor–thrombin interface to cooperatively encode protease specificity.

As shown in Table 9-1, the effects of the amino acid replacements are additive in both the *fast* and the *slow* forms of thrombin, indicating that S1, S2, and S3 sites behave independently; that is, perturbation of a given site of the enzyme does not affect the binding properties of the other two sites [69]. This result is of particular relevance, because it would allow the properties of a multiple mutant to be inferred directly from those of the singly mutated species and to engineer incremental increases in binding strength and selectivity for either allosteric form of thrombin. For instance, substitution of Val1 with *t*Bug, Ser2 with Arg, and Tyr3 with Bip would yield a synthetic analog about 15,750 more potent than the wild-type species, with a predicted K_d value of about 2.5 pM.

9.6 STRUCTURAL MAPPING OF THROMBIN RECOGNITION SITES IN THE NA^+-BOUND AND NA^+-FREE FORM

The effect of Na^+ binding on thrombin function is allosteric in nature [23, 70], and several crystal structures of the enzyme with and without Na^+ bound have been recently reported [71–74]. The structures of the pseudo-wild-type thrombin mutant (Arg77aAla), reported by Di Cera et al. [71, 72], in the presence or absence of Na^+,

display only small changes in the side-chain orientation of Ser195 in the active site, Asp189 in the S1 site, Glu192 and Asp222 on the protein surface, and some rearrangement of the water molecules filling the S1 site. Conversely, the structures of the *fast* and *slow* form reported by Huntington et al. [73, 74] show significant differences at the level of the S2 and S3 sites, which in the *slow* form protrude onto the protein surface and limit the access to the catalytic pocket. In particular, the apolar cavity of the S3 site is restricted by protrusion of Trp215, which is possibly caused by reorientation of the underlying Phe227 and 168–182 disulfide bond. Partial unfolding of the Na^+ site is observed, with a collapse of the 148-loop onto the groove leading to the catalytic pocket. Furthermore, all putative structures of the *fast* and slow forms reported so far display numerous contacts between thrombin monomers in the crystal lattice [71–74], and therefore, the packing effects can also influence the thrombin structure in the crystal.

Hence, we decided to use the N-terminal hirudin domain 1–47 as a molecular probe of the solution conformation of thrombin recognition sites in the *fast* and *slow* form [75]. The guiding idea is that structural information on thrombin sites in the two allosteric forms can be gained from the physico-chemical properties of the mutated residue at position 1–3 of hirudin and from the effects of the perturbations introduced on the value of coupling free energy ΔG_c, which is the difference in standard free energy of binding of the inhibitor to the *fast* and *slow* form of thrombin, $\Delta G_c = \Delta G^f - \Delta G^s$. Thrombin binding data reported in Table 9-1 can be summarized as follows: First, Ala-shaving at either position 1 or position 3 reduces affinity almost exclusively for the fast form; second, side-chain enlargement at position 3 with bulky and hydrophobic amino acids (i.e., βNal and Bip) strongly enhances affinity for both forms, but preferentially for the fast form; third, electrostatic perturbation of the primary specificity site S1, by Ser2 → Arg or Ser2 → *p*Gnd-Phe exchange, enhances affinity preferentially for the slow form. These data were analyzed within the theoretical framework of site-specific thermodynamics [75–77] and used to extract structural information on the specificity sites of thrombin in the two allosteric forms:

$$\begin{array}{ccccc} & & \Delta G^s & & \\ & S & \Leftrightarrow & SI & \\ \Delta G^0 & \Updownarrow & & \Updownarrow & \Delta G^1 \\ & F & \Leftrightarrow & FI & \\ & & \Delta G^f & & \end{array}$$

The *slow* (S) and *fast* (F) forms bind the inhibitor (I) with a standard free energy change ΔG^s and ΔG^f, whereas ΔG^0 and ΔG^1 represent the free energy changes for switching from the *slow* to the *fast* form in the absence or presence of the inhibitor. The coupling free energy (ΔG_c) for the cycle is given by the equation $\Delta G_c = \Delta G^f - \Delta G^s = \Delta G^1 - \Delta G^0$, where ΔG^f and ΔG^s can be determined experimentally. The preferential loss (or gain) in affinity of a mutated inhibitor for one of the two allosteric forms of the enzyme is a measure of the energetic contribution of the interactions being lost (or gained) upon mutation and provide strong, albeit indirect, means for identifying those regions on thrombin that have different structural features in the *slow* or *fast* form. On the other hand, mutations that affect both forms to the same extent reveal that the perturbations introduced in the inhibitor are important for binding to thrombin and that the site is not involved in the *slow* → *fast* transition

or, otherwise, that the entity of the perturbation introduced is too small to elicit a different behavior at that site in the two allosteric forms. In addition, because Na^+ binds the hirudin–thrombin complex with ~20-fold higher affinity than the free enzyme ($\Delta G^\circ \neq \Delta G^1$) [40], then from the linkage principles mentioned above, it follows that the inhibitor must bind with different affinity to the *slow* and *fast* forms ($\Delta G^f \neq \Delta G^s$), ruling out other possibilities.

In the case of Tyr3 → Ala and Val1 → Ala exchanges, elimination of the interactions of Tyr and Val side chains beyond the Cβ strongly reduces affinity for the *fast* form, by 65- and 15-fold, respectively, whereas it is practically ineffective on the *slow* form, which suggests that the presence of Tyr and Val is crucial to enhance binding exclusively to the procoagulant *fast* form. On the other hand, the presence of the larger side chain of βNal at position 3 enhances affinity for the *fast* form by about 40-fold and by only 15-fold for the *slow* form. Taken together these results suggest that the S3 site of thrombin in the procoagulant (*fast*) form is in a more open and accessible conformation in respect to the less forgiving structure it acquires in the anticoagulant *slow* form. Also consistent with our model are the effects of the replacement of Ser2 with Arg or *p*Gnd-Phe, whose long, charged side chain is expected to facilitate penetration of the inhibitor into thrombin recognition sites, to a greater extent in the case of the more closed *slow* form than in the case of the *fast* form of the enzyme, which is already accessible for binding. From the effects of amino acid substitutions on the affinity of fragment 1–47 for the enzyme allosteric forms, we conclude that the specificity sites of thrombin in the Na^+-bound form are in a more open and permissible conformation, compared with the more closed structure they assume in the Na^+-free form [75].

The structural picture of thrombin allosteric forms proposed above is consistent with detailed molecular dynamics (MD) simulations carried out for 18 ns in full explicit water [43], showing two well-defined conformational minima on the energy landscape. After about 5 ns, a concerted conformational transition, involving the S2/S3 sites, the 148-loop, and the fibrinogen binding site, leading the thrombin molecule from a more compact and closed form, which we propose can be related to the anticoagulant (*slow*) form in the Na^+-free state, to a more open and accessible conformation, which we propose can be related to the procoagulant (*fast*) form in the Na^+-bound state (see Figure 9-5). Moreover, the results

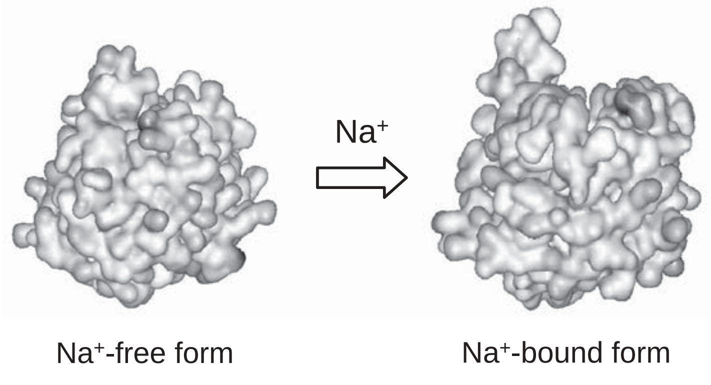

Figure 9-5. Surface representation of thrombin in the putative *slow* and *fast* form. The model was built on the basis of the coordinates derived form 18-ns MD simulations in explicit water solvent [43].

of MD analysis outline the high degree of correlation existing between the motions of all these regions of thrombin, all occurring after about 5 ns, and suggest that a structural network is present, capable of communicating the conformational changes, induced by Na^+ binding, between different structural domains of the enzyme.

Our model also provides reasonable explanation for the fact that those substrates that are related to the procoagulant activities of thrombin (e.g., fibrinogen, PAR-1, and factor XIII) orient a bulky side chain deep into the S3 site of the enzyme and, as expected, are cleaved by the *fast* form of thrombin 20–40-fold more efficiently than by the *slow* form [23]. In particular, fibrinogen interacts at the S3 site of the enzyme through the bulky Phe8 having a side-chain volume of 127 $Å^3$ [1bbr.pdb; 78], PAR-1 through Leu38 (Leu = 100 $Å^3$) [1nrs.pdb; 79], and factor XIII through two Val-residues (Val29 and Val34; Val = 79 $Å^3$) [1de7.pdb; 80]. On the other hand, protein C, which is related to the anticoagulant function of thrombin, does not seem to extensively interact with the S3 site of the enzyme [43], and as expected, it is cleaved with similar specificity by either the *slow* or the *fast* form (ΔG_c = 0.2 kcal/mol) [23].

9.7 INCORPORATION OF NONCODED AMINO ACIDS AS SPECTROSCOPIC PROBES IN THE STUDY OF PROTEIN FOLDING AND BINDING

A major application of protein engineering with noncoded amino acids regards the introduction into proteins of biophysical probes possessing physico-chemical properties (e.g., side-chain volume, hydrophobicity) similar to those of the corresponding natural amino acids, but spectral features distinct from those of the natural counterparts and highly sensitive to the chemical environment in which the probe is located [81]. Hence, by the use of the so-called “spectrally enhanced proteins” [82], it should be possible to effectively monitor the local structure and dynamics of the mutated protein during key events, such as protein folding and denaturation or ligand binding, without significantly perturbing the kinetics and equilibrium properties of the process under investigation. With respect to this, in a recent study, Cohen et al. could site-specifically introduce 6-dimethylamino-2-acyl-naphthylalanine (Aladan) into the B1 domain of staphylococcal protein G to obtain estimates of the local dielectric constant of the protein at different sites [83].

More specifically, the development of new spectroscopic tools for studying protein–protein interactions is central to many disciplines, including structural biology, biotechnology, and drug discovery [84]. Traditionally, the change in tryptophan (Trp) fluorescence has been exploited to study ligand–protein interactions [85]. However, the fluorescence signal of many proteins is insensitive to ligand binding [86], because fluorescence changes are mostly restricted to those cases where Trp-residues are embedded in the ligand–protein interface or when the ligand binding induces conformational changes in the protein, remote from the binding region and involving one or more Trp-residues. Furthermore, the presence of multiple tryptophans in proteins may lead to compensating effects that often complicate interpretation of the fluorescence data [85].

To overcome these problems, several extrinsic spectroscopic probes, characterized by well-defined spectral properties, have been covalently bound to protein

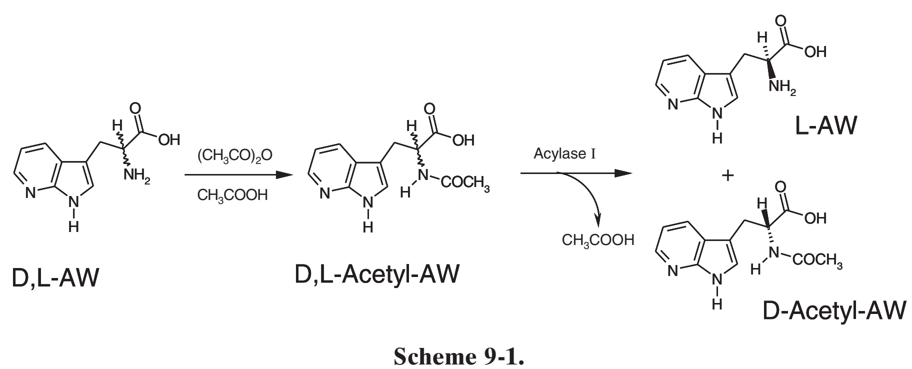
functional groups (i.e., Cys and Lys), to act as energy donors or acceptors in fluorescence resonance energy transfer (FRET) studies [84, 87–89]. This approach, however, is limited by possible labeling heterogeneity, nonquantitative modification, structural alteration of the proteins resulting from the labeling *per se*, and perturbation of the binding process, due to the large size of the fluorescent labels used [87, 88].

In the following, we show the utility of two noncoded analogs of tyrosine and tryptophan, namely 3-nitrotyrosine (NT) and 7-azatryptophan (AW), in the study of hirudin folding and binding to thrombin [90, 91].

9.7.1 7-Azatryptophan

Among the noncoded tryptophan analogs studied so far (i.e., 5-hydroxy- and 5-metoxy-Trp, benzo[b]thiophenylalanine and the spectrally silent fluorotryptophans), 7-azatryptophan (AW), an isostere of tryptophan (W), displays interesting absorption and fluorescence properties [92]. Unlike tryptophan, free AW displays single exponential fluorescence decay and the presence of a nitrogen-atom at position 7 in the indolyl-nucleus results in a red shift of 10 nm in the absorption and 46 nm in the emission of AW compared with Trp. Furthermore, the fluorescence λ_{max} and quantum yield of 7-azaindole (7AI) are strongly influenced by the polarity of the chemical environment. In particular, on going from cyclohexane to water the emission fluorescence of 7AI is shifted from 325 to 400 nm and the quantum yield is decreased by 10-fold. The quantum yield of AW increases from 0.01 in aqueous solution, pH 7, to 0.25 in acetonitrile [93]. Hence, it should be possible to selectively excite the fluorescence of AW at the red edge of its absorption (between 310 and 320 nm), where Tyr does not absorb and the contribution of Trp is negligible and, thus, investigate protein folding and binding processes through variation of the AW fluorescence signal.

Recently, we exploited the unique spectroscopic properties of AW to probe the disulfide-coupled folding of the hirudin N-terminal domain 1–47 and the binding to its the target enzyme, thrombin [90]. Before chemical synthesis, the resolution of the commercially available enantiomeric mixture of AW was carried out by treating the racemic mixture with acetic anhydride and subsequent enantioselective deacylation with immobilized *Asperigillus oryzae* acylase-I to yield L-AW (Scheme 9-1). Purified L-AW was then reacted with 9-fluorenylmethoxycarbonyl chloride



Scheme 9-1.

(Fmoc-Cl), to quantitatively obtain the Fmoc-derivative, which was subsequently used in the solid-phase synthesis of the analog of hirudin 1–47 in which Tyr3 was replaced by AW.

The replacement of tryptophan with the isosteric 7-azatryptophan leads to a significant reduction (~10-fold) in the affinity of fragment 1–47 for the *fast* form of thrombin, indicating that exchange of even a single atom (C → N) can substantially affect binding to the enzyme. These results can be explained by the lower hydrophobicity of 7-azatryptophan compared with that of tryptophan, as given by the values of octanol→water partition coefficient (logP) of indole ($logP_{indole} = 2.33$) and 7-azaindole ($logP_{azaindole} = 1.72$), determined experimentally [90].

The results of spectroscopic characterization indicate that the λ_{max} values in the absorption and fluorescence spectra of Y3AW are red-shifted by ~10 and 40 nm, respectively, compared with those of Y3W (Figure 9-6). The fluorescence spectra of Y3AW with the six Cys-residues in the fully reduced or correctly folded state are shown in Figure 9-7 and compared with those of the corresponding Y3W analog. The emission spectrum of the reduced, unfolded Y3AW reveals the presence of two distinct, well-resolved bands at 305 and 397 nm, assigned to the contribution of Tyr13 and AW at position 3, respectively. In the folded state the Tyr-band disappears, whereas the fluorescence of AW is blue-shifted to 390 nm and enhanced by about 20%. Our results can be rationalized by considering that in the reduced state, hirudin fragment 1–47 is in a random coil conformation (unpublished results), with the donor (Tyr13) and acceptor (AW3) amino acids far apart in space. In the native state, the chain folding brings Tyr13 in close proximity to AW3 and allows the energy absorbed by Tyr to be efficiently transferred to AW. In the case of Y3W, a single band at 350 nm is observed in the native state, whereas in the reduced state the contribution of Tyr13 appears as a very weak shoulder at 303 nm, overwhelmed by the stronger emission of Trp3 at 355 nm (Figure 9-7C).

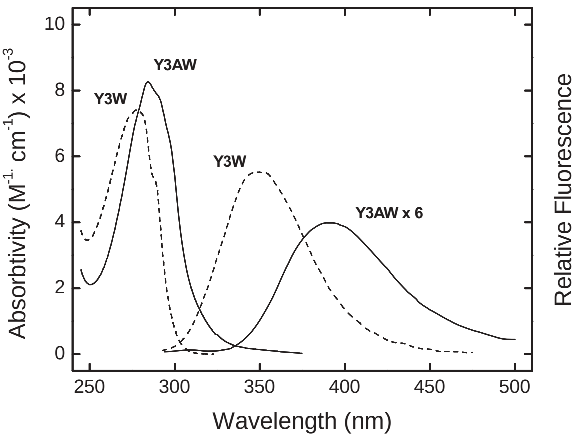


Figure 9-6. UV absorption and emission fluorescence spectra of Y3AW (—) and Y3W (--) analogs of hirudin fragment 1–47. The fluorescence spectrum of free Y3AW analog was multiplied by sixfold. All measurements were carried out at 25°C in 5-mM Tris-HCl buffer, pH 8.0, containing 0.2-M NaCl and 0.1% PEG-8000, at a protein concentration of 2 μM. Sample excitation was at 280 nm.

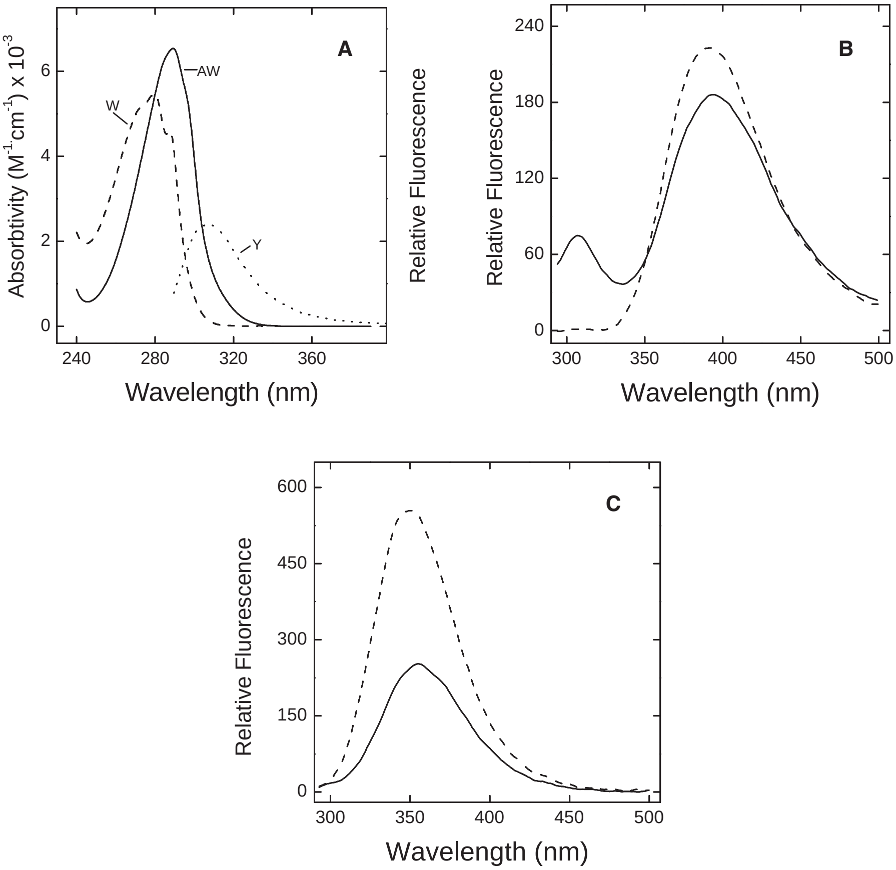

Figure 9-7. Disulfide oxidative folding of Y3AW analog monitored by fluorescence spectroscopy. (**A**) UV-absorption spectra of free tryptophan (W, --) and 7-azatryptophan (AW, —), acting as energy acceptors, and fluorescence spectrum of tyrosine (Y, ···), acting as an energy donor. Emission fluorescence spectra of Y3AW (**B**) and Y3W (**C**) in the reduced (—) and disulfide oxidized, native state (--). All spectra were taken at 25°C by exciting the samples (5 μM) at 280 nm in 0.1-M $NaHCO_3$, pH 8.3, except for that of the fully reduced form, which was recorded in 0.1-M morpholinoethane sulfonic acid buffer, pH 6.0. This pH value is sufficiently low to impair disulfide formation for at least 4 hours (not shown) and, concomitantly, avoid protonation of N^7-atom of the azaindole nucleus, which has a pK_a value of 4.5 [94].

This actually makes it difficult (if not impossible) to follow the folding process of hirudin by Tyr → Trp energy transfer measurements.

The strong dependence of the fluorescence properties of AW on solvent polarity [95] was exploited to investigate the binding of Y3AW analog to thrombin (Figure 9-8). To minimize the contribution of the nine Trp-residues present in the thrombin sequence, we excited AW at the red edge of its absorption range (320 nm), where the contribution of Trp is expected to be negligible [93]. The spectra reported in Figure 9-8 clearly indicate that the fluorescence of AW is strongly quenched upon binding to thrombin. Given the known solvent-dependent emission of AW and the apolar character of the S2/S3 binding sites of thrombin, this result is surprising. In

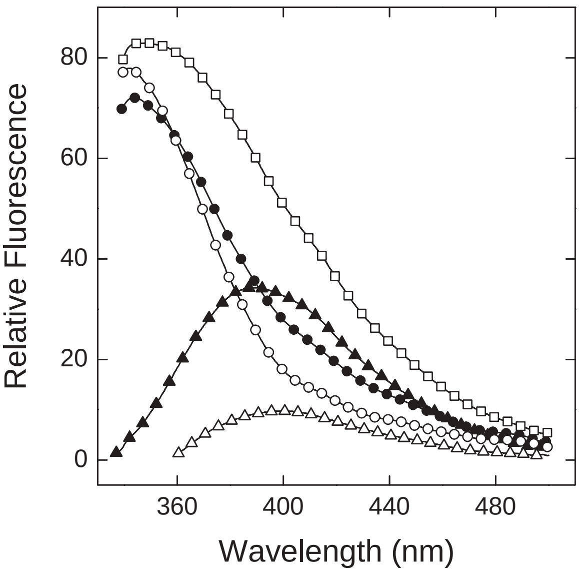

Figure 9-8. Hirudin–thrombin interaction probed by fluorescence spectroscopy. Fluorescence emission spectra of isolated thrombin (○–○) and Y3AW analog (▲–▲) and equimolar mixture of the enzyme and inhibitor (●–●). All spectra were recorded at 25°C in 5-mM Tris-HCl buffer, pH 8.0, containing 0.2-M NaCl and 0.1% PEG-8000, at a protein concentration of 2 μM, and by exciting the samples at 320 nm. Theoretical sum spectrum (□–□), obtained by adding the spectrum of free thrombin to that of the Y3AW analog. The contribution of Y3AW in the thrombin-bound form is estimated by the difference spectrum (△–△), obtained by subtracting the spectrum of isolated thrombin from that of enzyme-inhibitor complex. Given a K_d value of 60 nM for the thrombin–Y3AW complex and a concentration of enzyme and inhibitor of 2 μM, it is expected that about 20% of Y3AW remains in the free form. Notably, the intensity of the difference spectrum accounts for 25% of that of the free inhibitor, which suggests that the fluorescence of Y3AW in the complex with thrombin is almost totally quenched.

fact, we would have expected that binding of Y3AW to thrombin is accompanied by a blue-shifted emission of AW and a substantial increase in its fluorescence intensity. The fluorescence spectra of the model compound 7-azaindole (7AI) in different solvents (Figure 9-9) well document the extraordinary dependence of the fluorescence signal of 7AI on the solvent polarity, shifting from 325 nm in cyclohexane (not shown) to 345 nm in diethylether and 362 nm in acetonitrile. In particular, in water-restricted environments (e.g., water-saturated diethyl ether), the fluorescence signal is dramatically reduced, due to the formation of a 1:1 7AI-H_2O cyclic adduct that promotes formation in the excited state of a "tautomer" species that is poorly fluorescent [96–98].

In the light of these considerations, the strong quenching effect on the fluorescence of 7AW, observed upon binding of Y3AW to thrombin, can be explained on the basis of the model structure of Y3AW bound to thrombin. As shown in Figure 9-10, the –NH group of AW interacts with water molecule w432 (B-factor: 36 Å^2; occupancy: 1.0), whereas N^7 may be linked to Tyr60a through a water bridge involving the structural water molecule w606 (B-factor: 22 Å^2; occupancy: 0.52) [31].

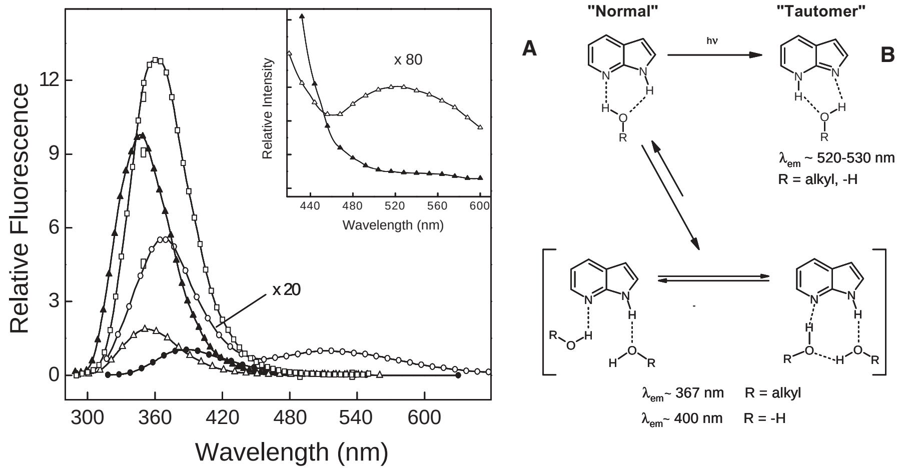

Figure 9-9. (**A**) Fluorescence emission spectra of 7-azaindole (7AI) in different solvents: acetonitrile (□–□), diethyl ether (▲–▲), *n*-propanol (○–○), water-saturated diethyl ether (△–△), and deionized water (●–●). The emission of 7AI in *n*-propanol is multiplied by 20-fold. *Inset*, fluorescence spectra of 7AI in diethyl ether (▲–▲) and water-saturated diethyl ether (△–△) expanded by a factor of 80 to show the growth of the second band at ~520 nm in organic-water solution. All spectra were recorded at 25°C and 2-μM 7AI, by exciting the samples at 280 nm. (**B**) Consensus scheme explaining the emission properties of 7AI in alcohol (R = alkyl) or water solution (R = –H). The polyhydrated species in water are more populated and emit radiation at 400 nm. In water-restricted environments (e.g., water-saturated diethyl ether), the concentration of the "normal" monohydrated species increases, and upon excitation, it is converted into the "tautomer" form, which is responsible for the longer wavelength emission at ~520 nm (*Inset* to panel **A**) [90].

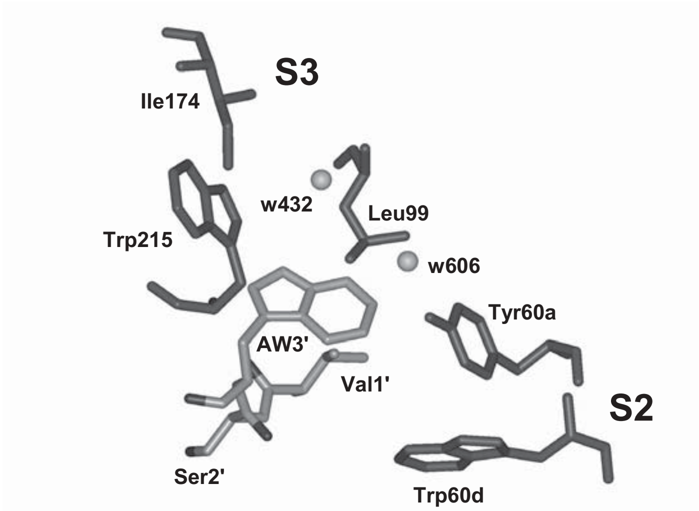

Figure 9-10. Schematic representation of the interaction of the N-terminal tripeptide of hirudin analog Y3AW with thrombin. The model structure of Y3AW was obtained by keeping the position of all atoms unchanged and using the same dihedral angles that Tyr3 has in the x-ray structure of wild-type hirudin complexed to thrombin ($\chi^1 = -61°$, $\chi^2 = -56°$, [4htc.pdb; 31]. Water molecule w432 (B-factor 36 Å^2, occupancy 1.0) is in the same plane of the azaindole ring of AW at position 3, whereas N^7 occupies the same position of the –OH group in Tyr3, which is linked to Tyr60a through a water bridge involving w606 (B-factor 22 Å^2, occupancy 0.52).

Hence, the rigid, structural water molecules at the hirudin–thrombin interface can have a crucial role in quenching the fluorescence of 7AW, because they promote the nonradiative decay of AW in the excited state more effectively than the labile water molecules solvating the 7AW in the free Y3AW analog.

In conclusion, our data demonstrate that the incorporation of 7-azatryptophan into proteins can be of broad applicability in structure-activity relationship studies, where a Trp-isostere is required, or as a spectroscopic probe in the study of protein folding and binding [90].

9.7.2 3-Nitrotyrosine

3-Nitrotyrosine (NT) is produced *in vivo* by reaction of protein tyrosines with peroxynitrite [99]. The NT side chain is only 30 Å^3 larger than the unmodified Tyr, and the presence of the electron-withdrawing nitro-group makes the phenolic hydrogen of free NT about 10^3-fold more acidic (pK_a 6.8) [100]. At pH < pK_a, where the neutral form is predominant, NT is more hydrophobic than Tyr, whereas at higher pH, where NT exists in the ionized form, it is much more polar [101, 102]. NT can form an internal hydrogen bond, and its absorption properties are strongly pH-dependent (see Figure 9-11). In particular, at basic pH, the UV/Vis spectrum

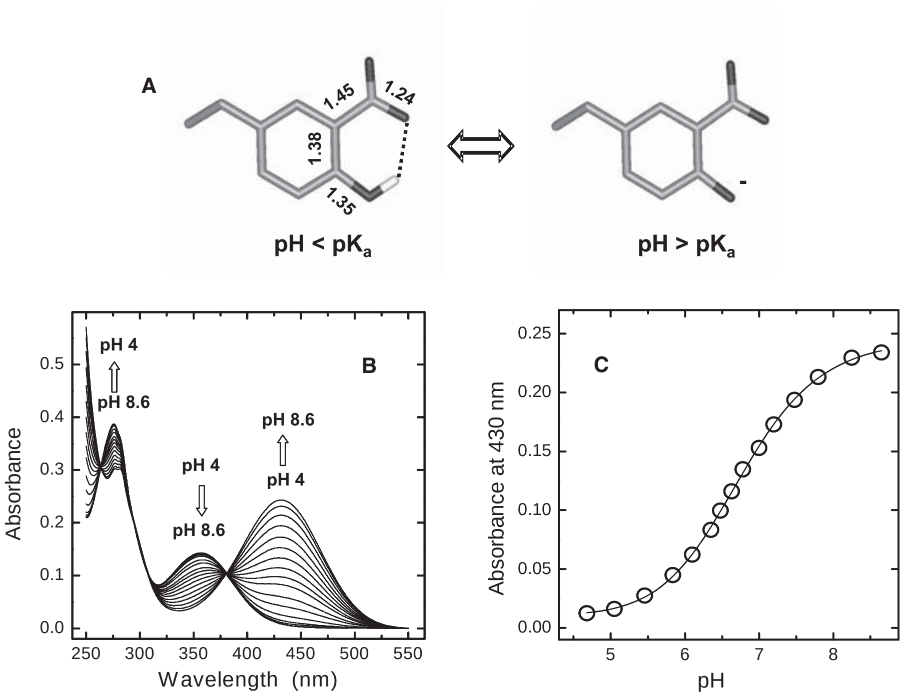

Figure 9-11. (**A**) Structure of 3-nitrotyrosine. Bond distances (Å) are taken from the crystallographic structure of free NT [103]. (**B–C**) Spectrophotometric titration of Y3NT by UV/Vis absorption spectroscopy. Absorption spectra (**B**) and plot of the absorbance values at 430 nm of Y3NT (2 mL, 48 μM) as a function of pH (**C**). Measurements were carried out in 2-mM citrate–borate–phosphate buffer, at the indicated pH. Fitting data points yields a pK_a value of 6.74 ± 0.02 for NT.

of free NT displays a major band at 422 nm, characteristic of the ionized form, whereas at acidic pH a prominent band appears at 355 nm, assigned to the contribution of the neutral form [100]. NT is essentially nonfluorescent and absorbs radiation in the wavelength range where both Tyr and Trp emit fluorescence, with a Trp-to-NT Förster's distance (i.e., the donor-acceptor distance at which the FRET efficiency is 50%) as large as 26 Å [104]. For these reasons, NT has great potential as an energy acceptor in FRET studies, and indeed, direct chemical nitration of Tyr was used to investigate the structural and folding properties of calmodulin [104] and apomyoglobin [105–107]. However, very little is known about the possibility of exploiting the unique spectral properties of NT to study molecular recognition [100, 108, 109].

Hence, we chose the hirudin–thrombin system as a suitable model for evaluating the potentialities of NT as a spectroscopic probe in the study of protein–protein interactions [91]. To this aim, we synthesized two analogs of the N-terminal domain (residues 1–47) of hirudin: Y3NT, in which Tyr3 was replaced by NT, and S2R/Y3NT, containing the cumulative substitutions Ser2→Arg and Tyr3→NT. In the presence of saturating concentrations of Y3NT or S2R/Y3NT, the fluorescence of thrombin is strongly quenched and approaches a similar value, under either *fast* (0.2-M NaCl) and *slow* (0.2-M ChCl) conditions (Figure 9-12A, B). We have demonstrated that quenching of fluorescence is mainly caused by FRET, occurring between (some of) the Trp-residues of thrombin (i.e., the donors) and the single 3-nitrotyrosine of the inhibitors (i.e., the acceptor).

FRET is a nonradiative decay process occurring between a donor and an acceptor, which interact *via* electromagnetic dipoles transferring the excitation energy of the donor to the acceptor. For a one-donor–one-acceptor system, the efficiency of energy transfer depends on the extent of spectral overlap of the emission spectrum of the donor with the absorption spectrum of the acceptor, on the donor quantum yield, on the inverse sixth power of the distance separating the donor and acceptor, and on their orientation [88]. In the case of hirudin–thrombin interaction, there is an extensive overlap of the emission spectrum of the enzyme (i.e., the donor) with the absorption spectrum of the inhibitor (i.e., the acceptor) (see Figure 9-12C). In addition, Trp-to-NT energy transfer is also favored by the relatively short distances separating Trp-residues and NT in the enzyme–inhibitor complex [31, 91]. To estimate the possible contribution of spectroscopic effects other than FRET (e.g, unspecific binding, dynamic or static quenching, inner filter effect), the fluorescence of thrombin was measured in the presence of increasing concentrations of free NT. The data reported in Figure 9-12D indicate that NT slightly (~14%) reduces the fluorescence of the enzyme, in keeping with the notion that nitro-compounds (e.g., nitromethane and nitrobenzene) quench the emission of polycyclic aromatic hydrocarbons mainly by a dynamic mechanism [110]. Moreover, we found that for concentrations of NT-containing analogs lower than 20 μM, inner filter effect can be neglected. These considerations allow us to conclude that quenching of thrombin fluorescence by Y3NT (or S2R/Y3NT) is mainly caused by Trp-to-NT energy transfer.

The quenching data reported above were used to obtain quantitative estimates (i.e., K_d values) of the binding of hirudin analogs to thrombin allosteric forms (see Figure 9-13 and Table 9-3). For both analogs, the excellent fit of the experimental data to the curve describing one-site binding mechanism is a stringent, albeit

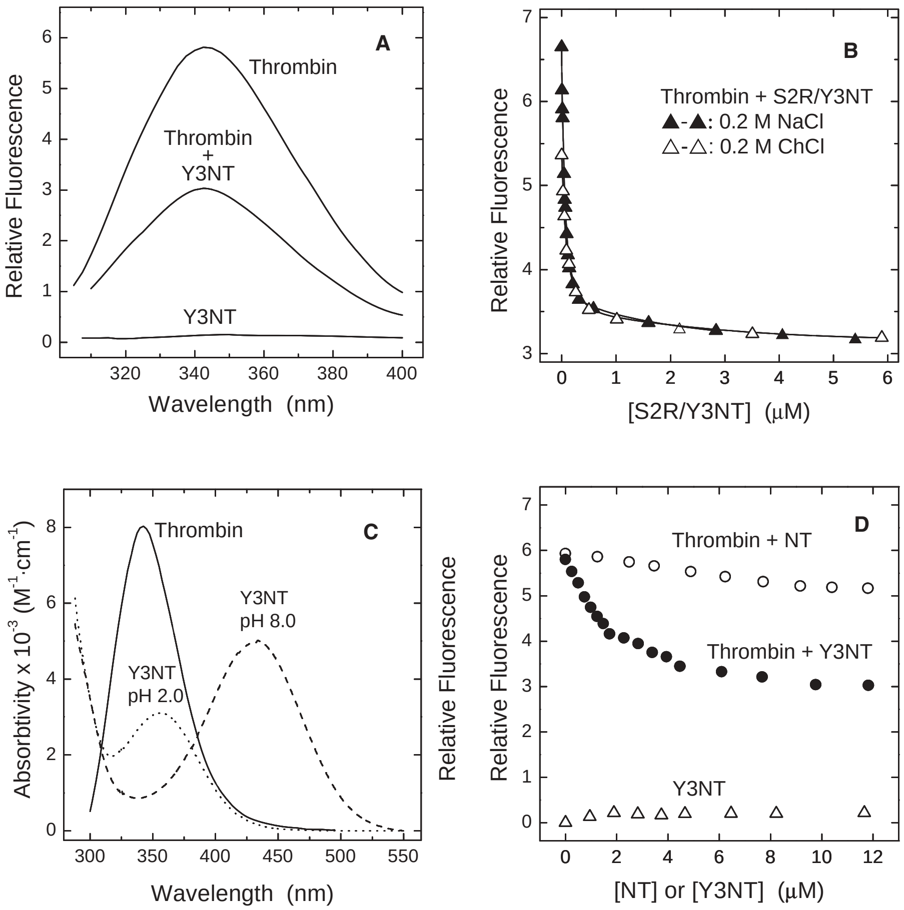

Figure 9-12. Binding of Y3NT and S2R/Y3NT to thrombin, monitored by Trp-to-NT fluorescence energy transfer. (**A**) Fluorescence spectra of thrombin alone (50 nM) and in the presence of Y3NT (10 μM). For comparison, the spectrum of the free inhibitor Y3NT (10 μM) is also reported. (**B**) Change in the fluorescence of thrombin as a function of S2R/Y3NT concentration, under fast (▲–▲, 0.2-M NaCl) and slow (△–△, 0.2-M ChCl) conditions. (**C**) Superimposition of the fluorescence spectrum of thrombin (continuous line) with the absorption spectra of Y3NT at pH 2 and 8.0 (dashed/dotted lines). (**D**) Change in thrombin fluorescence as a function of Y3NT concentration (●–●). As a control, the fluorescence intensity of thrombin in the presence of free NT (○–○) is reported. The signal of Y3NT alone (△–△) is also included. All measurements were carried out at 25°C by exciting the protein samples at 295 nm in 5-mM Tris-HCl buffer, pH 8.0, containing 0.1% (w/v) PEG 8000 and 0.2-M salt, as indicated, and recording the fluorescence signal at 342 nm.

indirect, proof of 1:1 binding stoichiometry. The replacement of Tyr3 with NT resulted in a drop in the affinity of Y3NT for thrombin, which was restored in the doubly substituted analog S2R/Y3NT by replacing Ser2 with Arg. The structural model of Y3NT bound to thrombin (see Figure 9-14), based on the crystallographic structure of the hirudin–thrombin complex [31], reveals that the $-NO_2$ group of NT might be easily accommodated into the S2 specificity site of the enzyme without

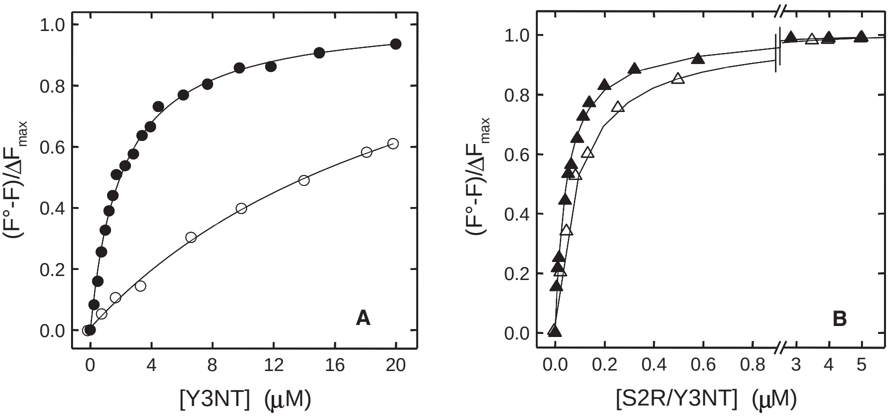

Figure 9-13. Determination of the dissociation constant (K_d) of the complexes formed by the synthetic analogs Y3NT (**A**) (●, ○) and S2R/Y3NT (**B**) (▲, △) with thrombin, under fast (filled symbols) and slow (empty symbols) conditions. Continuous lines represents the best fit of the data points to the equation describing tight binding [91], which allowed us to obtain the K_d values reported in Table 9-3.

TABLE 9-3. Thrombin Binding Data of the Synthetic Hirudin Analogs, as Obtained by Fluorescence Energy Transfer[1] and Enzyme Inhibition Assays[2]

1–47 Analogs	Fast Form		Slow Form		
	K_d (nM)	$\Delta\Delta G_b$ (kcal/mol)	K_d (nM)	$\Delta\Delta G_b$ (kcal/mol)	ΔG_c (kcal/mol)
WT[2] (Tyr3)	42 ± 0.5	—	1,460 ± 20	—	−2.10
Y3NT[1]	1,325 ± 80	2.06	17,000 ± 500	1.45	−1.51
S2R[2]	1.7 ± 0.02	−1.90	12 ± 2	−2.84	−1.16
S2R/Y3NT[1]	45 ± 2.2	0.06	91 ± 4.2	−1.64	−0.41

[1] The K_d values of Y3NT and S2R/Y3NT were obtained by fitting FRET data to the equation describing tight binding [91].

[2] The inhibitory potency of the wild-type (WT) and S2R analog was determined at 25°C by measuring at 405 nm the release of *p*-nitroanilide, *p*NA, from the synthetic substrate D-Phe-Pro-Arg-*p*NA. Additivity of mutational effects was calculated by the equation $\Delta G_I = \Delta\Delta G_b$(S2R/Y3NT) − [$\Delta\Delta G_b$(Y3NT) + $\Delta\Delta G_b$(S2R)], where ΔG_I is the free energy term that accounts for the energetic interaction between the mutated sites [9].

requiring steric distortion. Likely, the lower affinity of Y3NT reflects the lower hydrophobicity of NT at pH 8.0, where it exists by ~95% in the ionized form. With respect to this, the logP value of 2-nitrophenol, taken as a suitable model of the NT side chain, is −1.47 at pH 8.0 [101], whereas that of phenol, taken as a model of Tyr, is +1.50 [102]. Besides hydrophobicity, the presence of the nitro-group introduces a net (i.e., at pH 8.0) negative charge at position 3 of hirudin, which can oppose binding through unfavorable electrostatic interaction with the strong negative potential of the thrombin active site [111], in agreement with our previous structure-activity relationship studies [43]. The reliability of these data was verified by comparing the K_d values of Y3NT and S2R/Y3NT, obtained by FRET

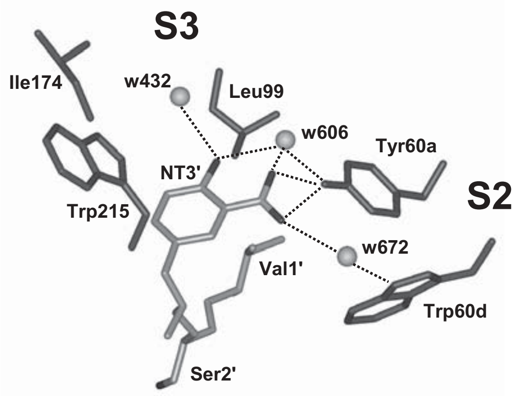

Figure 9-14. Schematic representation of the interaction of the N-terminal tripeptide of Y3NT with thrombin. The structure of Y3NT was modeled on the structure of the hirudin–thrombin complex [4htc.pdb; 31]. Relevant NT-thrombin distances, in the 2.5–3.5-Å range, are indicated by dashed lines. Of note, w606, which in the wild-type hirudin–thrombin structure connects Tyr3′ of the inhibitor to Tyr60a of the enzyme, is well suited as a hydrogen bond donor to stabilize the NT ring system [91].

measurements, with those determined by classic enzyme inhibition experiments, in which the rate of thrombin-mediated substrate hydrolysis was measured as a function of inhibitor concentration [91]. Strikingly, the K_d values for the binding of Y3NT and S2R/Y3NT to thrombin *fast* form were determined as 1.4 ± 0.1 μM and 41 ± 2 nM, respectively, in agreement (8–10%) with those obtained by FRET (Table 9-3).

The absorption spectra of S2R/Y3NT, recorded in the absence and presence of thrombin, are reported in Figure 9-15. Under *fast* conditions, the 430-nm band of S2R/Y3NT, assigned to the contribution of the ionized form of NT at pH 8.0, is reduced by 54%, whereas an additional band of similar intensity appears at about 362 nm, characteristic of NT in the neutral form. Of note, the binding of Y3NT to thrombin *fast* form yields very similar results [91]. These observations can be explained on the basis of the modeled structure of Y3NT bound to thrombin and assuming that NT interacts with the enzyme in the neutral form.

As shown in Figure 9-14, three structural water molecules at the enzyme–inhibitor interface (i.e., w432, w606, and w672), characterized by low thermal factors and high occupancy values, can variably interact with NT. In particular, w606, which in the structure of the wild-type hirudin–thrombin complex connects Tyr3′ of the inhibitor to Tyr60a of the enzyme [31], is suitably positioned as a hydrogen bond donor to stabilize the six-membered ring system of NT (see Figure 9-11A and Figure 9-14). As a result, the contribution of the protonated NT in the bound form appears as a distinct band at about 362 nm in the absorption spectrum of the thrombin–S2R/Y3NT complex (Figure 9-15). The residual intensity of the 430-nm band is contributed by the ionized form of NT in the free inhibitor that exists in equilibrium with the thrombin-bound form. Hence, we conclude that the phenate moiety of NT in the free state becomes protonated to phenol upon binding to thrombin and that a water molecule at the hirudin–thrombin interface, likely w606, functions as a

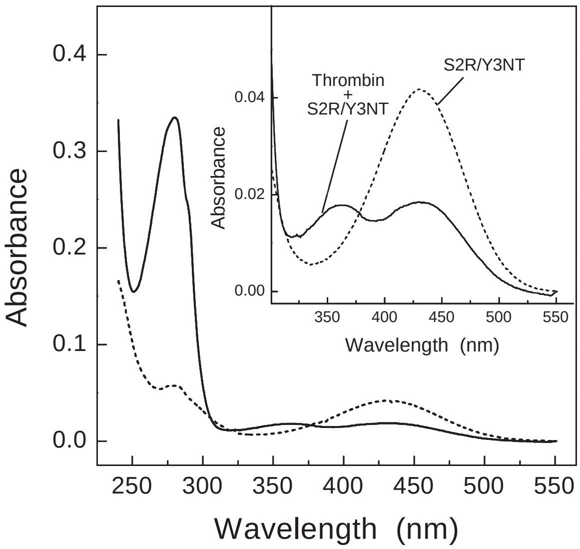

Figure 9-15. Binding of the synthetic analog S2R/Y3NT to thrombin, monitored by UV/Vis absorption spectroscopy. Spectra of the inhibitor (8.6 μM) were taken at 25° in 5-mM Tris-HCl buffer, pH 8.0, containing 0.1% PEG 8000 and 0.2 M NaCl, in the absence (--) and presence (--) of thrombin (4.1 μM). For clarity, the *Inset* shows the spectra in the wavelength range 300–550 nm.

hydrogen donor. Notably, w432 and w606 are conserved in the structure of thrombin bound to hirugen (i.e., the 53–64 peptide of hirudin) [1hah.pdb; 112], where the specificity sites of the enzyme are unoccupied, thus suggesting that these water molecules represent constant spots in the solvation shell of thrombin and, perhaps, key elements for molecular recognition, in keeping with the key role that protein–water interactions play in ligand binding [113].

Our results demonstrate that NT is a suitable spectroscopic probe for investigating ligand–protein interactions and suggest that its incorporation into proteins may have vast applications for identifying ligand–protein interaction.

9.8 CONCLUDING REMARKS

It is widely accepted that even the knowledge of the structure of the ligand–receptor complex provides only partial information for predicting ligand binding energetics [114]. In this view, we have demonstrated here that it is possible to transfer the quantitative structure-activity relationship (QSAR) approach, traditionally applied to low-molecular-weight bioactive compounds, to the study of recognition in macromolecular systems, such as the hirudin–thrombin complex. Recent advances in chemical and genetic methodologies will, hopefully, allow the researchers to extend this approach to other protein systems of relevant pharmacological application. Moreover, we have shown that incorporation of noncoded amino acids, possessing peculiar spectroscopic properties, can have great potentialities in biotechnology and pharmacological screening.

ACKNOWLEDGMENT

This work was supported by grants PRIN-2003 and PRIN-2005 from the Italian Ministry of University and Scientific Research. I would like to thank Prof. Angelo Fontana for stimulating discussions. The support of Dr. Olmetta Iadicicco is also gratefully acknowledged.

10.1.1 GENE THERAPY

10.1.1.1 Milestones

Gene therapy is a conceptually simple and attractive process, which consists of the introduction of one or more functional genes in a human/non-human receptor (*in vivo*, *in situ*, or *ex vivo*). It constitutes a promising alternative for the treatment, diagnosis, or cure of genetic defects such as cystic fibrosis [1] or acquired diseases like cancer [2] and AIDS [3]. DNA vaccines can also be developed on the basis of genes [4] to provide immunity against infectious agents (e.g., malaria [5]) or treat noninfectious diseases such as tumors and allergies [6].

Although gene therapy is a recent endeavor of the human mind, it has nevertheless come a long way since the early, nonauthorized administration of Shope papilloma virus to argininemia-suffering patients by Stanfield Rogers et al. [7, 8] (Table 10.1-1). Despite the flawed design and consequent failure of this clinical trial, Rogers was one of the first scientists to anticipate the therapeutic potential of viruses as carriers of genetic information [8]. The first federally approved gene therapy clinical trials took place in 1990 when an adenosine deaminase (ADA)-deficient patient was given her own T cells engineered with a retroviral vector carrying a normal ADA gene [9]. This experiment paved the way for further clinical trials. In 1993 an adenovirus vector (AdV) was first used in a clinical trial designed to evaluate the potential of direct transfer of cystic fibrosis transmembrane conductance regulator (CFTR) cDNA in the treatment of cystic fibrosis (CF) [10].

TABLE 10.1-1. Gene Therapy Milestones

Year	Vector	Target Disease	Comments	Reference
1970	Shope virus	Argininemia	First human trial, unauthorized	[7, 8]
1990	Retrovirus	ADA-SCID	First federally approved human trial	[9]
1993	Adenovirus	Cystic fibrosis	First clinical trial with an adenovirus vector	[10]
1999	Adenovirus	OTC deficiency	Death of patient due to an adverse reaction to the adenovirus vector	[11, 12]
2000	Retrovirus	SCID-X1 syndrome	Apparent clinical cure of two recipients	[13]
2003	Retrovirus	SCID-X1 syndrome	Development of leukemia-like syndrome in recipients due to retrovirus integration	[14]
2004	Adenovirus	Head and neck carcinoma	The first human GT product, Gendicine, received approval from the Chinese FDA	[15]

Abbreviations: ADA = adenosine deaminase; OTC = ornythine transcarbamylase; SCID = severe combined immunodeficiency.

The first setback faced by gene therapy came in 1999 when a patient suffering from ornithine transcarbamylase (OTC) deficiency died after administration of an adenovirus vector encoding OTC [11, 12]. The year 2000 saw gene therapy's first major success: A gene therapy protocol could correct the phenotype of an X-linked severe combined immunodeficiency (SCID-X1) syndrome in two patients who had been re-infused with autologous CD34 bone marrow cells transduced *ex vivo* with a retrovirus vector encoding the γC receptor gene [13]. These successes were later shadowed by the development of leukemia-like syndrome in recipients of the treatment as a consequence of retrovirus integration in proximity to the LMO2 proto-oncogene promoter [14]. In October 16, 2003, a recombinant adenovirus vector expressing the tumor-suppressor gene p53 was approved by the State Food and Drug Administration (SFDA) of China for the treatment of head and neck squamous cell carcinoma [15–17]. Developed and manufactured by Shenzen SiBiono GeneTech (China) and trademarked under the name Gendicine, it became the first human gene therapy product to reach the market in April 2004 [15]. As of September 2005, 2600 patients had been treated with Gendicine, with projections estimating 50,000 patients to receive the product by 2006 [18].

10.1.1.2 Vectors

The transport of the therapeutic transgenes toward the nuclei of the target cells can be carried out both by viral [19] and nonviral vectors such as plasmid DNA [20]. Plasmid DNA molecules are extra-chromosomal carriers of genetic information that have the ability to replicate autonomously. These vectors constitute an attractive gene transfer system because they are safer and easier to produce when compared with viral vectors [20–22]. However, plasmid DNA vectors are less effective in transfecting cells when compared with viral vectors, which have a natural ability to deliver and express their genes in a wide variety of cell types and tissues [11, 23].

The major drawback of viral vectors is undoubtedly related to safety aspects. When confronted with viral vector particles, the human immune system, which has evolved to tackle wild-type infections, will likewise generate an immune response [19]. The potency and severity of this response can ultimately lead to death, as occurred in the 1999 OTC gene therapy clinical trial (Table 10.1-1) [12]. Thus, a safe and effective use of viral vectors in gene therapy requires the modification of natural viruses to impair replication and expression of viral proteins and thus minimize toxicity and immunogenicity [19]. The infection pathway of these recombinant viral vectors should of course remain unaltered. Further goals of virus modification are to provide room in the viral genome for transgenes, to modulate transgene expression, and to improve the selectivity of infection.

Most recombinant viral vectors used in gene therapy clinical trials belong to one of the following categories (Figure 10.1-1): (1) adenovirus, (2) retrovirus/lentivirus, (3) pox/vaccinia virus, (4) adeno-associated virus (AAV), and (5) herpes simplex-1 virus (HSV-1). According to the data provided in the *Journal of Gene Medicine Database* (Wiley Database, http://www.wiley.co.uk/genmed/clinical/) and updated in July 2005, 25% of the total 1076 gene therapy clinical trials were using AdVs (Figure 10.1-1). The popularity and high expectations generated toward AdVs is well expressed by the fact that both the first gene therapy tragedy and success used adenovirus to deliver transgenes (Table 10.1-1).

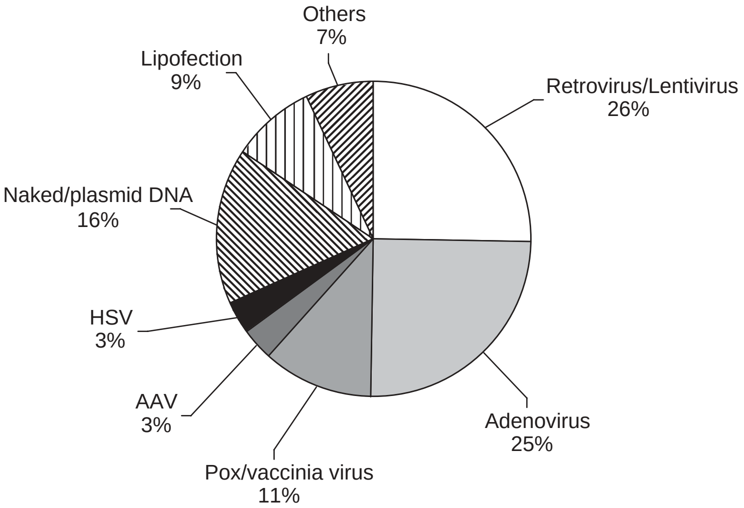

Figure 10.1-1. Breakdown of gene therapy clinical trials in terms of vector type ($N = 1076$) (source http://www.wiley.co.uk/genmed/clinical/, July 2005). Abbreviations: AAV—adeno-associated virus; HSV—herpes simplex virus.

TABLE 10.1-2. Characteristics of Adenoviruses Relevant for Human Gene Therapy Applications

Efficient transduction of a large variety of quiescent and actively dividing cells
Relatively high capacity for transgene insertion
Convenient and simple methods of vector construction
Ability to replicate at high titers in complementing cell lines
High stability, which allows efficient purification and long-term storage
Biology has been extensively studied and is well understood
Transient transgene expression due to episomal location of viral genome
Immunogenicity
Insert-size limit of 7.5 kb

10.1.2 ADENOVIRUS IN GENE THERAPY

10.1.2.1 Introduction

Adenoviruses were discovered in cultures of human adenoids in 1953 by Rowe et al. [24] and have since then been implicated in several respiratory, ocular, and gastrointestinal human diseases [25, 26]. Nonhuman adenoviruses have also been found in many other mammalian (dogs, horses, sheeps, chimpanzees, etc.) and nonmammalian (ducks, fowl, geese, etc.) species [26]. Overall, more than 100 members have been included in the *Adenoviridae* family. This section will only give a brief description of the major characteristics of the adenovirus and its vectors because this topic has been covered in depth in several recent reviews [26–31].

The extensive studies that followed the discovery of adenoviruses unveiled many features that make them a popular gene delivery vector (Table 10.1-2) [11, 26, 32]. For instance, adenoviruses are extremely efficient in the transduction of both

quiescent and actively dividing cells in most tissues [19, 26] and their genome can be manipulated easily to generate recombinant adenoviruses with improved properties. It is also possible to propagate them to high titers, and thus, it becomes relatively easy to generate sufficient amounts for research purposes and small-scale clinical trials [26]. On the down side, adenoviruses can generate potent immunogenic reactions in human recipients [28], although in some instances this immunogenicity may enhance antitumor effects [19] and vaccination efficiency [33]. Furthermore, and because adenoviruses persist in the nucleus of transduced cells as extra-chromosomal episomes, the expression of transgenes is transient [19, 26].

10.1.2.2 Biology and Properties

The 51 distinct serotypes of human adenovirus (Ad1 to Ad51) are classified into six groups (A to F) on the basis of sequence homology and hemagglutination properties [25]. Most AdVs used in gene therapy are derived from serotype 2 (Ad2) and 5 (Ad5) of the subgroup C [26]. The efficacy of Ad2 and Ad5 derived vectors, however, may be limited by the preexistence of humoral and/or cellular immunity to these serotypes in most human populations. Thus, other serotypes such as Ad11 and Ad35 to which most humans do not have neutralizing antibodies may be clinically useful [34, 35]. The antivector immunity may also be circumvented by the physical shielding of the adenovirus coat and the use of nonhuman adenovirus serotypes [36].

Adenoviruses are nonenveloped viruses with 26- to 45-kbp-long linear genomes of double-stranded DNA (the genome of human Ad2 comprises 35,937 base pairs) [37]. The genome is encapsidated in an icosahedral protein coat (12 vertices, 20 surfaces) made essentially of 240 nonvertex hexons and 12 vertex pentons, each with one or two protruding fibers (Figures 10.1-2 and 10.1-3). Each hexon protein is a trimer of the identical polypeptide II (pII), and each penton protein is formed by the interaction of five polypeptides (pIII). These pentons are tightly associated with one or two fibers made of three polypeptides (pIVs) each [37]. Overall, the fiber protein is composed of an N-terminal tail for penton binding, a rigid shaft, and a distal globular knob domain responsible for interaction with host cell receptors [38, 39]. The net charge of each hexon monomer in the Ad5 serotype is −23.8. This makes adenoviral capsids highly negative with an overall surface charge of over −17,000 [40, 41]. Other minor protein components can be found in the capsid, including protein IIIa, VI, VIII, and IX [37]. The size of the adenovirus particle is around 70–110 nm, and its molecular weight falls within the range $150–180 \times 10^6$ [39]. The buoyant density of an adenoviral particle in CsCl is 1.32–1.35 $g\,cm^{-3}$ [39]. Assuming a 170×10^6 MW and a 35,937-bp-long genome [42], the protein and DNA content of one Ad2 viral particle (VP) can be estimated to be 24×10^{-5} (86% of dry weight) and 4×10^{-5} (14% of dry weight) pg/VP, respectively. The corresponding water content, if a 100-nm viral particle is assumed, is approximately 60%.

The core of an adenoviral particle consists of the DNA genome complexed with four polypeptides (pV, pVII, mu, TP). Figure 10.1-4 schematically shows the structure of an adenovirus genome. The extremities contain inverted terminal repeat (ITR) sequences (100–140 bp), covalently linked to terminal proteins (TPs), which function as replication origins [23]. The nearby ψ sequence at the left end of the

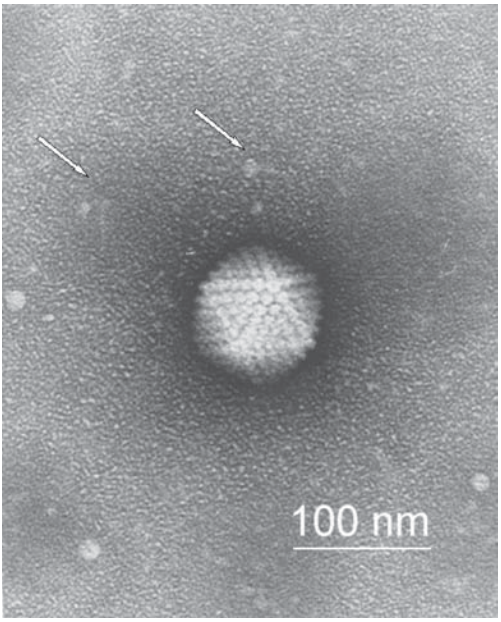

Figure 10.1-2. Human adenovirus C. The bar represents 100 nm. The arrows, upper left, point to fiber knobs. (Micrograph reprinted with authorization from Dr. H.-W. Ackermann, Department of Microbiology Medical Faculty Laval University, Quebec, Canada.)

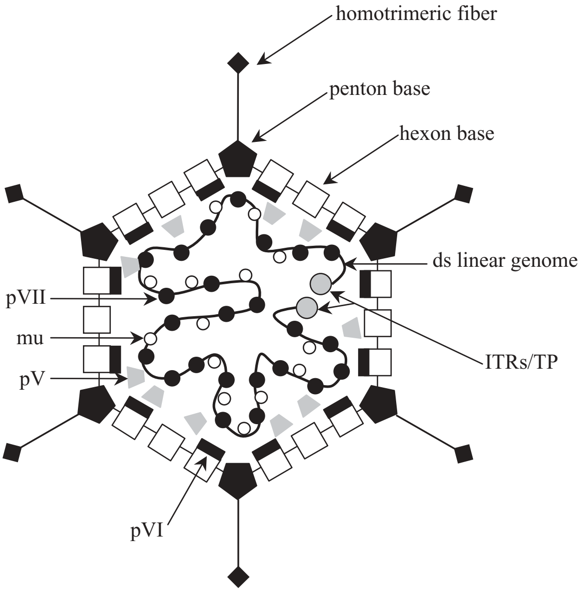

Figure 10.1-3. Schematic structure of an adenovirus particle. Major capsid (hexon, penton, fiber) and core (pV, pVII, Mu) proteins are shown. Abbreviation: ITR—inverted terminal repeat; TP—terminal protein. (Adapted from Ref. 27.)

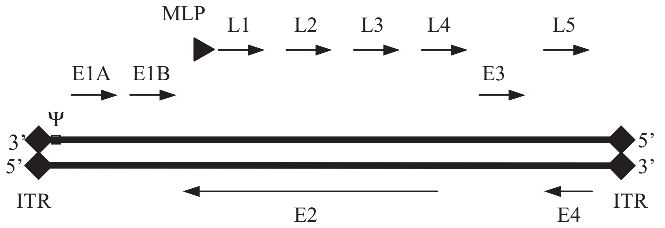

Figure 10.1-4. The adenovirus genome. The early (E1–E4) and late (L1–L5) transcription units are identified by the arrows. The inverted terminal repeats (ITRs), packaging sequence (ψ), and major late promoter (MLP) are also shown. (Adapted from Ref. 26.)

genome consists of a series of seven repeats and is required for efficient packaging [26]. The genes in both strands are grouped into early and late transcriptional units. The basis of this classification is the two-phase infectious cycle (30–40 h), which is characteristic of adenoviruses. In the "early" phase, the virus particles enter the host cell through binding of the homotrimeric protruding fibers to the coxsackievirus B and adenovirus receptor (CAR) [26]. After endosomal uptake, release, and capsid dismantling, the viral genome is transported and delivered to the nucleus [38]. The early genes E1 to E5 are then selectively transcribed and translated to modulate functions of the host cell and thus create an optimal environment for virus replication [26]. Specifically, this involves driving the host cell into S-phase (E1A gene), suppressing the host's cell apoptotic machinery (E1B gene), modifying the host's immunological environment (E3 gene), encoding proteins for viral DNA replication (E2 gene), and blocking cellular protein synthesis [43].

The "late" phase of the infectious cycle involves the synthesis of structural proteins of the virus, capsid assembly, genome encapsidation, and maturation of fully infectious viral particles. These events are associated with the transcription and translation of the "late" genes L1 to L5 [26, 27]. A key player in the transcription of the late genes is the major late promoter (MLP), which is activated early on via the E2 gene [27, 29].

10.1.2.3 Recombinant Adenovirus Vectors

A safe and effective use of AdVs requires the engineering of natural viruses into useful recombinant adenovirus vectors by using molecular biology tools [26]. These modifications are essentially designed to: (1) impair replication and expression of viral proteins and thus minimize toxicity and immunogenicity [19], (2) provide room in the viral genome for the therapeutic transgenes, and (3) modulate transgene expression. Once these recombinant vectors are available, transgenes can be inserted in their genome. In many cases, tissue- and cell-specific heterologous promoters are inserted along side to provide better expression [27, 29].

First-Generation Vectors. Most first-generation AdVs have been constructed by deleting the viral early gene E1 (Figure 10.1-5). The goal underlying this deletion is to impair viral replication and production of capsid proteins and thus prevent the vectors from causing disease in the gene therapy recipient [27]. Simultaneously, room is made for transgenes up to 6.5 kb, which are usually expressed under the

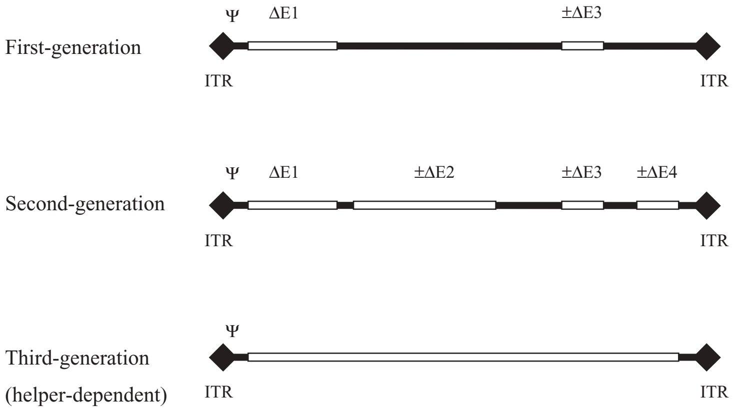

Figure 10.1-5. The three generations of adenovirus vectors. (A) First-generation vectors lack the E1 and sometimes the nonessential E3 region. (B) Second-generation vectors contain additional deletions of the E2 or E4 region. (C) Third-generation or "gutless" vectors are constructed by removing all or most viral genes and maintaining the *cis*-acting elements ITR and ψ. (Adapted from Ref. 26.)

control of an heterologous promoter [27]. The propagation of these E1 replication defective vectors can only be accomplished in complementing cells lines such as the human embryonic kidney 293 (HEK-293) [44] or the human retinoblast (PER.C6) [45]. These cells are transformed with the E1 gene and therefore transcomplement its deficiency in the recombinant vectors.

First-generation AdVs are characterized by several problems. For instance, recombination between the replication-defective virus and the E1 sequences in the complementing HEK-293 cell line can occur during propagation, giving rise to replication-competent adenoviruses (RCA) that will contaminate the recombinant virus being produced [26]. This problem has been circumvented in the PER.C6 cell line in which a rational design of the E1 transgene prevents generation of RCAs [45]. Another problem with first-generation vectors is that despite the deletion of the E1 gene, viral protein expression is not completely shut off. The concomitant low level of viral replication taking place in the transduced host cells, thus, can generate a cytotoxic-T lymphocyte (CTL) immune response that in the end will destroy the transgene-expressing cells and contribute to gene silencing [26]. Despite this residual immunogenicity, first-generation vectors may find application in cases such as cancer therapy and vaccination where a short-term transgene expression is desirable [26]. It is worth mentioning that the transgene product itself, depending on its own intrinsic immunogenicity, can also trigger a cellular immune response capable of destroying the transduced cells [29]. However, the magnitude and nature of this immune response seems to vary considerably depending on the specific transgene product being expressed [46].

Second-Generation Vectors. Second-generation AdVs have been constructed by additionally deleting the viral regulatory E2 and/or E4 coding sequences (Figure 10.1-5), on the expectation that progressive deletions should reduce viral antigen expression, increase *in vivo* persistence, and reduce antiviral immune response

[47]. The E2 gene encodes proteins that are required for initiation and elongation of viral DNA synthesis and the activation of the MLP, whereas E4 encodes proteins involved in the accumulation, splicing, and transport of early and late viral mRNA and in DNA replication and virus particle assembly [47]. As in the first generation, complementing cell lines able to express the missing functions must be generated and isolated to ensure propagation of the recombinant viruses. The HEK-293 cell line can be conveniently adapted to this end [48]. A first advantage of these doubly deleted vectors is the reduced probability of the emergence of RCAs, because this would require simultaneous reversions in the E1 and E2 or E4 regions [47]. Several studies with E1/E2 and E1/E4 deleted vectors have shown reduced synthesis of viral proteins, extended transgene expression, and reduced toxicity [49–51]. Other studies, however, have challenged these results [47].

Third-Generation Vectors. A third generation of AdVs has been further developed by deleting most or virtually all viral genes in the genome (Figure 10.1-5) [52–55]. These gutless or helper-dependent vectors can accommodate inserts up to 30 kbp and have shown reduced immunogenicity and prolonged transgene expression in mice [55]. The reduced immunogenicity still observed should be attributed either to the injected viral proteins or to the transgene product [29]. Growth of helper-dependent vectors depends on coinfection of an E1-complementing cell line such as HEK-293 by an E1-deleted helper virus (hence, the name helper-dependent) that provides missing replication and assembly functions *in trans* [26, 52]. The simultaneous propagation of the helper virus can be limited by resorting to a Cre-lox mechanism that allows the packaging sequence to be deleted [53]. In short, the helper genome is provided with loxP-sites that flank the ψ signal, whereas complementing 293 cells are engineered to stably express the enzyme Cre-recombinase. During infection, Cre-recombinase excises the loxP-flanked signal rendering the helper genome unpackable [29]. Nevertheless, the two types of viral particles (helper-dependent and helper) must be separated after propagation, a task that is difficult to accomplish [52].

Oncolytic Adenoviruses. A class of AdVs has been developed to specifically kill cancer cells, an approach that has been termed virotherapy [56]. Contrary to the approach pursued with first-, second-, and third-generation adenovirus vectors, these oncolytic or conditionally replicating adenoviruses (CRAds) are engineered in such a way that they retain the ability to replicate. This replication however, is tumor selective—the virus will only infect and proli-ferate in malignant cells with mutations in specific tumor suppressor genes [2, 19, 56]. Thus, a transgene is actually not required for the therapeutic effect to take place.

10.1.2.4 Targeting Strategies

Several therapeutically relevant human cells (e.g., skeletal and smooth muscle cells, endothelial cells, hematopoietic cells, and some tumor cells) are not easily transduced by adenovirus vectors due to low or inexistent levels of expression of the CAR receptor. On the other hand, the broad tropism of adenoviruses may lead to the undesirable expression of the transgene in nontarget cells. Thus, an improvement in the transduction selectivity of existing adenovirus vectors is crucial to

circumvent these limitations and improve efficacy in many clinical applications. The following strategies have been devised to meet this end: (1) structural retargeting, (2) tropism ablation, and (3) transcriptional targeting [38].

Structural targeting relies on the structural modification of the adenoviral capsid by genetic incorporation of peptides [57], IgG-binding domains [58], and fiber proteins from other serotypes [59], metabolic biotinylation [60], and PEGylation [61]. These ligands are selected or designed to direct vector attachment to alternative cell receptors in CAR-deficient cells [38]. The goal of tropism ablation, on the other hand, is to reduce transduction of nontarget, CAR-expressing cells. This "de-targeting" strategy can be accomplished by constructing "knobless" vectors or by introducing point mutations in the fiber protein knob [30, 38]. The capsid of these mutant vectors is then modified with ligands (e.g., peptides) adequate for transduction of the target cells (retargeting) [62–64].

In transcriptional targeting, cell-type-specific promoters are used to restrict transgene expression to specific tissues. The adenoviral particles may infect different cells, but the transgene is expressed only in those cells that actively express transcription factors required to drive expression from the cell-specific promoter [19, 33]. For instance, this approach has been used in the context of adenoviral-mediated treatment of gastrointestinal cancer [65]. This application has been limited by the undesirable expression of the transgene (which codes for HSVtk-herpes simplex virus thymidine kinase) in the liver due to the vector hepatotropism. Thus, the transgene was placed under the control of the cyclooxygenase-2 (cox-2) promoter, which is inactive in liver cells but active in many gastrointestinal cancers. Experiments showed that the cox-2 promoter could confine the cytocidal effect of HSVtk specifically to cyclooxygenase-2-positive gastrointestinal cancer, while mitigating the otherwise fatal hepatotoxicity [65].

10.1.2.5 Applications

Most adenovirus vector applications and clinical trials described and reported in the literature have targeted genetic diseases and cancer. This section will briefly mention the most significant applications. The reader is directed to several reviews for a more comprehensive description of applications [2, 19, 27, 33, 56, 66].

Genetic Diseases. In the case of genetic diseases, the transgene encodes a protein that is missing or is defective in the host organism. A typical and well-studied example is cystic fibrosis, the first human disease targeted in an adenovirus gene therapy clinical trial [10]. Cystic fibrosis is an inherited, recessive disease caused by a variety of mutations in the gene encoding the CFTR protein [1, 67, 68]. Although multiple organs are affected, the lung is the life-threatening organ [25]. The virus-vector mediated shuttling of a normal copy of the CFTR gene toward the affected lung cells could potentially prevent the onset, or halt the progression, of the disease. The choice of adenoviruses as CFTR gene delivery vectors is logical given their natural ability to infect lung cells. Nevertheless, barriers such as the lack of CARs in airway epithelial cells and alveolar macrophages, and the specific pulmonary-associated T-helper cell response, have prevented a successful transgene expression [27]. Significantly, all clinical trials currently under way involving AdVs and directed toward genetic diseases target cystic fibrosis (*Journal of Gene Medicine Database*, http://www.wiley.co.uk/genmed/clinical/).

Adenoviral gene therapy has also targeted muscular dystrophy, a genetic disease characterized by progressive muscle weakness [69]. Muscular dystrophy is caused by mutations in the X-linked dystrophin gene (DMD), which lead to prematurely aborted dystrophin synthesis. The lack of this important structural protein in muscle cells causes fiber damage and membrane leakage. In this context, gene therapy attempts to deliver a dystrophin expression vector to the nuclei of striated muscle cells. Given the huge size of the DMD gene (2.6 Mb), mini-gene cassettes (14 kb) have been generated that are capable of expressing therapeutic levels of a functional dystrophin protein [70]. Nevertheless, vectors with a capacity large enough to accommodate the 14-kb dystrophin cDNA are still required. Unlike first- and second-generation AdVs that are limited to 7–8-kb transgenes, third-generation adenovirus vectors adequately meet this requirement. The use of such vectors has resulted in a prolonged expression of the transgene in mice muscle cells [55, 69, 70]. Despite these promising results, barriers such as the lack of adenovirus receptors in the target muscle cells and potent immune response have to be overcome before a therapeutic use is developed [27, 69]. Further examples of the application of AdVs to treat genetic diseases include OTC deficiency, factor VIII deficiency, Tay-Sachs disease, and glycogen storage disease II [27].

Cancer. Different strategies have been pursued in an attempt to treat cancer via gene therapy, by taking advantage of molecular differences between normal and tumor cells [2, 27, 33]. Once transferred to the target cells, expression of the transgene delivers the antitumor effect. Clinical data suggest excellent safety when AdVs are injected locally. Synergistic effects with treatment options such as radiotherapy and chemotherapy have further improved the efficacy of cancer gene therapy [33]. Most efforts have relied on one of the following approaches: (1) tumor suppression, (2) suicide therapy, (3) cancer vaccination, and (4) virotherapy.

The tumor suppression approach attempts to induce apoptosis by delivering a tumor suppressor gene that is missing or defective in the tumor cells [2]. On the contrary, normal cells infected by the tumor suppressor delivery vector will not be detrimentally affected. The approach is perfectly illustrated with p53, a gene whose mutations have been associated with several tumors. The delivery of wild-type p53 gene efficiently induces apoptosis in cells of different tumors, as demonstrated in several phase I and II clinical trials [43, 71]. Additionally, this toxic effect can extend to neighbor, uninfected tumor cells, a phenomenon known as the “bystander effect”. This effect has been attributed to the ability of p53 to block angiogenesis [2]. Combination of p53 with immunomodulatory genes, cytotoxic drugs, or radiotherapy may further improve efficacy [2, 27]. Recombinant adenoviruses encoding the p53 gene have been used to treat more than 20 kinds of cancer indications, including head and neck squamous cell carcinoma, lung cancer, breast cancer, and liver cancer [15]. Studies have focused both on the effect of adenoviral gene therapy alone or in combination with conventional therapies such as chemotherapy, radiotherapy, and surgery [15]. The efficiency of the adenovirus/p53 strategy is well illustrated with the results of a phase II/III clinical trial using the commercial product Gendicine. In this study, 135 patients with head and neck squamous cell carcinoma were divided into two groups. The first group (63) received Gendicine in combination with radiotherapy, whereas the second group (72) received

radiotherapy alone. Significant difference in terms of complete or partial tumor regression was shown between the two groups, with 93% of the patients responding in the Gendicine/radiotherapy group *versus* 79% in the radiotherapy group [15].

The second approach used to kill tumor cells is suicide gene therapy, which combines the delivery of suicide transgenes with the separate administration of a harmless prodrug. Once reaching the target cancer cells, the suicide gene expresses an enzyme that metabolizes the prodrug into a cytotoxic agent that kills cells. The diffusion of the cytotoxic agent into neighbor cells further generates a "bystander" effect that increases the efficacy of the strategy [2, 27]. An example of such a transgene/prodrug combination that has been tested in the clinic is herpes simplex virus thymidine kinase (HSVtk)/ganciclovir [2, 27, 33]. The suicide HSVtk transgene is first delivered to cancer cells, for example, via AdVs. The administered ganciclovir is then metabolized by the expressed HSVtk into ganciclovir triphosphate, a nucleotide analoge that blocks DNA synthesis [72–75]. When a DNA strand incorporates this analoge, chain termination results and cells die upon induction of apoptosis [76]. This effect is, of course, more pronounced in tumor cells, which divide much more actively when compared with native cells. Another feature that contributes to the attractiveness of the approach is the use of a drug such as Ganciclovir that is widely used clinically [76]. Another example of suicide cancer therapy is the combined use of *Escherichia coli* cytosine deaminase (CD) with the prodrug 5-fluorocytosine. In this case, 5-fluorocytosine is metabolized by the expressed CD into 5-fluorouracil, a pyrimidine antagonist that blocks DNA and RNA synthesis [2]. The subsequent direct and bystander inhibitory effect can be enhanced further by combination with radiotherapy [77, 78].

Cancer can also be treated by the adenovirus-mediated delivery of transgenes to tumor cells with the goal of boosting antitumor immunity [27]. These adenoviral "cancer vaccines" can harbor either immunomodulatory genes (e.g., IL2 or IL12) and/or tumor antigens (e.g., MART 1 or gp 100 melanoma antigens), which once expressed should induce tumor regression. Human dendritic cells isolated from patients have also been transduced with AdVs designed to express tumor antigens. The therapeutic effect is achieved after reinfusion of the transformed cells [27].

Virotherapy constitutes a fourth approach that has been attempted clinically to treat cancer. The oncolytic vector Onyx-015 (previously d-1042) is a characteristic example of virotherapy. The mode of action can be explained as follows. Both adenoviruses and tumor cells need to block the p53 function to replicate. In normal cells the intact p53 function blocks replication of the Onyx-015 vector [2, 19, 56]. In tumor cells, however, and because the p53 gene is mutated, infection with the adenovirus vector Onyx-015 is followed by replication and cell destruction. Furthermore, because after cell destruction an increased number of viral particles is released, the infection/propagation/cell death process can continue in neighbor cells [43]. This approach has been tested in several phase I and phase II clinical trials as described in Ref. 43. In one phase II study, the intratumoural injection of Onyx-015 combined with chemotherapy resulted in an 83% tumor response in head and neck cancer patients [79]. The efficacy of oncolytic vectors can be further improved by resorting to transductional targeting, such has the genetic insertion of an integrin binding RGD-4C motif in the fiber proteins of the vector. This modification resulted in enhanced infectivity in ovarian cancer cells, which suggests improvements in clinical efficacy [33].

10.1.2.6 Safety Aspects

Adenovirus infection triggers both cellular and humoral responses. Viral proteins (either synthesized *de novo* or not) are processed by antigen-presenting cells and presented to CD8+ T cells (by means of MHC class I molecules) and CD4+ T-helper cells (by means of MHC class II molecules). This induces proliferation of cytotoxic T lymphocytes that specifically destroy the infected cells. CD4+ T-helper cells are also involved in the production of adenovirus-specific neutralizing antibodies directed toward the virus capsid [29]. The risks associated with this immunogenicity have been vividly demonstrated by the death of a patient in the 1999 OTC clinical trial. After the direct administration of a high dose of the adenoviral vector (3.8×10^{13} viral particles) to the liver, wide dissemination into the circulation triggered a massive activation of innate immunity followed by systemic inflammation that led to fever, intravascular coagulation, and multiorgan failure [19]. Responsibility for eliciting the immune response was attributed to viral capsid proteins rather than the transgene [19]. In subsequent years, a wealth of evidence accumulated confirming that AdVs may induce harmful immune and inflammatory responses, especially when large doses are administered systemically [19]. Adverse effects to adenovirus administration, however, may vary from individual to individual and depend on predisposing and underlying conditions [19].

The improvement of safety through minimization of toxicity and immunogenicity has been one of the major drivers in the development of recombinant AdVs. Nevertheless, even when third-generation "gutless" vectors are used, reduced immunogenicity due to the injected viral capsid proteins or to the transgene product is still observed [29, 55]. Thus, a need exists for the development of safe and effective methods capable of downregulating the host immune response against both adenoviral capsid proteins and transgene products. For instance, conventional immunosuppressive agents such as cyclosporine and FK506 may partially reduce immune responses and thus increase transduction and long-term transgene expression [46]. However, low doses of these agents must be used to prevent substantial organ toxicity. Improved results have been obtained by combining the use of immunomodulatory immunoglobulins and immunosuppressive agents. With this strategy, the immune response against adenovirus proteins and the transgene product dystrophin has been abrogated to a degree not achievable with the use of either agent alone [46].

Another problem associated with immunity to AdVs is the generation of memory cells. Upon subsequent administration of the same vector, the immune response is boosted by these cells, effectively reducing the efficacy of the repeated dosing [11].

10.1.3 ADENOVIRUS MANUFACTURING

The increasing number of adenoviral gene therapy applications that are moving from the laboratory to the clinic is creating a need for large amounts of highly purified recombinant AdVs. This demand is expected to increase as the first products reach the market. Thus, there is a clear need for a parallel development of efficient, scalable, and reproducible adenovirus manufacturing processes capable of delivering high amounts of infective AdV particles [80].

10.1.3.1 GMPs and Validation

Recombinant AdVs, such as all products that are to be administered to humans or animals, must be manufactured in accordance with a set of regulations issued by regulatory authorities such as the U.S. Food and Drug Administration (FDA) or the European Medicines Agency (EMEA) in the European Union. These regulations are known as current Good Manufacturing Practices (cGMPs) and cover all aspects of the production, from choosing and testing raw materials, to utilities, packaging, shipping, and transferring of final products to the clinic [32, 81]. If these items are not in conformity with GMPs, the product is deemed to be adulterated and cannot be legally approved [82]. In the specific case of AdVs, the facilities and processes used in manufacturing should be designed carefully to guarantee maximum protection to the product, to personnel, and to the environment [32, 83]. For instance, dedicated facilities should be used to prevent cross-contamination from previous or parallel batches of other bioproducts [32]. Confinement of production operations to class C clean rooms is also advisable to avoid dissemination of recombinant adenoviruses into the air [32].

One cornerstone provision of cGMPs is validation, a concept introduced to assure product consistency [84]. The validation of downstream processing operations aims to prove that they are capable of consistently removing impurities (e.g., host cell components, process-related materials, adventitious agents) to acceptable levels. Additionally, acceptance limits and operating ranges for each step must be determined [84]. Validation studies usually lead to optimized processes with reduced variability and, as a consequence, to a decrease in the number of failed batches. Thus, the development of adenovirus manufacturing processes (and associated facility) should be undertaken with validation in mind, not only to improve quality assurance and accelerate approval, but also to reduce costs [85, 86].

10.1.3.2 Product Specifications and Quality Control

One core concept hovering GMPs is quality assurance (QA). Among other attributes, QA is a means of guaranteeing the excellence, security, and dependability of the manufacturing process or its product [81]. QA is a key issue in process development, validation, and product approval, as well as on the assessment of the endproduct quality in comparison with product specifications. The characterization of recombinant AdVs thus constitutes a crucial aspect in all steps of product development, from basic research to clinical trials [87]. As it is the case for other biologics, adenovirus products have an inherent variability in their composition, stability, and potency. They are also subject to the variability inherent to the biological nature of some of the methods used to test them. An AdV should be well characterized to demonstrate that it is consistent in composition, exhibits long-term physico-chemical and biological stability, and is free of adventitious agents (microorganisms, adeno-associated viruses), contaminants, and impurities [88]. This requires the development and setup of a range of "validatable" analytical methodologies capable of fully characterizing the product during processing and in its final formulation, while ensuring the production of a consistent product [87]. The molecular structure of AdVs, hence their biological activity (potency), may be sensitive to factors such as temperature (labile for $T > 40°C$), pH (labile for $pH < 6$), and freeze/thawing cycles [89, 90]. Thus, a correct evaluation of product stability

requires the use of convenient analytical techniques (e.g., circular dichroism and light scattering [89]). Analytical techniques also play an important role in the analysis of source materials, in the assessment of the impact of changes in manufacturing processes, and in the validation of processes and cleaning.

The exact final specifications (identity, efficacy, safety, potency, and purity) for an adenovirus vector product will usually depend on the intended therapeutic use, and thus, they are defined during clinical trials. However, regulatory agencies such as the FDA, the EMEA, or the SFDA provide guidelines and quality standards that are helpful during product and process development [91–93]. Table 10.1-3 exemplifies some of the assays, methods, and specifications used in the quality control of Gendicine (adapted from Refs. 15 and 93).

10.1.3.3 Environmental and Safety Issues

An assessment of the environmental impact of a process is an essential part of the design [94, 95]. The costs associated with the treatment and disposal of the waste generated by a particular process solution should be estimated beforehand. This information is one key element in the final decision on which process to select. Environmentally unfriendly operations such as those that generate large amounts

TABLE 10.1-3. Specifications and Recommended Assays for Assessing AdV Purity, Safety, and Potency (adapted and abbreviated from Refs. 15 and 93).

Parameter	Analytical Method	Specification
	Adenovirus-transgene	
Appearance	Opalescence	Visual inspection
pH	pH meter	8.0–8.5
Identity		
adenovirus genome	Restriction mapping	According to sequence
p53 gene	PCR	396 bp
Viral titer		
viral particles (VP)	Absorbance at 260 nm	$\geq 6.7 \times 10^{11}$ VP/mL
infectious units (IU)	$TCID_{50}$	$2–4 \times 10^{10}$ IU/mL
IU/VP	—	≥3.3%
Purity	A260/A280 ratio	1.2–1.3
Potency		
expression	Western blot	Positive
bioactivity	Saos-2 cell bioassay	Positive
	Impurities	
RCA	A549 cell bioassay	≤ 1 RCA/3×10^{10} VP/mL
AAV	PCR	Negative
Proteins	ELISA	≤66 ng/mL
Genomic DNA	Southern blot	≤6.6 ng/mL
Endotoxins	*Limulus* ameobocyte lysate (LAL)	≤6.6 EU/mL

Abbreviations: $TCID_{50}$ = tissue culture infective dose; RCA = replication-competent adenovirus; AAV = adeno-associated virus.

of hazardous solvents and materials, which are usually costly to dispose of, should definitely be avoided. Additionally, adequate systems should be in place to provide an efficient decontamination of solid (e.g., autoclaving and incineration) and liquid wastes (e.g., heat or caustic inactivation) before release from the manufacturing area [32, 96, 97]. Once inactivated, these wastes should pose limited risk to the environment. Nevertheless, process optimization should always be geared toward minimization of waste generation [94, 95]. The formation of aerosols during processing should be minimized because adenovirus can spread via airborne transmission and contribute to dissemination within the manufacturing rooms and facility. Unit operations that need special safety precautions (e.g., explosion-proof tanks, blow-out walls, emission containment, personnel protection, etc.) to operate should also be carefully considered, because these requirements can dramatically increase the cost of equipment, building design, and construction. Overall, environmental and safety issues require an intimate knowledge of the process technology solutions available.

10.1.3.4 Process Considerations

A process for the manufacture of an AdV consists of several activities aimed at the production of a certain amount (measured as number of viral particle [VP] units or infectious viral particle [IVP] units) of the target product at an acceptable cost and quality (Figure 10.1-6). The generation of fully qualified cell banks and virus seeds is at the forefront of these activities [32, 83]. These banks should be extensively tested for contaminants, including RCAs [83]. A rigorous screening of raw materials, especially those of biological origin, is also mandatory to guarantee that extraneous organisms and contaminants are not introduced into the process [83]. Upstream and downstream processing unit operations are selected, arranged, designed, and operated to manufacture a bulk product. After filling and finishing, the product can be distributed and shipped. These activities should be GMP-compliant and thoroughly scrutinized under a quality control program, as discussed in the previous sections (Figure 10.1-6).

Flowsheets for the recovery and purification of biologicals are usually established with several rules of thumb and on the basis of accumulated experience with the target product [95]. Simulation tools can also be used to rapidly evaluate bioprocess alternatives and speed up development [95, 98–100]. The specifics of adenovirus purification were first addressed by researchers that have developed a range of

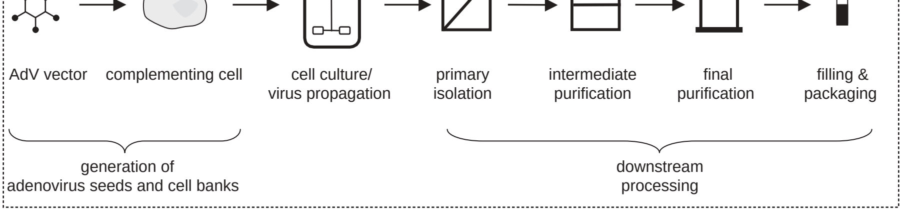

Figure 10.1-6. Outline of the activities involved in a typical AdV production process.

efficient lab-scale protocols, most of them based on CsCl density-gradient ultra-centrifugation [101]. Unfortunately, many of these protocols use reagents (e.g., CsCl is toxic) that are not acceptable for the manufacturing of a biological pharmaceutical. Furthermore, ultra-centrifugation is not amenable to scale-up due to the limited capacity of commercial ultra-centrifuges [41]. Nevertheless, many published adenovirus production processes include modifications or adaptations of specific steps used in these laboratory procedures [40, 101–107].

Cell culture is usually optimized to obtain high cell densities (cells/mL) and specific titers of infectious viral particles (IVPs/cell). The final goal is of course to maximize overall mass production (specific titer × cell density = IVP/mL) [80]. Next, a sequence of unit operations must be set up to recover the viral particles and eliminate host cell impurities (genomic DNA, RNA, proteins, RCAs, etc.) until the desired level of purity is met (Table 10.1-3). For a product with an intended use in humans, this removal of impurities is mandatory to avoid side effects upon administration to patients. The downstream processing unit operations can be grouped into three different stages: primary isolation, intermediate purification, and final purification (Figures 10.1-6 and 10.1-7). Ideally, the overall process should have a limited number of high-recovery steps, so that processing costs are reduced and acceptable yields are obtained [108]. The process should also use Generally Regarded As Safe (GRAS) reagents. Furthermore, lengthy operations and processes should be avoided to cut costs from overhead, amortization of equipment, and direct labor charges [109]. Processes with overall adenoviral particle yields of 32% [105], 50% [107], 60% [106], and 71% [104] have been reported in the literature.

10.1.3.5 Production

Most E1-deficient recombinant adenoviruses are propagated in the HEK-293 and PER.C6 cell lines (and derivatives thereof) as discussed in Section 10.1.2.3. The generation of RCAs is minimal in PER.C6 but remains a concern for HEK-293. Both cell lines have been documented for GMP manufacturing [110]. The production of these cells can be accomplished by a variety of methods, which depend on whether adherent or suspension cell lines are being used.

An adenoviral production process with HEK-293 and PER.C6 is a two-phase process. In the first phase, cultures are started at an appropriate seeding density (e.g., 0.3×10^6 cells/mL) and allowed to grow until a cell density around $0.5–1 \times 10^6$ cells/mL is reached. The second phase starts at this point with the infection of the culture at a ratio of virus titer to cell density (known as multiplicity of infection—MOI) adequately chosen (e.g., MOI = 10). An exchange of medium is usual, but not mandatory, before infection [111–113]. The cell density at the time of infection is a crucial parameter, with specific viral particle productivity (IVP/cell) usually dropping for cell densities higher than 0.5×10^6 cells/mL [80]. After infection, viral particles propagate and accumulate in the cells with maximum titers (~10^{10}–10^{11} VP/mL) typically obtained 48 hours postinfection (hpi). Maximum cell densities of 1×10^7 cells/mL have been reported [111]. Loss of viability and cell death ensue thereafter [80].

Adherent Cell Culture. Adherent or anchorage-dependent cell lines require attachment to a surface for their survival and replication. These cultures are labor

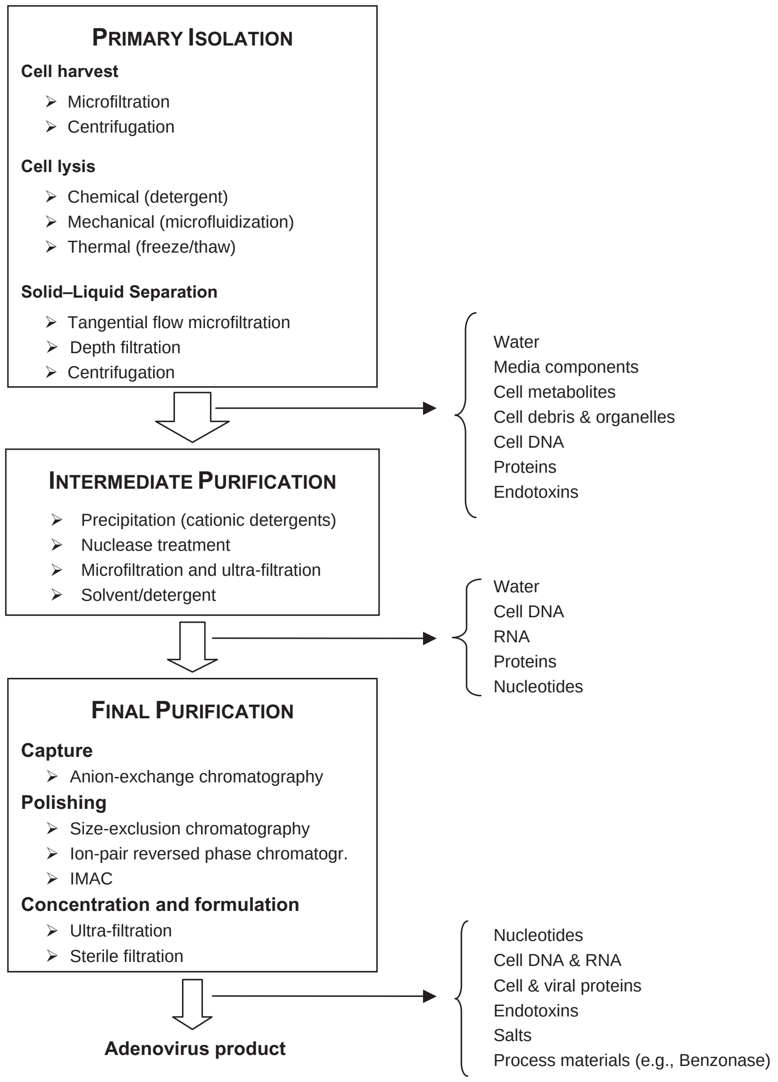

Figure 10.1-7. Generic block of downstream processing of AdV vectors showing unit operation options in each section.

intensive, require both a large amount of space and specific equipment handling, and have a limited potential for scale-up. Thus, they are more adequate during the early stages of product and process development [110, 114, 115].

Adherent cells can be grown in stationary or microcarrier cultures [116]. Stationary cultures use devices such as flasks, roller bottles, and cell factories that provide wall surface area for cell attachment [117]. Microcarrier cultures, on the other hand, can be implemented in agitated bioreactors [114, 116]. These microcarriers are small porous particles (0.2 mm) that provide large surface areas for cell attachment and can be suspended in the culture medium by gentle agitation. The culture environment is thus easily controlled and the scale-up is done by increasing the

bioreactor volume. In comparative studies, stationary cultures usually yield higher adenovirus titers (up to 1.1×10^4 VP/cell) than microcarrier cultures (up to 8.5×10^3 VP/cell) [114, 116].

Suspension Cell Culture. Suspension cell lines are more convenient for large-scale manufacturing [111, 112]. A further advantage is that they can be grown in serum-free media, without the addition of bovine-derived components [110]. This advantage reduces costs and batch-to-batch variability and facilitates downstream processing and validation [111]. Conveniently, both the HEK-293 [80, 111–114] and the PER.C6 [118, 119] cell lines can be adapted to grow on suspension cultures. When grown in serum-free media, these cell lines allow high growth rates and cell densities as well as high yields of adenoviral particles [111]. The tendency of cell derivatives to aggregate, however, is usually a recurrent concern with suspension cultures, especially at high cell densities [111, 120].

The cultivation of cells and adenovirus propagation in suspension bioreactors has been performed in batch, fed-batch, and perfusion modes. In batch operation, no nutrients are added during the course of growth or infection. Although batch cultures are simple to perform and contamination risks are low, essential nutrients are rapidly depleted from the medium and cell viability decreases [110, 121].

The fed-batch mode is used to maintain cell viability after infection by supplementing limiting nutrients (e.g., glucose, glutamine, and amino acids) or reducing the accumulation of toxic metabolites (e.g., ammonia and lactate) [48, 80, 112, 113]. It also improves viral titers by increasing the cell density at which cells can be infected up to 2×10^6 cells/mL, without reducing the per-cell yield of product [121]. Both the medium composition as well as the feeding strategy are important parameters [112]. Nutrient depletion and the buildup of toxic metabolites cannot be completely alleviated by fed-batch cultures [121]. Operation under perfusion mode can overcome this limitation by ensuring a constant renewal of medium in the bioreactor. Briefly, cells are retained at high concentrations inside the bioreactor by using devices such as hollow fibers and membrane units, whereas fresh medium is continuously supplemented [121]. Consequently, the cell density at which cells can be infected can be increased. With this strategy, HEK-293 cell densities of 8×10^6 cells/mL could be achieved at the time of infection, and viral titers of 7.8×10^9 IVP/mL were obtained at 60 hpi [121].

10.1.3.6 Downstream Processing

Primary Isolation and Intermediate Purification. The suspension generated during cell culture constitutes the starting point for downstream processing. In the primary isolation stage, cells are harvested and viral particles are released from the cells together with other impurities. A significant reduction in volume occurs, and the most plentiful impurities such as extracellular liquid, proteins, genomic DNA, and cell debris are removed. Cells are typically harvested by centrifugation or microfiltration. The resulting cell slurry is then resuspended in an adequate volume (1/10 to 1/20 of the culture volume) of a suitable buffer or of the culture medium itself. The subsequent cell lysis operation is typically performed using freeze/thaw cycles [40, 106, 118, 119], osmotic shock [80], sonication [101, 122], microfluidization [102], or by the addition of detergents such as Triton X-100 or

Tween-20 [104, 107]. Unlike lysis by freeze/thawing and sonication, cell shearing by microfluidization is more rapid, reproducible, and easy to scale-up [102].

After lysis, cleared lysates are obtained by removing cell debris and larger unruptured organelles with centrifugation [40, 118, 119], depth filtration [107], or tangential flow microfiltration [102, 106] operations. Treatment with nucleases (e. g., Benzonase [Merck, Gibbstown, NJ], Pulmozyme [Roche, Basel, Switzerland], DNase, RNase T1, and RNase I) is usually performed before or after clarification, to reduce the cellular DNA and RNA load [40, 80, 104]. This step not only improves purity, hence the safety of the viral product [40], but also it reduces agglomeration of viral particles, which is usually induced by adhesion of nucleic acids [104]. In some cases, nuclease treatment can be carried out at the end of the process, after chromatographic purification [106].

As an alternative to nuclease digestion, cationic detergents can be added during lysis to selectively precipitate cellular DNA. Recent experiments with the detergent domiphen bromide have shown that it is possible to obtain three logs of DNA clearance without losses in the infectivity of purified viral particles [107]. Thus, the use of DNA removal operations such as nuclease treatment and anion exchange chromatography may be eliminated or reduced.

The viral particle-containing solutions resulting from nuclease treatment and cationic detergent precipitation are typically filtered, concentrated, and conditioned before chromatographic purification [40, 80, 101, 106, 107]. The inclusion of a solvent/detergent step at this stage may be included to inactivate potential enveloped viruses that could have been coamplified [32].

Final Purification. A pharmaceutical product such as an AdV requires a high degree of purity. This level of purity is usually achieved with a combination of chromatography and filtration operations. The goal is to separate the viral particles from the most recalcitrant impurities that persist in the streams. The chromatographic operations described in the literature for virus purification explore properties such as size, charge, hydrophobicity, and metal affinity [41, 80, 102–107].

Anion-exchange (AEX) chromatography is widely used as a viral particle capture step. It explores the interaction between the negatively charged hexons in viral capsids and the stationary phases bearing positively charged ligands such as quaternary amines [41]. Impurities (media components, low-molecular-weight DNA, penton, hexon, and fiber proteins are eluted at low salt (<0.25-M NaCl), whereas bound capsids are displaced with a salt gradient [41, 102, 103, 106]. A recent study shows that the NaCl concentration required to elute viral capsids from the anion exchange column is a function of the serotype being purified (ranging from 0.27 to 0.45 M), and it correlates very well to the electrostatic properties of the hexon protein in each serotype [41]. Tentacular (e.g., DEAE-Fractogel; Merck, Gibbstown, NJ), perfusion (e.g., POROS.RTM.50D; PerSeptive Biosystems, Framingham, MA), and soft gel in rigid shell (e.g., Ceramic HyperD.TM.F; BioSepra, Villeneuve-La-Garenne, France) materials have all been used for AEX purification of adenovirus particles [102, 106]. The reported AEX viral particle yields range from 63% [104] to 80% [80].

AEX can also be performed in expanded-bed adsorption (EBA) mode [102]. Under this mode of operation, cell lysates can be applied directly to the column from below. Large debris and unlysed cells that can move freely around the anion-exchanger beads eventually leave through the top of the column, whereas

adenoviral particles bind to the anion-exchange matrix. Extensive washing from below limits nonspecific interactions between the particulates and the resin. Finally, the flow is reversed, the anion-exchanger beads are allowed to pack, and the viral particles are eluted under a salt gradient [102]. Due to its early use in the downstream processing, EBA can be considered as an intermediate purification unit operation.

Adenovirus particles have also been purified by affinity chromatography by taking advantage of an ingenious targeting approach. Briefly, the fiber capsid protein of adenovirus 5 vectors was genetically fused to a biotin acceptor peptide (BAP). These BAP-modified fibers were then metabolically biotinylated during virus propagation in the HEK-293 cell line. The resulting covalently biotinylated viral particles could then be purified from crude lysates by avidin-affinity chromatography [122].

AEX alone is unlikely to be sufficient to produce an adenovirus product with the required purity [106]. The inclusion of a chromatographic polishing step may thus be necessary as a means to remove traces of DNA and protein impurities. Size-exclusion [80, 103], ion-pair reversed phase [106], and metal affinity [105] chromatography have all been used toward this end. In the case of size-exclusion, if an adequate matrix is selected (e.g., Superdex 200; GE Healthcare, Piscataway, NJ), virus elute in the flowthrough because of its large size, whereas low-molecular-weight impurities are retarded. The column loading volume can be increased up to 20% of the bed volume, because a group separation is achieved [102]. An extra advantage of size exclusion as a polishing step is that it can also be used to exchange buffer [103]. This enables formulation to be carried out simultaneously with polishing. In the case of ion-pair reverse phase chromatography, elution conditions are carefully selected to retain impurities in a PolyFlo matrix (Puresyn, Inc., Malvern, PA) and to allow the viral particles not to bind. Under this negative chromatography operation mode, viral particles are recovered in the flowthrough with an 87% recovery yield [106]. This leads to some dilution of the adenovirus stream, as is always the case when products are recovered in the flowthrough.

Processes for adenovirus purification typically end with concentration, formulation, and sterile filtration operations [40, 80, 106]. Concentration and formulation are usually carried out in ultra-filtration units equipped with 100–300-kDA membranes [40, 106]. The exact composition of the formulation buffer will depend on the intended application, mode of administration (injectable, aerosol), and required short-term and shelf stability [104, 123]. A typical liquid formulation may include an aqueous buffer supplemented with cryoprotectants (e.g., sucrose) and stabilizers such as the nonionic-surfactant polysorbate-80, the chelating agent EDTA, and the oxidation inhibitors ethanol and histidine [123]. Filtration under sterile conditions is typically performed with 0.22-μm membranes [103, 106].

10.1.4 ANALYSIS AND EVALUATION OF AN ADENOVIRUS PRODUCTION PROCESS

In this section, a pilot-scale process that has been developed specifically for the production and purification of AdVs for gene therapy [80] is analyzed and evaluated for large-scale manufacturing with the use of the process simulator software SuperPro Designer (Intelligen, Inc., Scotch Plains, NJ). The major objective of the

analysis presented here is to estimate the cost of the production of an adenovirus therapeutic product. Results further provide insights into process weaknesses and strengths, effectively directing bioprocess engineers toward better processes.

10.1.4.1 Process Description

As a design basis we have assumed a plant capacity of around 1×10^{18} viral particles of purified recombinant adenovirus produced per year. This amount of product is sufficient to treat 125,000 patients per year on the basis of 1×10^{12} VP doses given weekly for a total of 8 weeks, as described in a Gendicine clinical trial [15]. The plant is designed to operate 330 days a year, with a new batch initiated every 11 days—this corresponds to 30 batches at 33.3×10^{15} VP/batch. The total batch time is around 17 days. Guidelines and quality standards issued by regulatory agencies have been used to set up product specifications in terms of final purity (Table 10.1-3). Finally, we have assumed that, at the end of the process, the bulk adenoviral product will be distributed in vials, each containing a 1×10^{12} VP dose of 0.6 mL of sterile formulation buffer. This corresponds to a viral titer of 167×10^{11} VP/mL, which is higher that the specified value of 6.7×10^{11} VP/mL (Table 10.1-3).

The entire flowsheet for the production of adenovirus is divided into cell culture and virus propagation (Figure 10.1-8) and downstream processing (Figure 10.1-9)

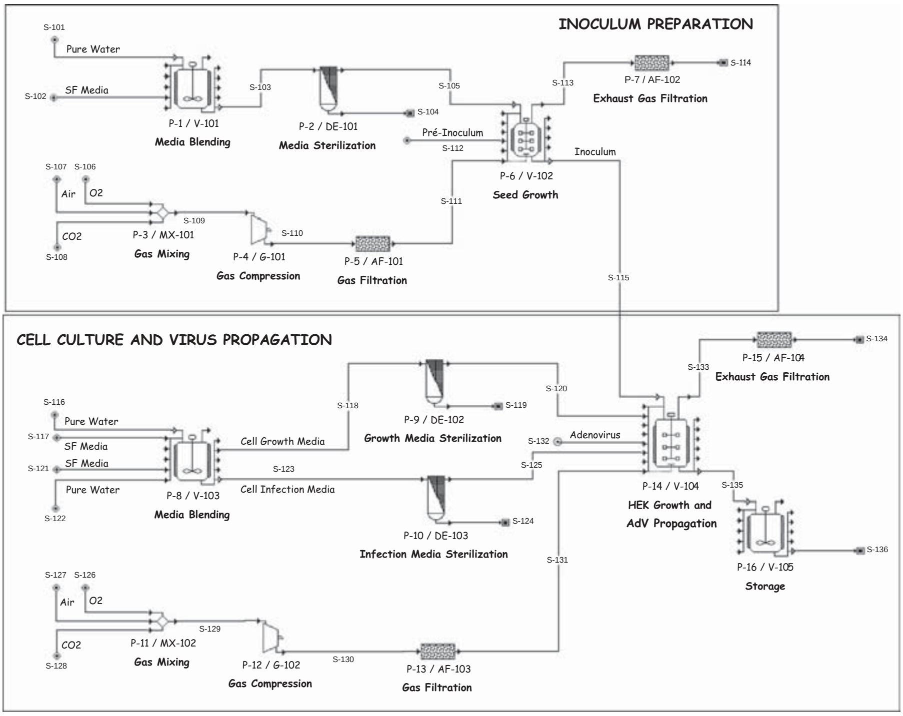

Figure 10.1-8. Adenoviral vector production flowsheet showing the cell culture and virus propagation section (implemented with the process simulator software SuperPro Designer [Intelligen, Inc., Scotch Plains, NJ]).

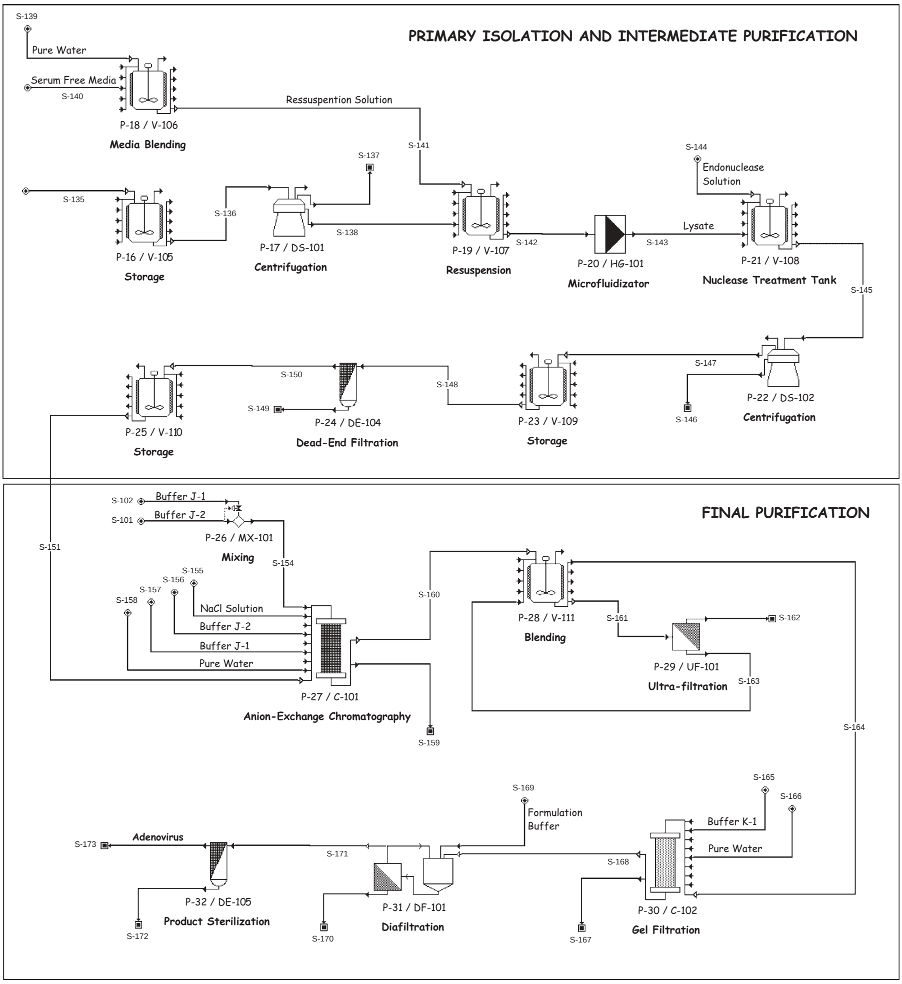

Figure 10.1-9. Adenoviral vector production flowsheet showing downstream processing section (implemented with the process simulator software SuperPro Designer [Intelligen, Inc., Scotch Plains, NJ]).

sections. The overall adenovirus particle recovery yield per batch is around 67% (33.3×10^{15} VP are recovered out of the 5×10^{16} VP that are present in the whole cell lysate). This figure is within yields reported in the literature for similar processes [104]. Input data used in the simulation software SuperPro Designer were taken from the reference publication [80] and supplemented with information from other published processes [40, 106, 107]. Educated guesses were made to provide for missing data. Table 10.1-4 summarizes the most important data—process volumes, step yields, and viral particle titers.

Cell Culture Section. The activities in this section include media sterilization, inoculum preparation, cell growth, and virus propagation (Figure 10.1-8). Serum-free (SF) medium is sterilized by 0.2-μm filtration and used for both inoculum preparation and cell growth/virus propagation. The culture is assumed to take

TABLE 10.1-4. Summary of Input Data Used in the Bioprocess Simulator SuperPro Designer

Step	Volume (L)	AdV Titer ($\times 10^{10}$ VP/mL)	Step Yield (%)
Cell culture	1000	5.0	—
Harvest + resuspension	109	46	100
Cell Lysis	109	45	98
Benzonase digestion	109	45	100
Centrifugation + dead-end filtration	106	46	99
Anion exchange chromatography	118	36.5	89
Ultrafiltration	11.8	350.0	96
Size exclusion chromatography	59.0	66.5	95
Ultrafiltration	19.7	169.3	85
Sterile filtration	19.7	169.3	100

Notes: An overall yield of 67% is obtained. The final viral titer is higher than the specified value (67 $\times 10^{10}$ VP/mL).

place in fed-batch mode (with a single nutrient addition), in a bioreactor with a working volume of 1000 L. This size is a reasonable assumption, given that cultures with volumes as high as 10,000 L are currently being developed for production of HIV adenoviral vaccines [118]. The inoculum is added to 500 L of culture medium at a seeding density of 3×10^5 cell/mL, and cells are allowed to grow for 6 days. Then, 500 L of fresh SF medium are added, and cells at a concentration of 0.5×10^6 cell/mL are infected at a MOI of 10. Cell growth and virus propagation are conducted at 37°C and pH 7.2, with constant addition of a gaseous mixture (80% air, 10% CO_2, 10% O_2) at 0.05 vvm [80]. Harvest is performed 48 hpi, with typical values assumed for the final cell concentration (1×10^6 cells/mL), adenovirus titer (5×10^4 VP/cell), and ratio of infectious viral particle to total viral particles (1 : 10) [80].

Downstream Processing Section. The activities in this section include cell harvest and cell lysis, nuclease digestion, and chromatographic purifications (Figure 10.1-9). Cells from the suspension culture (1 m^3) are harvested by continuous centrifugation, resuspended in SF medium (1/10 of the original volume), and lysed by microfluidization (e.g., 2000 psi and 1 pass) [80]. Cell DNA is then drastically reduced (≈4.5 logs) by adding Benzonase up to a final concentration of 150 IU/mL [107]. After removal of debris by centrifugation, the supernatant is clarified in a 0.2-μm dead-end filtration unit [80]. Adenovirus capture and purification is performed by AEX chromatography column (Fractogel EMD-DEAE, 0.4-m bed height, 0.6-m bed diameter) according to the instructions presented by Tang et al. [103]. Briefly, each cycle comprises six distinct operations: (1) equilibration with 22 bed volumes (BVs) of buffer J1 (50-mM sodium phosphate pH 7.5, 265-mM NaCl, 2-mM $MgCl_2$, 2% (w/v) sucrose) at 4 cm/min, (2) loading of 106 L of feed at 1 cm/min, (3) washing with 4 BVs of buffer J1 at 2 cm/min, (4) washing with 8 BVs of 94% buffer J1 and 6% buffer J2 (50-mM sodium phosphate pH 7.5, 600-mM NaCl, 2-mM $MgCl_2$, 2% (w/v) sucrose), (5) elution of bound adenovirus particles with 10 BVs of linear gradient from 6% to 100% buffer J2 at 2 cm/min, and (6)

column cleaning with 4 BVs of 1-M NaCl at 4 cm/min. The total cycle time is 12.26 h. The bound viral particles are eluted with an overall yield of 89% [103]. The adenovirus pool is then concentrated 10 times by ultra-filtration using a 100-kDa membrane [80]. A step yield of 96% is assumed based on data published for ultra-filtration of different viral particles [124]. A size exclusion chromatography column (Superdex 200, 0.8-m bed height, 0.4-m bed diameter) is included as a polishing step (95% step yield) [103]. The column is loaded with the totality of the viral solution (12% of the bed volume), and upon elution with an adequate buffer (e.g., 20-mM sodium phosphate pH 8.0, 100-mM NaCl, 2-mM $MgCl_2$, 2% (w/v) at 0.43 cm/min), a pool of adenoviral particles is obtained that is five times diluted relatively to the feed [103]. The total cycle time is 18.3 h. Concentration and formulation into an adequate buffer (2.5% glycerol, 25-mM NaCl, 20-mM Tris, pH 8 [80]) is subsequently carried out in an ultra-filtration unit equipped with a 100-kDA membrane. Finally, the adenovirus product is sterile filtered into glass vials (1×10^{12} VP in 0.6 mL).

Process Scheduling. The scheduling and equipment utilization for one production batch is shown in Figure 10.1-10. The plant batch time is approximately 405 hours, with a new batch (i.e., inoculum preparation) initiated every 264 hours. This batch start time roughly corresponds to the fourth day of the cell culture in the previous batch. The inoculum preparation, cell culture, and virus propagation procedures, with a duration of approximately 367 hours, are clearly identified in the chart as the time bottleneck. Comparatively, the downstream processing is complete within a mere 38 hours. The time bottleneck in this section is the size-exclusion chromatography polishing step, which takes about 18 hours.

10.1.4.2 Inventory Analysis

The overall material balance per year is summarized in Table 10.1-5. Remarkably, the annual mass production of purified adenovirus vector constitutes a minor fraction (~0.3 ppm) of the total amount of materials required for its production. Apart from the adenovirus vector, cell debris, and gases, all output materials end up in liquid waste streams, which are disposed of after adequate treatment (e.g., heat or caustic inactivation) to minimize environmental impacts. Water is the major raw material used (~97%), most of it for equipment cleaning. This is typical in the production of biopharmaceuticals as can be seen by checking IgG [95], recombinant β-glucuronidase [125], and plasmid DNA [100] production examples. Serum-free medium (~0.2%) and gases (~1%) are used in the cell culture and virus propagation step. Large amounts of sodium chloride, sodium phosphate, and sucrose (~0.8%) are required as buffer components in the chromatographic operations. A substantial amount of sodium hydroxide (~0.5%) is also used for equipment cleaning.

10.1.4.3 Cost Analysis and Economic Assessment

Table 10.1-6 shows the key economic evaluation results for this project. Economic evaluations were based on the following assumptions: (1) the entire direct fixed capital is depreciated linearly over a period of 10 years assuming a 10% salvage

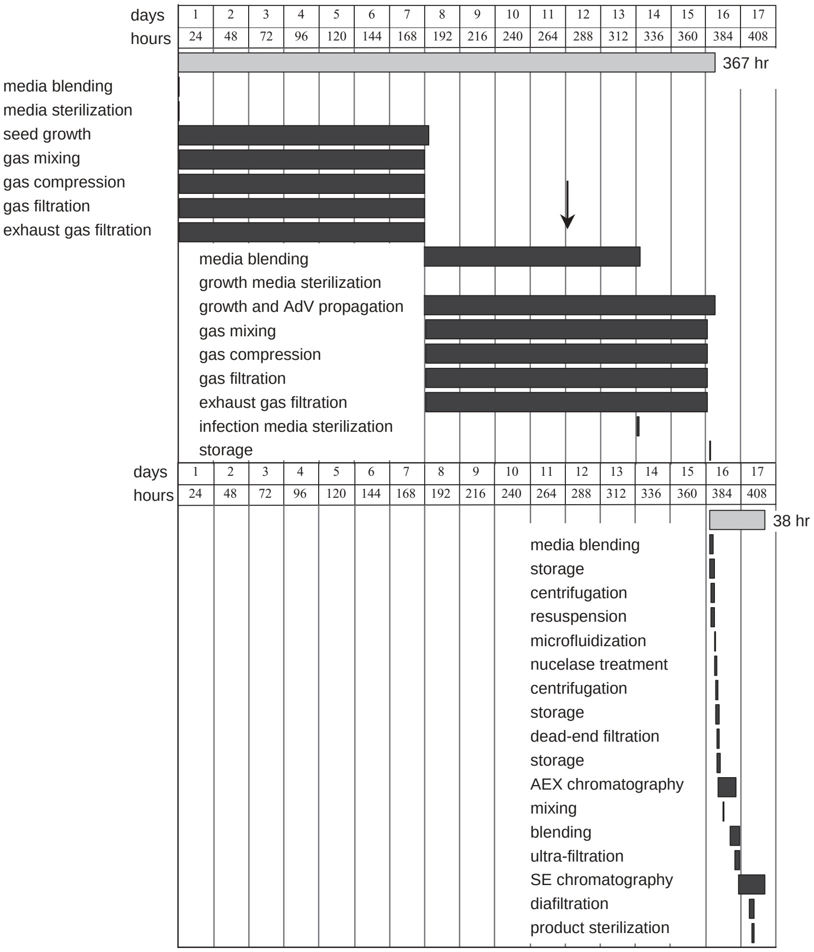

Figure 10.1-10. Gantt chart for production scheduling of one batch of adenoviral vector. The top and bottom charts show the duration of each operation in the cell culture and downstream processing sections, respectively. The total process time is 405 hours. The arrow indicates the start of a new batch at 264 hours.

value for the entire plant, (2) the project lifetime is 15 years, and (3) 1×10^{18} VP of adenoviral product will be produced per year. For a plant of this capacity, the total capital investment is around $17.8 million. The unit production cost is ~$7.2/dose ($10^{12}$ VP) or $24,715/g. This figure is considerably higher when compared with production costs of other biopharmaceuticals such as β-glucuronidase ($43.0/g [125]), insulin ($42.2/g [95]), IgG ($908/g [95]), and plasmid DNA ($375/g, [100]).

The total equipment purchase cost was estimated to be around $2.8 million. The most expensive piece of equipment is the bioreactor used for cell culture and virus propagation, priced at $506,000. The cost of unlisted equipment (including the equipment used in the inoculum preparation section) was assumed to represent 20% of the total equipment cost.

TABLE 10.1-5. Overall Material Balances for the Annual Production of 1×10^{18} VP (~0.285 kg) of AdV (kg/year). This Amount Corresponds to 67% of the Total AdV Propagated in the Culture Section.

Component	Total Inlet	Total Outlet
Adenovirus	0	0.425
Carbon dioxide	1,050	1,077
Debris	0	17
DNase	0.095	0.095
Glycerol	91	91
Magnesium chloride	30	30
Nitrogen	6,444	6,444
Nucleic acids	0	0
Nucleotides	0	9
Oxygen	3,006	2,995
Proteins	0	81
SF media	1,628	1,498
Sodium chloride	3,582	3,582
Sodium hydroxide	5,013	5,013
Sodium phosphate	1,066	1,066
Sucrose	3,171	3,171
Tris base	11	11
Process water	734,446	734,446
Water for injection	210,860	210,860
Total	970,398	970,392

TABLE 10.1-6. Key Economic Evaluation Results for Adenovirus Production

Direct fixed capital	$16,593,000
Total capital investment	$17,820,000
Plant throughput	0.29 kg (10^{18} VP) AdV/year
Operating cost	$7,149,000/year
Unit production cost	$7.17/dose

The breakdown of the annual operating cost (AOC) is shown in Figure 10.1-11. Facility-dependent cost (44% of the AOC) is the principal operating cost in this process, as is typical for high-value products that are produced in small quantities [95]. Labor-related costs come next, accounting for 34% of the AOC. The annual cost of raw materials is around $1.0 million, 92% of which are associated with the culture SF medium (priced at $28/L). The cost of consumables is around $193,000, representing approximately 3% of the AOC. The chromatographic resins in the AEX and size-exclusion chromatographic steps represent 84% of this value. The cost of utilities (electricity, steam, and cooling agents) is minimal, representing less than 0.1% of the AOC.

Figure 10.1-12 shows the return on investment (ROI) and payback time for different product selling prices ($/dose). The ROI increases around 3.5% for every $1 increase in the selling price of each AdV dose, whereas the payback time declines for every $1 increase. If one assumes that a dose of product is sold at $30,

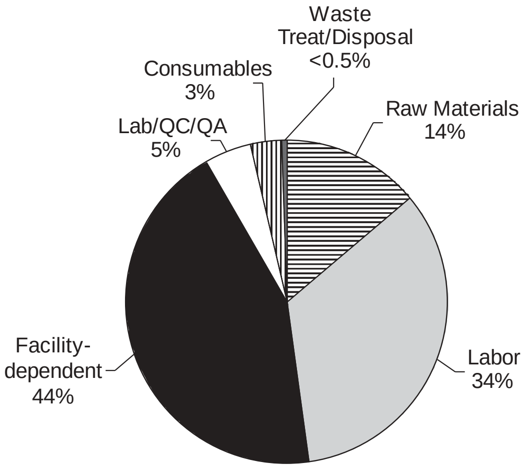

Figure 10.1-11. Breakdown of the annual operating cost.

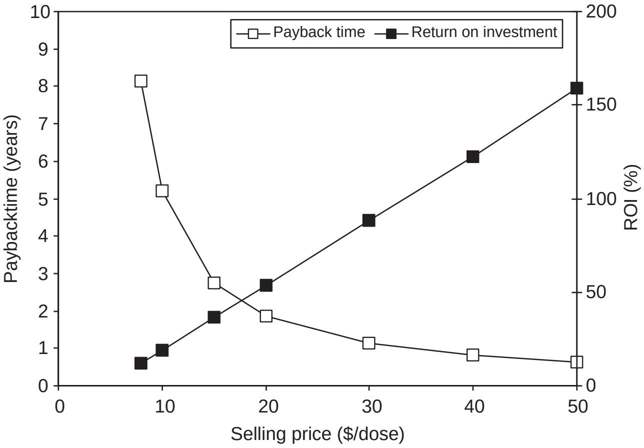

Figure 10.1-12. Return on investment and payback time at different AdV selling prices.

the annual revenue will amount to $30,662,000 for an annual production of 1×10^{18} VP. This corresponds to a gross profit (i.e., revenue-operating cost) of $23,513,000. At this selling price, the payback time is 1.14 years with an ROI of 88%. This economic picture could change slightly by the inclusion of costs that were not accounted for in this case study (filling & packaging section, R&D, process validation).

10.1.5 CONCLUDING REMARKS AND OUTLOOK

Adenoviral gene therapy has matured to the point where several products should be hitting the market in the wake of Gendicine. Many of the initial drawbacks and barriers (e.g., immunogenicity, lack of specificity, and transient expression of

transgenes) have been tackled with innovative solutions and strategies (targeting, gutless vectors) that have proved valuable in some cases. To provide sufficient material for the ongoing gene therapy clinical trials, production and purification processes must be developed and optimized in parallel to deliver the required selectivity, yield, efficiency, and productivity. The design of these processes under cGMPs should be based on a profound knowledge of the target molecule and associated impurities and on the performance of the available unit operations. Although several well-established processes have been documented in the literature, new developments are likely to surface within the coming years because of increased investments from academia and industry in the area. The analysis presented in this chapter indicates that the production and purification of a therapeutic adenovirus product is economically viable, even with a suboptimized process. Process improvements will certainly reduce costs. As an educated guess, we may estimate selling prices to be in the range \$20–\$50/10^{12} VP.

10.2.1 TECHNOLOGICAL ADVANCES APPLIED TO IMAGING OF GENE TRANSFER

At the dawn of the twenty-first century, cancer and cardiovascular disease are the first causes of mortality and the focus of considerable attention and mobilization of financial and human resources. Increased understanding of pathogenesis and its underlying molecular processes has led to proven or investigational therapies, such as gene therapy. The concept of gene therapy (and gene transfer) first appeared in the 1960s when the structure of DNA was defined, and much effort has since been devoted to developing suitable strategies. Although gene therapy was initially considered primarily in terms of treatment of genetic disease, the concept has evolved,

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.
Copyright © 2007 John Wiley & Sons, Inc.

and now the two main fields of gene therapy are cancer and cardiovascular disease. Gene therapy consists of overexpressing a functional gene, replacing a mutated gene, or expressing an exogenous gene with the aim of correcting a malfunction, inducing an immune response, or stimulating angiogenesis. Currently, stem cell research is generating new hope in the field of cell therapy, with which gene transfer is increasingly associated.

The first challenge was to transfer DNA into cells, and *in vitro* and *in vivo* gene transfer techniques were developed: mechanical (gene gun), physical (calcium phosphate precipitation), chemical (synthetic gene transfer agents), and biological (viruses). Some of these techniques are commonly used, at least *in vitro*, and have been evaluated in clinical trials, whereas others are currently under investigation. Clinical testing is contingent on technical quality and reproducibility and finding answers to a variety of questions:

- Does the vector or gene transfer procedure work as expected? Optimally?
- Is the preparation optimal?
- What about the route of transfer?
- What is the fate of the nucleic acid and of the vector (if any)?
- When do the vector and nucleic acid dissociate?
- Does the nucleic acid reach its target (and only its target)?
- Does the procedure have any deleterious effect?
- How long is it before expression occurs?
- How long does the transgene persist in the targeted cell or organ?
- How long is transgene expression effective?

Before addressing these questions, it is first essential to ensure that the nucleic acid is transferred into the cell (or organ) and is active. Transfer can be observed *in vitro* by means of microscopy or electron microscopy. Using nucleic acid probes tagged with gold particles, it is possible to observe the presence of a DNA sequence [1]. Direct labeling is also possible using radionuclides, such as phosphorus 32, and is mostly applied *in vivo* in animal models because of its low resolution. Direct labeling is sometimes impractical, so indirect labeling has been developed. Staining techniques have been improved in parallel.

Although imaging approaches can be used to observe, understand, and document all phenomena involved in gene transfer, many are destructive or "invasive" and often require sacrifice of the animal, as in all histopathological, immunohistological, and immunofluorescent techniques. These techniques yield information that is valuable but that only offers a snapshot of a particular moment in time: Researchers are usually interested in a longer-term image of induced phenomena. The use of several groups of the same animal species to obtain this longer-term image is not really satisfying, and so noninvasive techniques tend to replace invasive or destructive ones. These noninvasive techniques can track processes in a single group of animals and have the ethical advantage that they reduce the number of animals used. Also, invasive approaches can be applied to *in vitro* and *in vivo* research experiments, but not to clinical studies, which may explain why we lack information on the fate of gene transfer agents and transgenes in humans. This technological drawback may be partially responsible for the slowness with which gene therapy is being transferred from the lab bench to the bedside.

The most studied imaging methods are positron emission tomography (PET), single-photon emission (computed) tomography (SPE(C)T), bioluminescence, magnetic resonance imaging (MRI), and gamma imaging. Whereas TEP, SPECT, MRI, and gamma imaging are easily performed on animals, bioluminescence is largely limited because of tissue absorption, with a 90% decrease in signal for each centimeter of tissue. Given this limitation, it is clear that better reporter proteins and reporter genes are needed. Optical imaging is usually performed with proteins that emit green light [luciferase or green fluorescent protein (GFP)], and a shift toward red or near-infrared emission is considered to restrict this absorption and allow the signal to leave the animal's body. Bioluminescence usually yields just planar information, but never devices give 3D information. One technique combines laser scanning, which defines the animal's topography, and filters to select the emitted photons (different wavelengths). Software is used to reconstruct a 3D image of the animal. In another, tomographic, approach, a charge-coupled device (CCD) camera rotates around the animal giving whole-body information on photon emission.

Improvments in molecular biology also exists in the MRI field. The ferritin reporter gene was developed for use with MRI. Overexpression of the transgene in the modified cells (various methods of gene transfer are possible) leads to intracellular ferritin excess and iron entrapment. Ferritin associates with iron, which accumulates (aggregates) in the cell as nanomagnets that can be imaged by MRI [2]. Initially, the very common reporter gene beta-galactosidase was used for MRI. The paramagnetic ion is "blocked" using a galactopyrannoside screen and so is not accessible to water. When the reporter gene beta-galactosidase is expressed, its enzymatic activity alters the galactopyrannoside structure and frees the paramagnetic ion, which can then be imaged by MRI [3]. Another approach for MRI uses a reporter gene that encodes a membrane transferrin receptor. The transgene receptor is modified to be resistant to downregulation, so the receptor is largely overexpressed in comparison with untransfected cells. Internalization of superparamagnetic structures (such as MION) conjugated to transferrin is increased in modified cells [4].

As noted above, gene transfer is increasingly associated with cell therapy. Imaging can provide information on the fate of the reinfused modified cells and also on the expression of the transgene or the corrected gene. By loading the cells of interest with contrast agents, it is possible to use MRI to track their movements through the animal's body [5]. The exitation devoted to quantum dots also spreads to cell therapy. Indeed, recently the fate of cells reinjected to mice was studied after labeling those cells by means of self-illuminating quantum dots. It was then possible to image the cells migration by fluorescence imaging *in vivo* [6].

10.2.2 *IN VITRO* IMAGING STUDIES

10.2.2.1 Characterization of Gene Transfer Agents

Structure. Unless DNA is transferred by a physical method, it is necessary to generate a structure able to carry the nucleic acid. When virus capsid or synthetic molecules are involved, they must be characterized physically to allow rational studies on how they ensure vectorization. The structures of gene transfer agents have to be defined to understand how they interact or associate with other

components. Visualization of the structures alone is currently possible only by microscopy. Classically, transmission electron microscopy (TEM) is performed after negative staining with uranyl acetate [7] (Figure 10.2-1). Vector characterization is frequently combined with characterization of the "nucleic acid-vector" association. TEM is also used, for example, to confirm that the DNA has intertwined with the polymer assembly [8]. Atomic force microscopy is a relatively new tool that enables the visualization of nanostructures. It will probably give much information on the

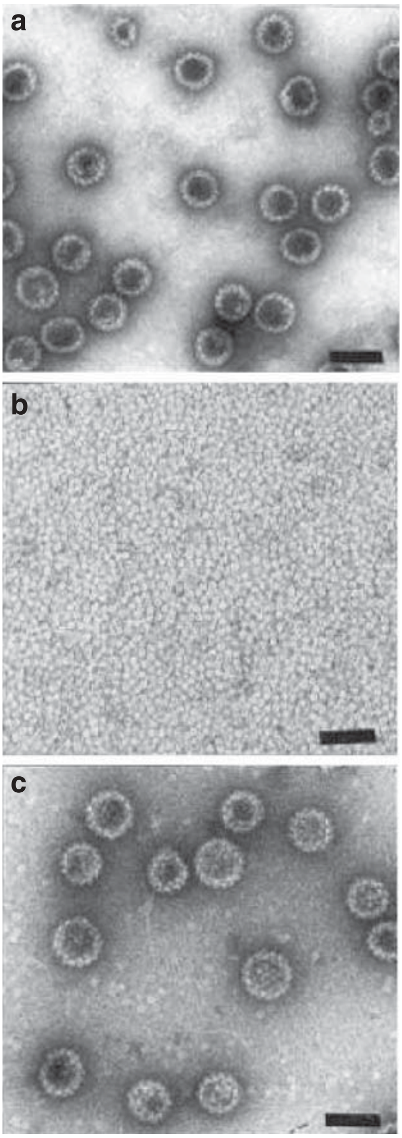

Figure 10.2-1. Electron microscopy to image gene transfer structures. In this example, the authors have imaged the gene transfer structure they developed (human papillomavirus-like particles) after uranyl acetate negative staining. Reprinted from Ref. 7, with permission from Oxford Journals.

structures obtained according to the preparation way and also on the association of the nucleic acid with its vector.

Nucleic Acid—Vector Interaction and Kinetics. One way to confirm that the vector interacts with or encapsulates the nucleic acid is to visualize the interaction. Scanning force microscopy has shown that polymers and cationic lipids interact with DNA in a similar way [9] (Figure 10.2-2). TEM has been used to observed this kind of interaction between DNA and synthetic gene transfer agents [8]. Although fluorescence resonance energy transfer (FRET) data are usually represented graphically [10], it is theoretically possible to obtain images of the fusion events using fluorescence microscopy, which shows how lipids used to prepare lipoplexes interact and mix and also gives information on the capacity of a structure to interact with a membrane model representing the cells.

10.2.2.2 Gene Transfer Agent Pathways: Localization and Persistence of the Transgene at its Target

To improve gene transfer agents, we need to know which hurdles they will have to overcome. Early studies of intracellular trafficking of the vectors were performed by means of electron microscopy.

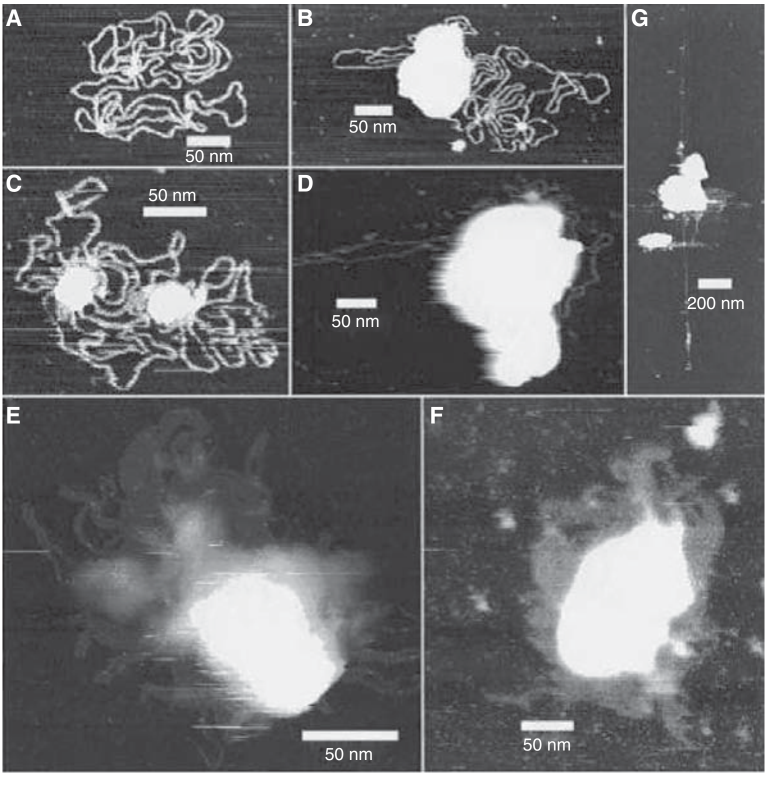

Figure 10.2-2. Scanning force microscopy to image the association between the nucleic acid and the vector. The authors have imaged DNA and its condensation by synthetic gene transfer agents. Reprinted from Ref. 9, with permission from Oxford Journals.

Transmission Electron Microscopy. To observe polyplexes, thin cell sections are negatively stained using uranyl acetate and observed by TEM [8], which can track gene transfer agents. Existing structures can be observed, but when the polymer dissociates, nothing is visible any more. To observe the nucleic acid either free or associated with its vectors, a labeling using gold-labeled probes can be used. The nucleic acid sequence is recognized by a probe that has been tagged with gold particles. The intracellular progression of the nucleic acid can thus be visualized [1] (Figure 10.2-3).

Fluorescence Microscopy. This microscopic approach is used to study the trafficking of either the vector or the nucleic acid. By a fluorescent labeling of the structure of interest (with fluorochrome such as FITC or TRITC), it is possible to visualize the internalization and trafficking processes using fluorescence microscopy or confocal microscopy. Using this approach, Midoux's group studied the internalization of polyplexes in HepG2 cells [11]. An interest of this last technique is that both the vector and the nucleic acid can be labeled. The complex evolution (and its disruption) can be observed.

Magnetic Resonance Imaging. MRI can be used to track complexes during transfection even at the cellular level [12]. MRI microscopy achieves a resolution of about 1 μm. It is based on the co-complexation of the DNA and the contrast agents with a cationic polymer (theoretically, it is also possible with all cationic gene transfer agents). By adding selective molecules, it is possible to target specific cells. A gadolinium derivative is used to follow the fate of the complex (DNA

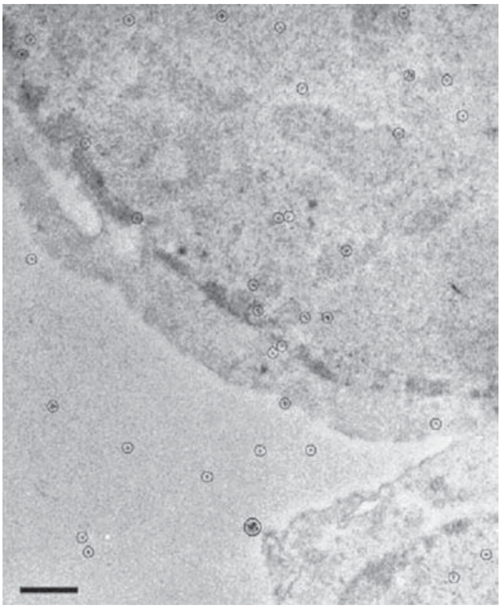

Figure 10.2-3. Study of the intracellular trafficking of a plasmid complexed with a synthetic phosphonolipid using electonic microscopy. Cell lines were transfected with lipoplexes. Then, DNA probes specific to the plasmid used and tagged with gold particles was incubated with the cells pellet sections. The DNA migration was also observed. Reprinted from Ref. 1, with permission from Elsevier.

polymer) within the cell. This real-time visualization reveals only the contrast agent aggregates. No information is given on the organization of the visualized structure, and it is not possible to say whether or when the complexes have been disrupted.

10.2.2.3 Evaluation of Gene Transfer Efficiency

Given how hard it is to demonstrate the functional activity of genes, a nucleic acid delivery system is usually developed using reporter genes encoding proteins that are easily detected through enzymatic reaction or their intrinsic fluorescence.

Fluorescence Microscopy. To ensure that a delivery system or a vector efficiently transfers a nucleic acid into a cell, the easiest approach is to use a reporter gene encoding a protein that can be visualized directly. Reporter genes such as GFP or its new derivatives RFP (red) or BFP (blue) are satisfying because gene expression can be easily visualized by fluorescence microscopy. Moreover, by using a fusion protein, this approach not only reveals expres-sion but also defines cellular localization, particularly when using confocal microscopy. Indirect visualization can also be performed using a nucleic acid that encodes a tagged protein. By incubating the cells with a fluorescent ligand that specifically forms a covalent bond with the tagged protein, the transfected cells appears fluorescent.

Bioluminescence. The bioluminescence approach is not frequently used for *in vitro* studies because of the scarcity of the equipment required. The classic reporter gene luciferase can be used to visualize changes in cells, which is of particular interest when working with a nucleic acid that encodes both luciferase and its substrate, luciferin.

Magnetic Resonance Imaging. When used with MRI, classic contrast agents can track complexes but give no information on gene expression, which is why new reporter genes were developed to modify and hence activate contrast agents, including the gene-encoding ferritin, transfer agents, and enzymes that enable "smart" MRI contrast agent activation [13]. These smart contrast agents are prepared in a weak relaxivity state. When they enter a cell genetically modified by gene transfer, they are transformed into a strong relaxivity state, which is the case of EGad, a gadolinium complex. When Egad interacts with β-galactosidase, a widely used reporter protein, the Egad chelate is disrupted and the relaxation properties of gadolinium can be imaged.

All these MRI approaches applied to cells and to animal models are potentially applicable to humans. MRI is particularly interesting because it gives real-time information potentially at high resolution.

10.2.3 *IN VIVO* IMAGING EXPERIMENTS

10.2.3.1 Imaging Biodistribution of Gene Transfer Agents

It is essential to study the biodistribution of components involved in gene transfer (virus, synthetic vector, or nucleic acid) to identify all *in vivo* barriers. This study indicates what proportion of the administered dose actually reaches the target, as well as any unexpected localizations (according to the quantity at each site) or blocking sites, which is of particular interest because it allows prediction of the

dose that will produce a significant therapeutic effect. Biodistribution studies indicate the time when the nucleic acid is released from its vector. Using markers specific to each component (by labeling or conjugating), it is possible to follow both of them separately and also to observe their separation and fate (i.e., their elimination route and metabolism).

The most frequently used approach is direct, in which a radionuclide (usually a β-emitter) is used to label the different components. Indirect studies are also possible, such as the use of markers that are supposed to mimic the behavior of the studied molecules. Invasive imaging methods are used less frequently. In some, the compounds involved are radiolabeled and administered before sacrifice of the animal. The animal's body is thinly sectioned using a cryomicrotome and visualization is done either by classic autoradiography or phosphorus imaging. Gene vectors may also be labeled with fluorescent markers and visualized on microsections. As a result of whole-body dilution, this approach is essentially used to pinpoint a component in the cells of a defined organ, after localization by scintigraphy or autoradiography. Although invasive approaches have been widely used, live imaging is now largely preferred, mainly using the methods described below.

Radioisotopic Imaging. Radioisotopic imaging (using γ-emitters) efficiently tracks the distribution of viral [14] and nonviral vectors [15, 16]. In these two cases, the adenovirus and the GLB43 lipid vector (Figure 10.2-4) were labeled with ^{99m}Tc pertechnetate using a stannous tin procedure. Although most available devices give planar imaging, this approach is quantitative. Scintigraphic imaging can be applied to all kinds of animals and also to humans (depending on the radioactive dose). The method used to label the vector is not always suitable for the nucleic acid, as nucleic acid chelation may inhibit its expression. It is, therefore, necessary to choose between information on expression and on location.

Magnetic Resonance Imaging. MRI is a multivalent approach that also predicts gene transfer efficiency (i.e., whether the transgene actually reached the targeted site). The transgene pathway can be mimicked using a contrast agent, which is administered as the nucleic acid would have been (i.e., associated with a gene vector or directly injected into the targeted tissue). Thus, a gene transfer approach can also be validated by MRI. Moreover, as MRI visualizes tissues and organs, any deleterious effects after gene transfer can be monitored [17].

10.2.3.2 Imaging Gene Transfer Efficacy

The sites of gene transfer clearly must be defined whatever the animal model used or clinical application. For most applications, a specific target is considered. Different administration routes will result in particular expression levels and accuracy of targeting. Direct visualization on thin sections is a common approach in which immunofluorescent probes of the expressed protein are used to study transgene expression (Figure 10.2-5). For example, Bartoli et al. visualized the transgenic protein (α-sarcoglycan) by immunohistochemistry using a secondary antibody conjugated to the fluorochrome Alexa488 in animal models of muscular dystrophies [18].

Animal care and ethical issues are of increasing importance even in research, and so when suitable technology is available, it is preferable to use noninvasive methods

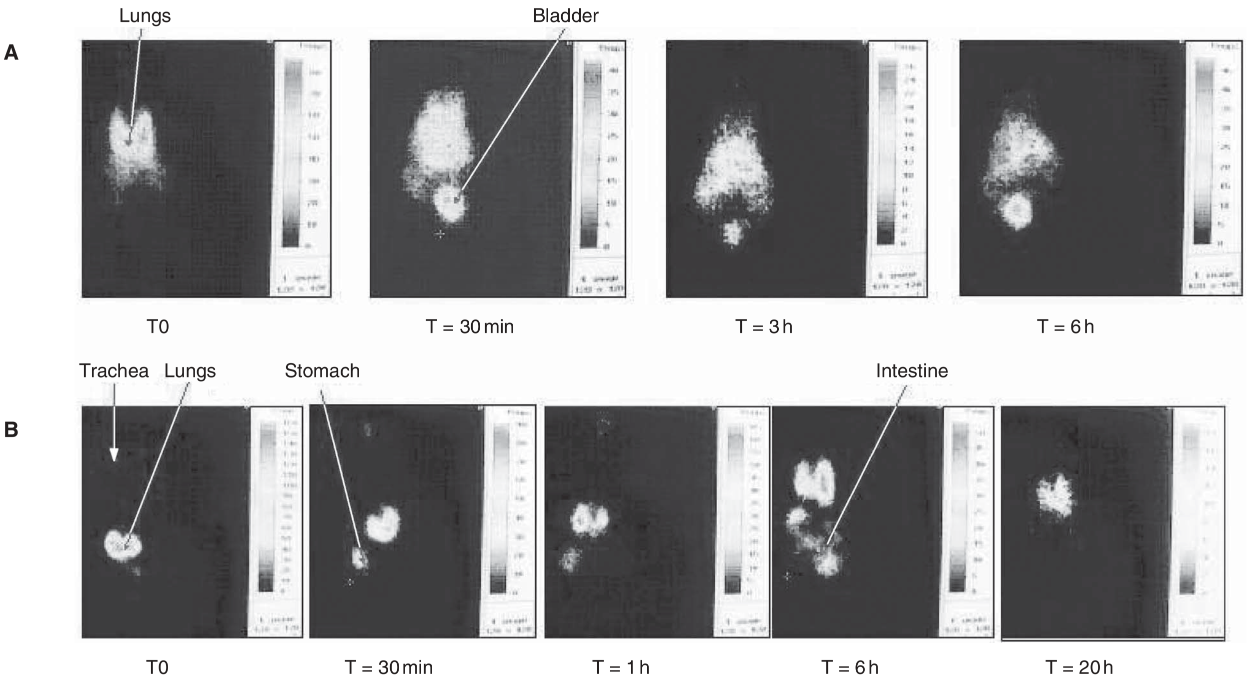

Figure 10.2-4. Scintigraphic biodistribution study. A plasmid encoding the reporter protein luciferase was labeled with ^{99m}Tc. The lipoplexes, resulting from the association of the phosphonolipid GLB43 with the radiolabeled plasmid, was administrated to mice either by intravenous injection or endotracheal nebulization. The animals were imaged using a gamma camera dedicated to small animals. Reprinted from Ref. 15, with permission from Nature Publication Group. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_med/pharmaceutical_biotech/.)

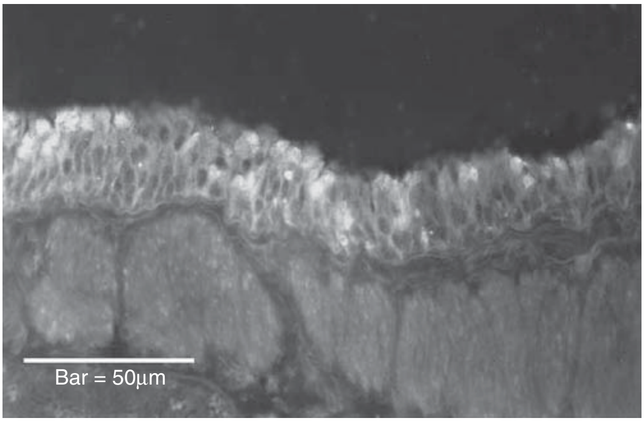

Figure 10.2-5. Immunohistofluorescence imaging to visualize the cells that express the transgene. After mice transfection with a reporter gene (luciferase) associated with the synthetic amphiphiphilic vector (KLN47), the transgene expression was visualized using a primary antibody directed against the luciferase protein. The secondary antibodies were FITC labeled. The expressing cells are thus identified in the targeted tissue (from Delépine et al., unpublished data). (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

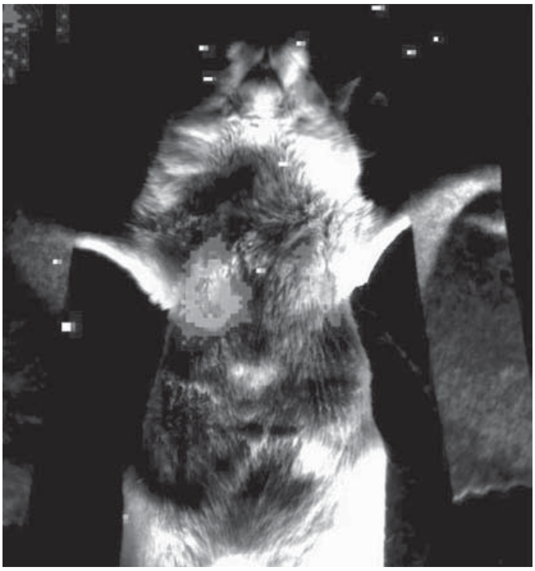

Figure 10.2-6. *In vivo* bioluminescence imaging. The luciferase transgene expression was observed using a CCD camera 24 hours after an intravenous injection of a lipoplexe (KLN20 phosphonolipid + pCMVLuc) [19]. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

to study gene transfer. Tomography is useful in this regard as it gives information on gene expression in terms of time lag, duration, magnitude, and location.

Bioluminescence [19] *(Figure 10.2-6).* Since a pioneering 1998 study of bioluminescence in living mammals [20], bioluminescence technology has advanced

greatly and is probably now the most accessible and common approach to *in vivo* imaging. It is, however, limited by the data acquisition, as the most frequently used devices equipped with a CCD camera do not give tomographic information (because of the cost of the tomographic apparatus) and the main part of the emitted light is absorbed by the tissues. Moreover, this absorption depends on tissue type and depth, so it is difficult to extrapolate the results from one animal to another. Another limitation is the diffusion of the substrate. In most cases, the luciferase substrate is injected intraperitoneally. If the transfected site is less accessible because of disease or another cause, the substrate concentration is reduced locally, as is the luminescent signal. This bias can be prevented by using a genetic construction that simultaneously expresses both luciferase and its substrate.

New tomographic devices based on bioluminescence are able to generate a 3D reconstruction, using software to calculate photon absorption for the various tissues. Two advantages accrue from this ability: First, this approach is quantitative and, second, it more precisely localizes the source(s) of luminescence induced by the gene transfer procedure. Although bioluminescence techniques are evolving, they are still only applicable to small animals. The hurdles inherent to this imaging approach and to the use of such reporter genes prevent its application to humans.

Fluorescence. Most bioluminescence imaging devices are also equipped for fluorescence imaging. Fluorescent markers are less sensitive than bioluminescent ones and so are used less. Most of the frequently used reporters emit at a wavelength similar to that of natural molecules, particularly GFP and DsRed. The background is also high with these probes, so few markers are wholly satisfying. However, whole-body fluorescence imaging has been used to visualize gene expression [21].

Positron Emission Tomography. PET can be used to study gene transfer expression in living animals. It has a satisfactory resolution (around 1 mm) for definition of organ targeting and, above all, gives a quantitative signal. The most commonly used positron-emitting radioisotopes are ^{18}F, ^{15}O, ^{13}N, and ^{11}C. PET imaging is used diagnostically in humans to monitor function or localize tumors. Its potential has been progressively enhanced and the increased resolution of microPET methods enables imaging in small laboratory animals [22] (Figure 10.2-7). The three main PET approaches to *in vivo* imaging involve an intracellular enzyme-encoding reporter gene, a membrane receptor-encoding reporter gene, or a membrane transporter-encoding reporter gene [23, 24].

The enzyme approach consists of a genetic modification using an enzyme-encoding reporter gene, usually encoding an HSV-tk mutant (HSV1-sr39tk) [25]. When the genetic modification is performed, the neo-synthesized enzyme is able to phosphorylate uracil derivatives such as [^{124}I]FIAU and acycloguanosine derivatives such as [^{18}F]FHBG. The phosphorylated substrate is unable to leave the cell and the intracellular accumulation of radiolabeled molecules generates a detectable signal. Using the reporter gene HSV-tk, a significant correlation has been demonstrated in rats (after adenovirus gene transfer) between the transgene expression and tissue accumulation of the reporter probe [^{18}F]FGCV [26].

The receptor approach consists of a genetic modification using a reporter gene encoding a receptor, usually the dopamine D2 receptor [27] or the SSTr2 receptor [28]. Using positron-emitting labeled probes that specifically target the receptor, it is possible to identify the sites where the genetic modification occurred.

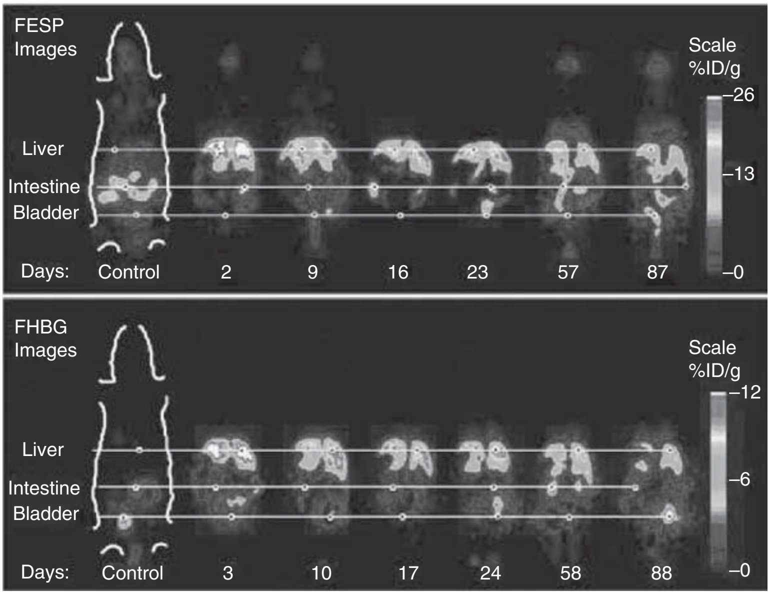

Figure 10.2-7. MicroPET imaging to visualize the kinetics of gene expression in mice. Mice were transduced with either a D2R PET or a HSV1-sr39TK PET reporter gene by intravenous injection of adDTm. Reprinted from Ref. 22, with permission from Elsevier. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

The transporter PET strategy consists of modifying the cells of interest with a gene that encodes a transporter able to generate intracellular accumulation of a radiolabeled reporter probe. The sodium iodide symporter (NIS) is one of the most used transporters in this application [29].

Using sequences that enable simultaneous expression of two genes (such as IRES), it is theoretically possible to define expression of the gene of interest in terms of location, magnitude, and duration by studying reporter gene expression [30].

Magnetic Resonance Imaging. MRI can be used to assess gene transfer expression, which is visualized and localized in the animal's body through planar or spatial (2D or 3D) images. *In vivo* transgene expression can be observed in real time, thereby giving information on the time lag between gene transfer and gene expression. MRI has the great advantage of visualizing surrounding tissues. It is therefore possible not only to assess gene transfer efficiency but also any deleterious (inflammation, necrosis, and so on) or beneficial (such as tumor regression) effects [31]. Any effects of gene transfer are defined early and at high resolution and sensitivity, whatever the gene transfer process adopted. MRI can be used for whole-body imaging of gene expression. In mouse brain, gene expression can be monitored after stereotaxic injection of recombinant adenovirus that encodes ferritin [2] (Figure 10.2-8). The relevance of gene transfer to rat muscle by electrotransfer has also been documented by MRI. Expression of the reporter gene luciferase was well correlated with contrast agent entrapment (Gd-DOTA) when administered by the same procedure [17]. Coadministration of the contrast agent and the reporter gene

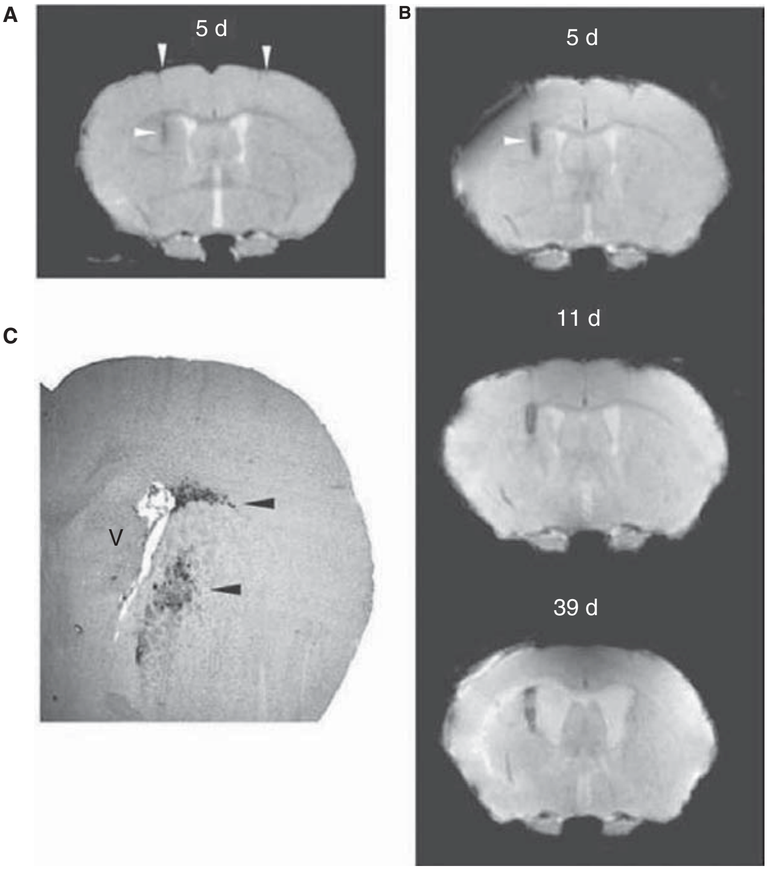

Figure 10.2-8. MRI imaging for gene expression study. In this example, Genove et al. [2] have documented the expression of a ferritin-encoding gene after stereotaxic injection of a recombinant adenovirus. In this study, the MRI imaging approach was validated by an X-Gal staining after injection of an AdV-LacZ. MRI allows a kinetic study of the gene expression. Reprinted from Ref. 2, with permission from Nature Publication Group. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

does not modify reporter gene expression. So, once the experimental parameters have been optimized, MRI can be used to indirectly evaluate gene transfer expression and location.

10.2.3.3 Advantages and Drawbacks of Imaging Approaches

Gene transfer approaches are not only used to study gene transfer agents. Some reporter genes introduce tags into *ex vivo* modified cells, thereby allowing imaging of their fate (migration, homing, and so on).

To complete the gene transfer studies, safety can be studied in animal models by using ultrasound or X-ray computed tomography to document any tissue or organ alteration. Planar imaging is valuable and easy to perform, but does not really

reflect the true situation, as photon emission depends on tissue type and depth. Moreover, emission is multidirectional, whereas collection is planar, which leads to a large loss of information. PET is currently only used to characterize gene expression (time lag, level, and duration), which may seem quite limiting with regard to the questions initially posed.

Biodistribution studies using PET can be imagined in which a positron emitter is used to label vectors (either viral or nonviral) or the nucleic acid. Such an approach will be contingent on efficient labeling that does not alter the various components.

MRI of cells or small biological samples requires high magnetic fields (often up to 11.7 T), and the requisite equipment is limited in availability because of its prohibitive cost. Experimentally, MRI is very satisfying because the signal obtained not only yields an image but also provides information on sample content (MR spectroscopy). This twofold analysis will become increasingly powerful as higher magnetic field strengths are used. MRI will soon be able to give information simultaneously on changes in structure (by imaging) and in chemical composition (by spectroscopy) of the targeted site.

Bioluminescence devices are also able to give 3D images, but quantification is indirect and based on mathematical treatment that involves considerable extrapolation.

10.2.4 CONCLUSION

Advances in gene transfer have gone hand in hand with developments in the imaging technologies used to assess transfer efficiency. In gene expression studies, the most frequently used imaging methods are optical (particularly bioluminescence) and nuclear (PET). Whereas optical approaches are limited by the tissue absorption of the signal, the nuclear approach suffers from insufficient resolution. Magnetic resonance offers high resolution, but higher magnetic fields and more relevant and sensitive probes are needed.

No single imaging method can fulfill all research requirements. For large-scale screening or preliminary validation of a new approach, the least expensive method is to be preferred. More costly methods can be applied once the gene transfer approach has been shown to be feasible for gene therapy. Some molecular systems enable two imaging strategies. Using a fusion protein encoding both luciferase and an HSVtk enzyme, gene transfer has been documented using optical bioluminescence and PET [32]. Such fusion proteins are very promising and current improvements might be of great value in gene transfer imaging. An alternative to these fusion proteins is to use two reporter genes (delivered by the same route) to enable a combination of methods, such as PET and fluorescence imaging. Reporter genes may also be coupled with a therapeutic gene through an IRES sequence to monitor modified cells after subcutaneous injection in the mouse [33]. This approach visualizes where expression occurs and its therapeutic effects. But what of functional changes induced by the reporter gene? In the case of PET, three approaches can be envisioned, involving enzymes, receptors, or transporters. How might these proteins impact on cell function? Is therapeutic gene expression really representative of the effects in normal conditions? And how reliable a picture of reality is

given by imaging techniques? Proposed solutions to such outstanding questions may be interesting in research terms but are not always appropriate in a clinical setting. It seems best to tackle these problems by comparing and combining data from various imaging approaches.

11.1 INTRODUCTORY REMARKS

Research on stem cells allows us to get the information about how an organism grows and develops from a single cell and how healthy normal cells replace damaged cells in adult organisms. This promising area of stem cell studies is fascinating scientists to investigate the possibility of cell-based therapies to treat a wide range of diseases, which is referred to as regenerative medicine. Stem cells have two important characteristics that distinguish them from other types of cells. First, they are capable of renewing themselves for long periods through cell division. Second, under some experimental conditions, the cells can be induced to be the functional cells, such as the beating cells of the heart muscle, the albumin-producing cells of the liver, or the insulin-secreting cells of the pancreas. Thus, it is now hypothesized by researchers that stem cells may, in the near future, play a basic role in treating diseases such as heart disease, liver disease, and diabetes. Toward that goal, it is important to understand stem cell biology and its therapeutics. Eventually, control of the growth and differentiation of stem cells will be a big tool in the fields of regenerative medicine, tissue engineering, drug discovery, and toxicity testing.

Although normal human cells are ideal to develop cell therapy, it is unlikely that human cells can be isolated on a scale sufficient to treat many patients. The use of animal cells results in the concerns related to the transmission of infectious pathogens and immunologic and physiologic incompatibilities between the donor and humans. Human embryonic stem cells and bone marrow multipotent adult progenitor cells have receive much attention as a possible source for such cell therapy and drug discovery. It is unlikely that perfect control of differentiation of these multipotent cells will be achieved in very near future. Another attractive cell source is human-derived cell lines. In particular, the use of tightly regulated clonal human cell lines are of value. Such cell lines grow economically in tissue culture and provide the advantage of uniformity, sterility, and freedom of pathogens. Reversible immortalization mediated by Cre/loxP site recombination seems to be the most reliable approach to construct human cells for the clinical setting. In Section 11.2, the authors review the nature of embryonic stem cells and their potential. In Section 11.3, somatic stem cells are discussed. In Section 11.4, the authors describe the general concepts of senescence, crisis, telomeres, telomerase, and immortalization of the cells. Finally, the authors introduce the construction of artificial human liver cells and pancreatic beta cells by the use of Cre/loxP-based reversible immortalization.

11.2 EMBRYONIC STEM CELLS

11.2.1 Introduction

Embryonic stem cells have become a very important source for basic research and possible clinical applications since more than 20 years ago when the establishment of mouse embryonic stem cells (ES cells) was achieved by Evans and Kaufman [1] and Martin [2]. They established the pluripotent cells from the inner cell mass of the blastocyst, mouse ES cells, and developed the culture conditions for the cells *in vitro*. The achievement evolved the studies on teratocarcinomas, tumors that arise in the gonads of several inbred strains and consist of an array of somatic tissues juxtaposed together in a disorganized fashion, and gave the origins of the concept of embryonal carcinoma (EC). As teratocarcinomas could also induced by grafting the blastocyst to ectopic sites, it was likely that pluripotent cell lines could be derived directly from the blastocyst. As expected, a stable diploid cell line that could differentiate into all embryonic cell types was established and formed functional germ cells after transplantation into chimeric mice [1–3]. Testicular teratocarcinomas occur spontaneously in humans, and pluripotent cell lines were derived from the teratocarcinomas [4]. In 1998, human ES cell lines were established from pre-implanted embryos by Thomson et al. [5]. Frozen human embryos that were produced by *in vitro* fertilization at an early stage were thawed and cultured to the blastocyst stage. Fourteen inner cell masses were isolated, and five ES cell lines were established. During the first 8 months of culture, no period of replicative crisis was observed in any cell lines. The principal characteristics of the established cells were that the cells expressed high levels of telomerase activity, which suggests that their life span exceeds that of somatic cells. These cells also expressed surface markers that are typical of human embryonic carcinoma cells, such stage-specific embryonic antigen (SSEA)-3, SSEA-4, TRA-1-60, TRA-1-81, and alkaline phosphatase. The cells also expressed the Transcription Factor Octamer binding protein 4 (Oct-4) to undergo somatic differentiation [6]. ES cells could be used for many different purposes, including early development research [7], toxicology and drug screening [8], and gene and protein screening. One of the most important uses is for regenerative medicine and cell therapy, which involves the transplantation of healthy, functional, and propagating cells to restore the viability or function of deficient tissues and organs [9]. The availability of reliable cells is essential for the toxicology and drug discovery process. The primary cells, immortalized cells, and genetically modified cells have been used for drug discovery; however, the inconsistent availability of the primary cells and the genetic abnormalities of transformed cells are the current problems with such application. ES cells could offer considerable advantages due to their plasticity, proliferative capacity, and the ability to undergo homologous recombination at relatively high frequency. In conclusion, ES cells may offer several important advantages in the field of basic biology, drug discovery, and the future cell therapies in various human diseases.

11.2.1.1 Properties of Embryonic Stem Cells

Pluripotency

MOUSE ES CELLS. Culturing mouse ES cells from the inner cell mass of the preimplanted blastocyst were first reported more than 20 years ago [1, 2]. To date only

three species of mammals have yielded long-term cultures of self-renewing ES cells: mice, monkeys, and humans [1, 5, 10]. Mouse ES cells lines have shown an unlimited capacity of proliferation and ability to contribute to all cell lineages, which are defined as pluripotency to all definitive tissues: ectoderm, mesoderm, and endoderm. Leukemia inhibitory factor (LIF), a cytokine belonging to the IL-6 family, has been identified as an exogenous signal to maintain ES self-renewal [11]. LIF was initially identified by its activity to induce differentiation of M1 leukemia cells [12], whereas it mediates the opposite cellular responses in ES cells. The signal transduction of LIF consists in the LIF-specific receptor subunit LIFRβ and the common signal transducer gp130, which is shared between the members of the IL-6 cytokine family; the gp130 signaling regulates several cell functions through signal transduction and activation of transcription factor STAT3 that may interact and affect the function of common target genes. Cytokines, including IL-6, IL-11, oncostatin M, ciliary neurotrophic factor, and cardiotrophin-1, show similar properties maintaining the pluripotency of mES cells [12]. A coculture of mouse ES cells on an inactivated mouse embryonic fibroblast layer is also required to maintain the undifferentiated stage. Thus, production of some critical factors of the fibroblast layer is required either to promote self-renewal of mouse ES cells or to suppress their differentiation. The activation of STAT3 is essential to the LIF signaling pathway, but it plays an accessory role to maintain ES cell identity [13]. Moreover, there are two major pathways of intracellular signal transduction downstream of gp130; the Jak-Stat pathway and the Shp2-Erk pathway. As Jak and Shp2 interact with separate subdomains of the intracellular domain of gp-130, it has been demonstrated that the activation of Jak but not Shp2 is sufficient to preserve an undifferentiated status of mouse ES cells. The finding means that the LIF signal is mainly transmitted to the nuclei by the Jak-STAT signal pathway [14] and the Shp2-Erk pathway does not contribute directly to stem cell renewal as demonstrated when adding Erk kinase inhibitor PD98059 in the medium resulting in self-renewal [14]. Although STAT3 acts as a transcription factor to activate target genes, there is only one gene whose specific function in pluripotent cell population is confirmed, that is, the POU-family transcription factor octamer-3/4 (Oct-3/4) encoded by Pou5f1 [12]. The essential role of Oct-3/4 in mouse development has been revealed by targeting gene deletion [15]. Oct-3/4-deficient embryos fail to initiate fetal development because the prospective founder cells of the ICM do not require pluripotency and become diverted into the trophoectoderm lineage, which indicates that Oct-3/4 is essential to establish a pluripotent cell population in preimplantation development [15]. ES cells require a critical level of Oct-3/4 to maintain stem cell renewal, and at least a twofold increase in the expression of Oct-3/4 causes differentiation of mouse ES cells into the endoderm and mesoderm, whereas reduction to less than 50% of the normal expression level of Oct-3/4 triggers de-differentiation of mouse ES cells into the trophectoderm [16]. Recently identification of the homeodomain protein Nanog as another key regulator of pluripotentiality has opened another door of the complicated system of pluripotency; the dosage of Nanog is a critical determinant of cytokine-independent colony formation, and the forced expression of this protein confers constitutive self-renewal in ES cells without gp-130 stimulation; Nanog may act to restrict the differentiation-inducing potential of Oct-3/4 [17]. Other investigators have reported that the induction of the expression of Inhibitor of differentiation (Id) by addition of TGF-β1/bone morphogenetic protein

(BMP) in combination with LIF sustains self-renewal via the Smad pathway [18]. Recent studies have implicated the importance of Wnt-signaling pathways in the maintenance of ES cell pluripotency [19]. Components of the β catenin Wnt-signaling pathway are expressed in ES cells, and it is likely that activation of the Wnt-signaling pathway using a glycogen synthase kinase (GSK)-3-specific inhibitor (BIO) that maintains the pluripotent state of human ES and mouse ES cells [19] (see Figure 11.2-1).

The pluripotency of ES cells depends on the balance of various signaling molecules, and thus, such imbalance causes differentiation of ES cells. Many other molecules, such as Genesis [20], Rex-1 [21], Sox2 [22], GBX2 [23], and UTF1 [24], have been identified with a potential role in defining pluripotency.

Human ES Cells. The murine models of isolation, derivation, culture, and characterization in ES cells have provided valuable information to the generation of human ES (hES) cell lines derived from the embryos at the preimplantation stage, which involves culturing embryos to the morula or blastocyst stage (see Figure 11.2-2). These embryos are donated for research to establish hES cell lines. Thomson et al. isolated from the ICM of human blastocysts, placed on inactivated

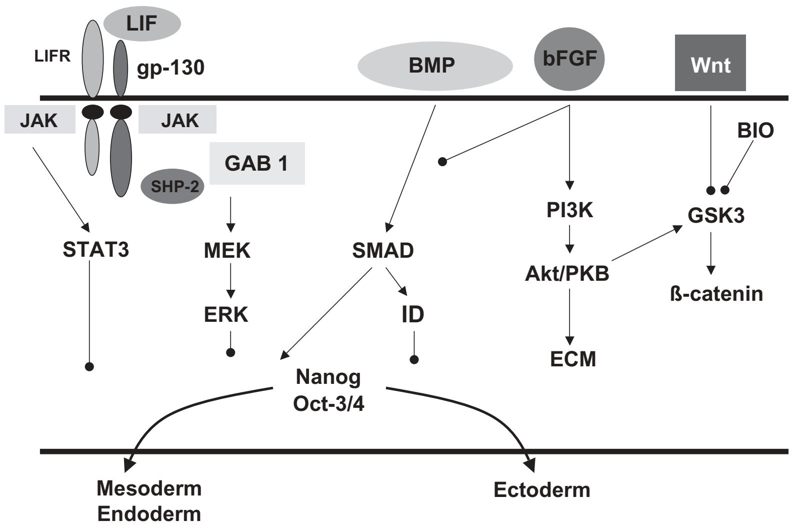

Figure 11.2-1. ***Regulation pathways of self-renewal in the undifferentiated stage of ES cells.*** The undifferentiation of ES cells is regulated by Nanog, Oct-3/4, and interactions between LIF-dependent JAK/STAT3 pathways principally in mouse ES cells. In human ES cells, the mechanism involved is the BMP-dependent activation of Id target genes; the role of bFGF is to activate the (PI3K)/Akt/PKB pathway, which subsequently down-regulates the expression of ECM molecules; and finally the Wnt pathway activation by specific pharmacological inhibitor BIO of GSK-3 maintains the undifferentiated phenotype in both mouse and human ES cells. The balanced expression level of Oct-3/4 determines the fate of ES cells. Adapted from Niwa.[30] Abbreviations: LIF (Leukemia Inhibitor factor), BMP (bone morphogenetic protein), bFGF (basic fibroblast growth factor), ECM (extracellular matrix), BIO (6-bromoinduribin-3′-oxime), GSK3 (glycogen synthase kinase-3). (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

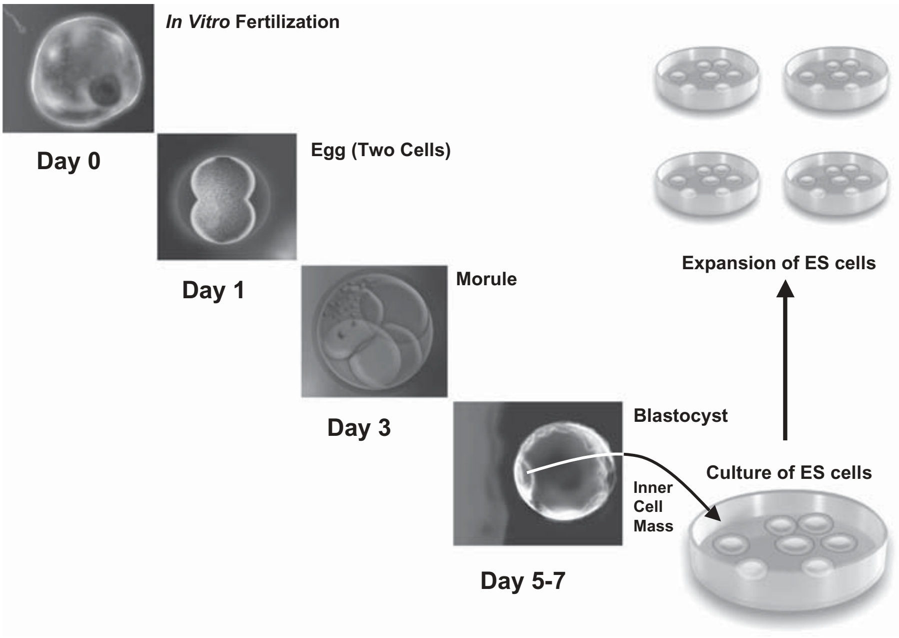

Figure 11.2-2. ***Developmental origin of embryonic stem cell lines.*** Illustration demonstrates the derivation of embryonic stem cells and their culture.

murine feeder cells, and successfully performed initial derivations of hES cell lines [5]. Since that time, many laboratories have applied the same techniques to derivate hES cell lines (see Figure 11.2-2). hES cells have been currently characterized by a set of markers and their differentiation capacity. These criteria include the expression of several surface markers and transcription factors that associated with an undifferentiated state. In addition, maintenance of extended proliferating capacity, pluripotency, and normal euploid karyotype without marked change in the epigenetic status of hES cells is a crucial issue for the future use of the cells in clinical trials. Several surface markers have been identified to characterize hES cells, in which glycolipids and glycoproteins, such as SSEA-4, TRA-1-60, and TRA-1-81, that are expressed in human embryocarcinoma cells are present in hES cells. Some surface antigens initially described in other stem cells are AC133, CD-9, CD-117, and CD-135, which are also expressed in hES cells [25]. The stability of the expression of these surface markers in hES cells after culture for prolonged periods of time has been maintained.

Several critical transcription factors that play a critical role in maintaining self-renewal of stem cells have now been identified, and these analyses are also useful for characterization of hES cells. One of these transcriptional factors is Oct-3/4, and several Oct-3/4-targeting genes have been identified in hES cells, which are Utf-1, Rex-1, PDGFαR, Otx-2, Lefty-1, and Nanog. However, their specific roles have not been identified, and their expression has been retained in hES cells for over a year in culture [15–19, 25]. Additionally, all hES cell lines express high levels of telomerase, an enzyme that helps to maintain telomeres that protect the end of the chromosomes. Telomerase activity and long telomeres are characteristics of proliferating

cells in embryonic tissue and germ cells. As cells divide and differentiate throughout the life span of an organism or cell line, the telomeres become progressively shortened and lose the ability to maintain their length. The functions of telomeres and telomerase seem to be important in the cell division, normal development, and aging [26]. Mouse ES cells have shown to require activation of the gp-130/STAT3 pathway to maintain the cells in the undifferentiated stage. This activation is generally achieved by the addition of LIF to the culture medium. In contrast, it has been demonstrated that the addition of exogenous LIF to hES cell culture does not maintain the pluripotent capacity of hES cells [27]. However, common intracellular signaling pathways exist between mES cells and hES cells to regulate self-renewal and to maintain an undifferentiated state. These signaling pathways have not yet been clarified, although transcriptional profiling or gene expression technology has identified several genes, transcription factors, ligand/receptor pairs, and secreted inhibitors of signaling pathways. hES cells can be maintained in several different conditions by the use of growth factors belonging to the TGF-β1/BMP superfamily, fibroblast growth factor (FGF) family, and Wnt family.

Previous studies have demonstrated that prolonged propagation of undifferentiated hES cells requires culture of the cells on embryonic fibroblast feeder layers. The use of bFGF has become a common thread in the culture medium formulas, which have been recently developed by using feeder-free conditions [28]. hES cells can be maintained in serum replacement-containing medium that has been supplemented with 36–40 ng/mL of bFGF, in which culture condition the cells can retain the expression of surface markers, transcription factors, normal karyotype, telomerase activity, and pluripotency of hES cells conventionally cultured on embryonic fibroblast feeder layers. The mechanism of bFGF activity in hES cell culture remains unclear, but it has been demonstrated that treatment with 40–100 ng/mL of bFGF inhibits BMP signaling in hES cells. A further role of bFGF in hES cells to maintain pluripotentiality is activation of the phosphatidylinositol 3-kinase (P13K/Akt, PKB) pathway, which subsequently enhances the expression of extracellular matrix molecules (ECMs). Removal of bFGF in hES cell culture or the treatment of the cells with chemical inhibitors of the PKB pathway results in downregulation of the expression of hES cell markers as well as a decrease in ECM components [29] (see Figure 11.2-1).

Differentiation. Pluripotency is one of the defining features of ES cells. The most definitive test of pluripotency of the cells is the formation of chimeras in mice in which the mES cells are injected into the blastocyst. The approach cannot be applied to assess pluripotency of hES cells, therefore, and teratoma formation after injection of embryonic bodies (EBs) of hES cells *in vitro* into immunocompromised mice is currently used to validate the pluripotency of the established hES cell lines in culture. In the case of mES cells, once differentiation of ES cells has started, the cells representing the primary germ layers spontaneously develop *in vitro* in the absence of LIF. The culture conditions to form EBs include hanging drops [30], suspension mass culture [31], or the use of methylcellulose [32]. Initially, an outer layer of endoderm-like cells forms within ESs, followed by the development of an ectodermal layer and subsequent specification of mesodermal cells over a period of a few days [33]. The generation of specific functional cell types from hES cells has been demonstrated both *in vitro* and *in vivo*. In fact, with the rapid interest in

gene targeting for the development of genetically modified mice, most of the efforts directed toward ES cells have been made in the maintenance of ES cells in an undifferentiated state. Although research on *in vitro* differentiation of ES cells has been limited, investigators have demonstrated differentiation protocols, which assess the differentiated cells via expression analysis of cell-specific markers. However, very few markers are specific for one cell type, and for that reason, panels of markers must be used in these experiments. Understanding of cellular differentiation during embryogenesis has led to methods for enriching populations of specific cell types: First, genetic manipulation of ES cells facilitates differentiation and serves as a framework for genetic engineering of ES cells by key transcription factors to regulate their cell fate [34]. Second, culture conditions supplemented with established growth factors can be used. Several samples of clinically and pharmacologically relevancy have been proposed, including almost any kind of cells, such as chondrocytes [35], atrial and ventricular cardiomyocytes [30], hepatocytes [36], pancreatic islet cells [37], and motor neurons [38]. Third, coculture conditions have been reported to facilitate and produce differentiated cells [39] (see Figure 11.2-3). Fourth, ectopic implantation of ES cells into syngenic or immune-compromised mice produces specific cell types [40]. Although such transplantation is a powerful approach, this is not a practical method for deriving cells to be evaluated in clinical experiment. Currently the desired cells cannot be developed on a stable large scale. Inductive differentiation protocols have generated many cell types to further enrich *in vitro* differentiated populations by the use of selective methods that are based on the expression of specific marker proteins. Such

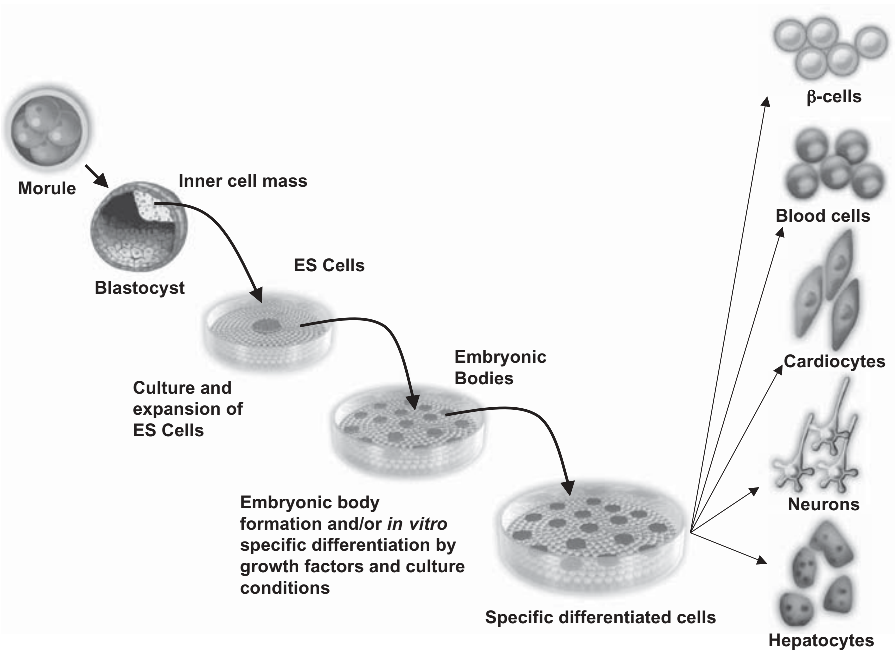

Figure 11.2-3. ***Differentiation potential of embryonic stem cells.*** Illustration shows the possible application of ES cells for cell therapy.

selective protocols can include promoter-based recovering strategies, based on GFP-dependent cell sorting [41], or antibiotic selection [42], and have allowed the enrichment of increasingly defined phenotypes from ES cells. Cell sorters have been applied to enrich the populations by using specific cell surface markers of ES cell derivatives.

Investigators have used the forced gene expression to influence *in vitro* differentiation of ES cells. For example, constitutive overexpression of murine *Pax 4* in ES cells combined with an inductive protocol has resulted in an enrichment of nestin-positive progenitors and insulin-producing cells among other cells found in pancreatic islets [43]. Finally, the next step in developing clinical trials and drug discovery is the use of internal bioimplants using bioactive materials that provide biological signals at the site of damaged tissues *in vivo*. This next generation of implantable bioartificial devices can permit the evaluation of the potential of ES cell derivatives *in vivo* without having direct contact with the blood circulation. Such an approach allows researchers to avoid a risk of tumor formation of ES cell derivatives and to examine the fate of such cells in an isolation manner from the body.

ENDODERMAL DIFFENTIATION. The pancreas and liver are the derivatives of the definitive endoderm; hepatic and pancreatic cells are of special therapeutic interest for the treatment of diabetes mellitus and hepatic failure. Theoretically, both cells can be generated from ES cells. Researchers have demonstrated different strategies *in vitro* to differentiated mES cells in hepatocyte-like cells; these cells have shown specific transcription factors and proteins of normal hepatocytes; they also have been shown the presence of the two lineages of the liver cells, bile duct epithelial cells and oval cells. Once the cells are transplanted, these cells can integrate into the hepatic parenchyma and function in the host liver. It has been previously demonstrated that ES cells can differentiate into hepatocyte-like cells [36, 40, 44] through *in vivo* differentiation of mES cells in the damaged host liver and subsequent recovery of mES cell-derived hepatocytes by the use of an albumin-promoter-derived GFP expression system [40]. Briefly, mES cells in which an albumin-promoter-derived GFP expression cassette was externally introduced were injected into the spleen of the hepatic-injured mice and tumors were developed after 3 weeks. Examination of the tumors showed the presence of hepatocytes derived from mES cells. These hepatocytes were positive for hepatic markers for at least 3 weeks and were capable of proliferating. The cells were highly characterized by revealing correspondence in 98% of gene expression profiles compared with primary mouse hepatocytes [45]. It is known that the formation of EBs itself can raise the cell population expressing hepatocyte phenotype [46], but such a population in EBs is estimated to be considerably small. Differentiation and isolation of hepatocyte-like cells from hES cells has been demonstrated by using hES cells that are stably transfected with the reporter gene of GFP fused to an albumin-promoter [47]. The generation of ES-derived insulin-producing cells may represent a critical cell source for the treatment of diabetes. In this field, ES cells hold a great hope as a source of β-cells, but unfortunately this has proven to be more complicated than expected. Both mouse and human ES cells can be manipulated to contain insulin and even to regulate insulin secretion [37, 48, 49]. Several methods have been used to obtain enriched populations by the stable transfection with a cDNA construct

containing a neomycin-resistance gene under the control of the insulin or Nkx6.1 promoter [49], by the selection with nestin-positive cells [37, 50], or induction of critical transcription factors, such as pax4 and pdx-1 [43, 51]. Although these reports have encouraged that ES cells can generate cells containing insulin and pancreatic β-cell markers, a recent report has demonstrated that insulin-positivity of ES cell derivatives was considerable due to insulin uptake from culture media by apoptotic cells [52]. Measurement of C-peptide, which is excised from proinsulin in the process of maturation of insulin, has been strongly recommended when demonstrating differentiation of ES cells to pancreatic beta cells. Differentiation protocols have to clarify that ES cells are directed to definitive endoderm, not to visceral endoderm, which has similar markers of gene expression but different pathways from pancreatic beta cell lineage. According to the latest research, the differentiation ratio of insulin-positive cells from ES cell populations is about 2.7% compared with less than 1% in undifferentiated controls [53].

ECTODERMAL DIFFERENTIATION. Epithelial cell differentiation from ES cells has been identified by the presence of cytokeratines and specific keratinocyte markers [54]. Enrichment of keratinocytes *in vitro* from ES cells has been achieved by seeding the cells on various extracellular matrices in the presence of bone morphoprotein (BMP-4) and/or ascorbate; such protocols promote the formation of epidermal equivalents. It has been reported that the resulting tissue displays patterns similar to the embryonic skin. The cells express the late differentiation markers of fibroblasts, which suggests that ES cells have the capacity to reconstitute fully differentiated skin *in vitro* [55]. Researchers have reported a differentiation capacity of ES cells into neurons and glial cells [56, 57]. The neural differentiation ratios have significantly improved by the introduction of numerous strategies, including lineage selections (dopaminergic, serotonergic [57–63], or γ-aminobutyric acid (GABA)-ergic neurons [57]), astrocytes, oligodendrocytes [64], glutamatergic and cholinergic neurons [58], and growth factors. The possibility of producing dopaminergic neurons from ES cells has been demonstrated by the use of both fibroblast growth factor 8 (FGF8) and sonic hedgehog, which were implicated as tandem initiators of dopaminergic neurogenesis [58]. Later, the enrichment of dopaminergic neurons has been acheived by mimicking the oxygen tension of the developing midbrain [59]. When such cells were implanted into 6-OHDA-lesioned rats, where nigrostrial dopaminergics afferents are largely lost, the brain function restored normalcy to the dopamine-depleted animals [60]. Similar results were observed in animal experiments by the transplantation of monkey ES cell-derived dopaminergic neurons into 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-lesioned adult cymolgus monkeys, in which treatment-associated behavioral improvement was noted by 10 weeks after transplantation [61]. In general, proliferation of neural precursor cells is induced by the addition of FGF and epidermal growth factor (EGF) into the culture medium. Thereafter, neural differentiation can be facilitated by the addition of neural differentiation factors, such as glial cell line-derived neurotrophic factors (GDNFs), neurturin (NT), TGF-β3, and IL-1β [62]. Although the ability of hES cells to generate derivatives of the neural ephitelium has been demonstrated, the selective derivation of neuron subtypes has been difficult to achieve until now. Therefore, long-term survival of the grafted cells has not been

successful in experimental models, and a potential risk of teratoma formation by undifferentiated cell populations after implantation should be carefully studied before any therapeutic clinical trials can be considered.

MESODERMAL DIFFERENTIATION. The mesodermal germ layer has the capacity to differentiate into muscle, bone, cartilage, blood, and connective tissues. ES cells also have been successfully used to reconstitute mesodermal developmetal processes *in vitro* by generating several mesodermal cell types, such as adipogenic cells [63], chondrogenic cells [65], osteoblasts [66], and myogenic cells [67]. One of the mostly studied cell lineages in ES cells is cardiomyocytes. Similar to other differentiation protocols, the generation of cardiomyocytes from ES cells requires an initial aggregation step to form EBs. Within EBs, cardiomyocytes are located between an epithelial layer and a basal layer of mesenchymal cells [30]. Cardiomyocytes are easy to identify *in vitro*, because they spontaneously contract after 3–4 days of culture. The number of spontaneously beating cells can be increased by adding differentiation-inducing factors, such as dimethyl sulfoxide (DMSO), retinoic acid, Dynorphin B, and cardiogenol derivatives [30, 68–73]. Developmental changes of cardiomyocytes can be correlated with the length of time in culture and divided into three stages: early (pacemaker-like cells), intermediate, and terminal (atrail-, ventricular-, nodal-, His-, and purkinje-like cells) [30]. hES cell-derived cardiomyocytes have showed the expected molecular, structural, electrophysiologic, and contractile properties of nascent embryonic myocardium [68, 69]. hES cell-derived cardiomyocytes differ from those of mouse in an important and potencially exploitable capacity, that is, proliferation. In contrast to the limited proliferation of mouse ES cell-derived cardiomyocytes [70], human ES cell-derived cardiomyocytes show sustained cell cycle activity both *in vitro* [71] and *in vivo* (in the heart of the nude rats) [72]. *In vivo* studies with hES cell-derived cardiomyocytes have increased lately [72, 73] and suggested that hES cell-resulting cardiomyocytes engraft and integrate into the host myocardium in experimental immunosuppressed animals [73]. These data represent an exciting proof-of-concept evidence for the potential application of hES cell-derived cardiomyocytes in the formation of biological pacemakers. Several important challenges include long-term follow-up of the grafts to confirm whether such cells maintain their pace-making ability over time and development of efficient protocols for large-scale production of highly purified cells without any risks of teratoma formation of the cells *in vivo*.

Hematopoietic cells and blood vessels are believed to arise from common progenitor cells, hemangioblasts. Cystic EBs increase the generation of blood islands containing erythrocytes and macrophages [31], and differentiation of the cells on semi-solid medium is efficient for the formation of neutrophils, mast cells, macrophages, and erythrocytes [32]. Application of fetal calf serum (FCS), cytokines such as IL-1 and IL-3, or granulocyte–macrophage colony stimulating factor (GM–CSF) in ES cell culture generates early hematopoietic precursor cells expressing both embryonic z globin (βH1) and adult β major globin RNAs. Experiments to identify potential inducers of the hematopoietic lineage indicate that Wnt3 is one of the most important signaling molecules that play a significant role in enhancing hematopoietic commitment during *in vitro* differentiation of ES cells [74].

11.2.1.2 Use and Applications of ES Cells One of the uses of mES cells is the development of genetically modified mice. Researchers have conducted genetic modifications in mES cells to generate genetically modified mice to evaluate specific functions of the targeted genes. These engineered mice have selectively inactivated specific genes to evaluate their target functions and toxicity [75]. This technology can be applied to *in vivo* assays to test for clinical conditions of the central nervous system, cardiovascular diseases, tumors, and metabolic changes in muscle, fat, and bone. The approach has become a crucial method for the utility of different targets in toxicology. Another significant use of ES cells is achieved by a homologous recombination that allows the preplanned replacement of mutations in endogenous murine alleles. Base changes allow an inactivation of specific domains or an alteration of binding sites of a specific protein. For example, single-base changes allow the expression of conserved human mutations. An allelic variant in presenilin 1 is associated with early onset of Alzheimer's disease [76].

Undifferentiated ES Cells. The use of undifferentiated ES cells has been rapidly facilitated to gain functional information and to generate and evaluate knockout mice. An example was the development and evaluation of a nuclear factor-κβ precursor p105 in ES cells [77]. The genetically modified ES cells had specific deletions in the C-terminal region of the p105 gene. These cells demonstrated that p105 was important in the control of NF-κβ-binding activity, detailing the role of NF-κβ in inflammatory responses.

Researchers have also used ES cells deficient in specific genes in the undifferentiated state to evaluate the gene function in the cell development *in vitro* [78].

Differentiated ES Cells. Researchers have demonstrated that cells derived from ES cells *in vitro* reflect the cellular physiology of relevant to primary cells. Gene inactivation has been applied to study events in signaling pathways that could be relevant in specific cell types. For example, there is the role of mitogen-activated protein kinase kinase-1 (MEKK1) in a cellular model of postischemic reperfusion injury using ES cell-derived cardiomyocytes [79]. This approach clearly allows time- and cost-saving evaluation of target genes. In addition, results from knockout cells derived from ES cells can provide clues as to the developmental cause of embryonic lethality.

Teratoma formation has been used to evaluate the role of target gene expression on the cell proliferation and differentiation of the resulting tumor formation. This kind of strategy was applied to demonstrate a reduced proliferative capacity of ES cells null for cyclooxygenase 2 compared with cyclooxygenase 1-deficient or wild-type ES cells [80]. The strategy can be used to evaluate the role of potential cancer-inducing targets on cell proliferation. Reproductive toxicity is a target where ES cells could be applied to *in vitro* teratology assays [81]. Such a procedure could reduce the use of animal procedures. It has been reported that 78% of correlation exists between the data of *in vivo* and *in vitro* experiments using ES cells as an alternative to animal testing in teratology and embryo-toxicity testing [82]. The aim is to overcome the limitation of availability of primary cells or the genetic abnormality of immortalized cell lines. Generation of specific cell and tissue types is necessary rather than heterogeneous populations that can result from spontaneous differentiation of ES cells. For this reason, ES cell lines expressing GFP selec-

tively in the specific differentiation to cardiomyocytes [83] or hepatocytes [40] have been designed [84]. Finally, therapeutic concepts of ES cells must be well argued. Some difficulties can be identified in the application of adult stem cells or embryonic stem cells, in order to develop stem cell-replacement therapy. We need to meticulously select the best candidates of cells in terms of the facilities to propagate, manipulate, and select the most purified population of the desired cell type. We need to produce immune tolerance when allogenic cells are used for stem cell-based cell therapy. In addition, ES cells bring certain advantages against the rest of stem cells. Firstly, adult stem cells are difficult to isolate and hard to propagate in culture; in contrast, ES cells are derived easily once an embryo has been obtained and they can grow indefinitely in culture. ES cells can be manipulated genetically by homologous recombination to correct a genetic defect [85]. On the other hand, adult stem cells can be genetically manipulated only by the introduction of retroviral gene delivery, which overexpress the transduced genes and could happen in an insertional mutagenesis [86]. ES cells have the capacity to differentiate into any kind of tissue of the body, that is, pluripotent, but adult stem cells are multipotent and their differentiation capacity seems to be restricted. Protocols must be well developed in ES cells to generate an enrichment population of cells of a specific lineage or cell type. Furthermore, if therapeutic application is the final goal of ES cells, culturing techniques need to be scaled up for mass production of clinically relevant quantities of the specified cells. Finally, immunological barriers must be overcome. Regarding this issue some promising alternatives have been suggested lately. Nuclear transplantation denotes the introduction of a nucleus from an adult donor cell into an enucleated oocyte to generate a cloned embryo. When transferred to the uterus of a female, this embryo has the potential to become an infant that is a clone of the adult donor cell; this process is referred as to “reproductive cloning” (see Figure 11.2-4). When explanted in culture, this embryo can give rise to ES cells that have the potential to become almost any type of cells present in the adult body. The resulting ES cells by nuclear transfer are genetically identical to the donor and thus potentially useful for therapeutic applications; this process is called “therapeutic cloning” (see Figure 11.2-4). Therapeutic cloning may substantially improve the treatment for neurodegenerative diseases, blood disorders, or diabetes, because the therapy for such diseases is currently limited by the availability or immunocompatibility of tissue transplants. Indeed, experiments in animals have shown that nuclear cloning combined with gene and cell therapy represents a valid strategy for treating genetic disorders [85].

11.2.2 Conclusions

Considerable progress has been made toward the generation of more defined culture conditions of ES cells since the initial isolation and growth conditions were described. There have been many modifications of the procedures, including growth of ES cells, differentiation potential, and cell lines establishment. The availability of hES cells represents an extraordinary opportunity for cell transplantation that may be applicable to humans in the future. Despite exciting advantages and advances in the field of hES cell research, many challenges have to be addressed in the near future. The culture conditions have to improved and be humanized. The cells cultured in xenogeneic conditions are likely to be considered and

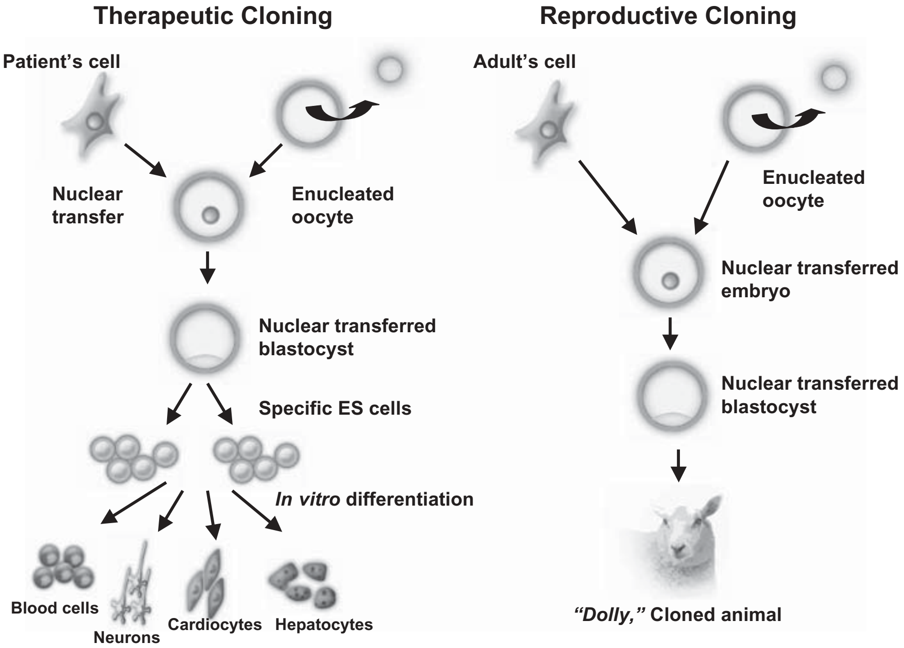

Figure 11.2-4. ***Comparison of therapeutic cloning and reproductive cloning.*** In therapeutic cloning (left panel), the diploid nucleus of an adult donor cell is introduced into an enucleated oocyte and it divides into cloned blastocysts that will provide lines of embryonic stem cells that can be differentiated *in vitro* into any types of cell for therapeutic purposes. In contrast, reproductive cloning (right panel) requires the transfer of the cloned blastocysts into surrogate mothers and a few of the cloned blastocysts will give rise to the cloned animals.

regulated. Concerns about the infection from nonhuman pathogens are the most discussed issues for the clinical application. Although ES cells offer great promise for regenerative medicine, the near-term applications could be in drug discovery. Researchers might have a store of stem cells lines derived from many human populations from different ethnicities and gene variations. These cells can be of extreme importance in the development of effective and safe therapeutics.

11.3 ADULT SOMATIC STEM CELLS OR POSTNATAL STEM CELLS

11.3.1 Introduction

In the past few decades, a true revolution has been occurring in a spectacular way in the field of medicine and biology. Regenerative medicine with the intention of tissue regeneration, and thus the curative treatment of diseases, has awoken maximum interest from scientific communities all over the world [1].

The likelihood that the human body contains the cells capable of regenerating and repairing the damaged or disease tissues has turned from an implausible subject to a virtual belief. It has been well known that stem cells with differentiating potential to replenish progeny are present in postnatal tissues of mammals. Recently many studies have demonstrated the abilities of stem cells to form multiple types of cells and the presence of such cells in an increasing number of tissues. We attempt here to provide an overview of adult stem cells in terms of possible mechanisms of their differentiation and their potential in therapeutic use.

The presence of adult somatic stem cell or cell progenitor has been clearly identified in several tissues. It has primarily been easily identified in tissues with high cell replication. These cells contribute to repair and regeneration throughout the life span in adult tissues, which also have the capacity of cell renewal [2, 3]. Recently, the concept of stem cell niches was proposed, in which stem cells exist in small numbers in silence under normal conditions but become activated after tissue injury or other pathological conditions [4]. Some stem cells possess enormous plasticity to differentiate into any cell types derived from the germinal layers (mesoderm, ectoderm, and endoderm). In contrast, other stem cells can only terminally differentiate into the same germinal layer from which they originated. Several factors, which are not clearly understood, are involved in the regulation of stem cells in terms of their potential of differentiation, tissue repair, and regeneration. On the other hand, the tragedy includes the development and progression of malignancy due to their longevity with respect to the body life span and their ability to give rise to multiple cell phenotypes [5]. Based on the nature of stem cells, there

is a worldwide interest in stem cell research to understand the natural growth and senescence of the cells and to balance tissue repair and regeneration through the life span. Studies on the mechanism that controls the maintenance of stem cells and differentiation signals is useful to understand how external (toxins, radiation, etc.) and internal injuries (cytogenetic alterations, mutation, etc.) potentially modify the fate of stem cells and eventually lead them to malignant transformation [5–7]. Stem cells can withstand over stressful environmental events associated with tissue damage after surgical procedures [8], exposure to toxics agents [8, 9], and extreme cold [10] and then repopulate and repair adult tissues. Although such *in vivo* environments seem to be transient and hostile against host cells and mature cells are easily destroyed, stem cells can survive, differentiate, and regenerate the tissue [8]. Their differentiation capacities investigated under a variable controlled environment may allow us a window into the regenerative process of adult tissues. To facilitate stem cell research, *in vitro* culture should mimic native niches of stem cells *in vivo* by application of matrices, growth factors, and drug delivery systems [11–15].

11.3.1.1 General Concepts of Stem Cells The name *stem cells* is commonly used to refer the cells that are relatively undifferentiated while retaining the ability to divide and proliferate throughout postnatal life, providing progenitor cells that can differentiate into tissue-specific cells. The ability of stem or progenitor cells to give rise to different populations of terminally differentiated cells is referred to as plasticity. Thus, their potential is called totipotent, pluripotent, or multipotent. The term *totipotent* should be strictly reserved for the unique stem cells that can form embryonic and extra-embryonic membranes [6, 16], which are the most primitive about 4 days after fecundation [17]. The term *pluripotent* is used to refer to the stem cells' ability to form all cell types of the proper embryo, except for the extra-embryonic membranes and their tissues. In contrast, the term *multipotent* is used to name those that give rise to a subset of cell lineages. During the development process, the totipotent stem cells originate and pluripotent stem cells come out of the germ layers. Afterward multipotent stem cells are generated [16]. These cells, in turn, form the oligopotent progenitor cells in the developing organs. Moreover, intestinal progenitor cells are considered to be quadripotent; they can form progeny that become mucous, absorptive, neuroendocrine, or Paneth cells. In the case of bronchial lining cells, the progenitors are tripotent: Progeny turn into neuroendocrine, mucous, or ciliated cells. The oval cells of the liver are bipotent; they can derivate into duct cells and hepatocytes. Other type of cells, such as epidermal progenitors, are unipotent to produce only a single progeny [6, 16, 17].

Tissue Homeostasis and Stem Cell Renewal. Physiological tissue renewal is accomplished by a delicate balance among specialized cells, young progeny, and their tissue-specific stem cells. They perpetually renew, which is evident in many tissues, such as, blood, skin, gastrointestinal tract, respiratory tract, and testis. In contrast, other tissues, including cardiac and neural tissues, seem to have a limited response under regenerative circumstances. Thus, it was considered that cardiac and neural tissues had no regenerative capacities [16, 18]. Asynchronous division is a typical *in vivo* pattern of stem cells; it is defined by the division of one stem

cell to give rise to one daughter cell that remains as a stem cell while another undergoes the process of differentiation. The transiently amplifying cells provide an expanded population that differentiates into more mature cells, which can no longer proliferate and eventually die [3, 6, 17]. Such phenomenon is observed in most tissues, however, others, such as the liver [19] and pancreas [20], are mainly driven by replication of mature cells rather than stem cell division and differentiation under normal conditions. Occasionally, in those tissues under toxic DNA-damage conditions when replication of mature cells is compromised, facultative stem cells accomplish the tissue regeneration [19].

Stem Cells and Their Niches. The microenvironment or the stem cell niche tightly regulates the behavior of the cells. A combination of cells and extracellular matrix components, soluble factors delivered to the tissue from the vasculature, and the growth factors produced by the cells govern all aspects of the behavior of stem cells. For example, in the intestinal mucosa, the pericryptal myofibroblasts that surround the crypts may serve as niche cells, whereas in the hair follicles, the region just below the sebaceous glands seems to be a stem cell niche [17, 18]. The niches themselves control many dynamic facets of the stem cells, intrinsically regulating the internal signaling, synthesis of structural and metabolic proteins, their mitotic activities, axes, and growth pattern. These events certainly play a pivotal role in leading intrinsic and extrinsic factors that will define the physiological function of stem cells or the first step in the pathological transformation of stem cells in carcinogenesis [17, 18].

11.3.1.2 General Classification of Stem Cells Because adult somatic stem cells consist of a different population of the cells that share some common characteristics, it is difficult to rigorously divide the cells into some classifications. A new theory has currently proposed that stem cells are generated from a single cell source [21–24]. Thus, we review here adult stem cells according to the commonest classification as follows:

1. Hematopoietic stem cells (HSCs)
2. Mesenchymal stem cells (MSCs)
3. Multipotent adult progenitor cells (MAPCs) isolated by fluorescent-activated cell sorting (FACS) from the bone marrow
4. Side-population phenotype cells (SPs)
5. Tissue-specific cell progenitors (TSCPs)
6. Umbilical cord blood-derived stem cells (UCBDSs)

Bone Marrow Stem Cells. The bone marrow has been considered to provide an adequate microenvironment for stem cells to survive forever. Stem cells in the bone marrow can migrate into blood vessels, circulate around the body, and return home when needed [25]. A long time ago, only a few stem cells were recognized in humans and they were thought to be a restricted population with a limited potential to differentiate in a single organ system. Such reasoning was examined through the study of bone marrow, which contains a wide range of cell populations. The complex constitution of bone marrow also attracted the interest of scientists. Such investigations changed the original thought to a new one, which implies that stem

cells also have the ability to give rise to the cells of other tissue types as well as to the cells of the original, referred to as the "plasticity of stem cells." Bone marrow has been described to contain at least two [26, 27] different types of stem cells. One type includes HSCs, which produce the entire progeny of blood cells of the body, and the other includes MSCs, which are a promising source for tissue repair [28]. It is also believed that another population exists, called MAPCs [27], which could be generated from the adult bone marrow of several species, and can differentiate into multiple cell types *in vitro* [29, 30] (Figure 11.3-1).

11.3.1.3 General Characteristics of Stem Cells Stem cells possess a wide range of different characteristics, which have made them an attractive cell source for cell biology, ontogeny, toxicological studies, and cell therapy [12–16, 18, 24, 31]. Several types of stem cells have been reported, and each possesses particular characteristics that determine their potential (Table 11.3-1).

11.3.1.4 Hematopoietic Stem Cells (HSCs)

Characteristics. For the past three decades, HSCs have been considered important cells. In 1963, the origin of hematopoietic cells was first reported [33]. One of the main characteristics of HSCs is the capacity to give rise to intermediate precursor

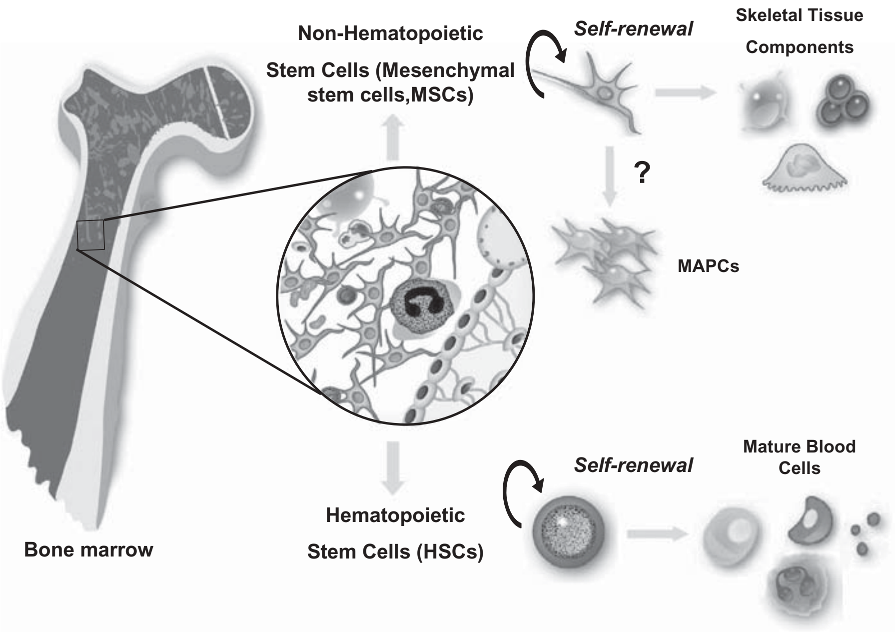

Figure 11.3-1. ***Schematic model of bone marrow niche.*** Bone marrow (BM) harbors a heterogeneous population of progenitor cells, which can generate a diversity of different cells. BM is composed of the osteoblastic zone and the vascular zone. In the vascular zone, HSCs exist that are capable of giving rise to all hematopoietic progeny, in direct contact with MSCs, which are known as progenitors for skeletal tissue components such as bone, cartilage, hematopoietic-suporting stroma, and adipose tissue. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

TABLE 11.3-1. Stem Cell Types and Their General Characteristics

	Tissue-specific cell progenitors[1]	Pluripotent and multipotent stem cells[2]	Embryonic stem cells[3]
Cell commitment	Lineage-commitment*	Uncommitment	Uncommitment
Cell quiescence under neither serum supplemented medium nor analogous knockout replacement	Quiescence	Quiescence	Non-quiescence
Telomerase activity	Absent	Most present but variable activity	High activity
Cell life span	Hayflick's limited	Extended	Unlimited
Cell growth at confluence	Inhibited by cell contact	Inhibited by cell contact	Non-contact inhibition
Inducible plasticity	Limited*	Usually unlimited	Unlimited
In vitro preservation of undifferentiated stage	Possible but limited	Possible but limited	Certainly possible
Cell membrane markers or antigens	Often lineage-commitment*	Various according to their cell phenotypes	Alkaline phosphatase SSEA-1,-3,-4 Oct-3/4

[1] Tissue-specific cell progenitors are commonly quadri-, tri-, or bipotent; therefore, even though they give rise to progeny with different phenotypes, the fate of the progenitor cells is lineage-specific. Each progenitor cell has a unique profile on the cell surface markers, but the profile is similar to that of both the tissue and the progeny that they will originate [6, 16, 32].

[2] Pluripotent and multipotent stem cells are heterogeneous population. These cells are practically the entire populations of postnatal stem cells [16]. They include HSCs, MSCs, SPs, MAPCs, and UCBDSs. Although they have different phenotypes, some of their characteristics are frequently shared.

[3] Embryonic stem cells are the prototype of all stem cells. Characteristics are well-defined because ES cell lines were established.

* Even though these populations are localized in adult tissues having lineage-commitment and exhibiting limited plasticity and local cell markers, some of these cells are capable of de-differentiating and then becoming multipotent stem cells.

or progenitor cell populations that partially differentiate and commit to various types of blood cell lineages [34, 35]. HSCs need to possess the hallmark properties to equilibrate cell self-renewal, whereas the cells quickly generate progenitors as a workforce as well as additional stem cells without depleting the reserves. Therefore, HSCs need to be multipotent; that is, a single HSC can produce several different lineages of mature blood cells and proliferate to yield a broad number of mature progeny. HSCs in the bone marrow of the mice are a rare population with a frequency of 1 in 10,000 to 100,000 of total blood cells, and the cells may be even less in humans [36–38]. HSCs are thought to be relatively in-active in the adult

hematopoietic system, with 1–3% in the progression of the cell cycle and approximately 90% in the cell cycle G0. The cells divide only a few or not at all until they are required to differentiate [39–42]. Abnormal clonal expansion of HSCs may result in chronic myelogenous leukemia, polycythemia vera, and myelodysplastic syndromes. HSCs are believed to have the ability to live for a long period of time, probably a lifetime in the recipient after bone marrow transplantation. In fact, HSCs require the bone marrow microenvironment, which regulates their migration, proliferation, and differentiation, to maintain active hematopoiesis throughout their lifetime [43, 44].

Isolation and Phenotypic Characteristics of HSCs. Recent experiments have demonstrated that HSCs in bone marrow from many different species can be purified by FACS as SP cells [40, 45, 46]. In 1994, multipotent cells committed to the hematopoietic lineage in mouse according to their different array of cell-surface markers were isolated [39]. This cells were described as KTLS c-kit^{+} (K), Thy-1.1^{low} (a marker on stem cells) (T), Lin$^{-/low}$ (Lineage-marker) (L), and Sca-1^{+} (Stem cell antigen-1) (S) [1]. The cells showed >80% for hematopoietic multilineage differentiation and represented only 1/2000 cells in the bone marrow. HSCs were proposed to be divided into three compartments based on both the expression of the surface markers and their self-renewal ability [39, 47].

1) Long-term HSCs (LT–HSCs): LT–HSCs habitually reside in the bone marrow and have for all intents and purposes six developmental alternatives: remain quiescent, differentiate, self-renew, migrate, enter senescence, or undergo programmed cell death. The cells represent only 0.007% of cells in the bone marrow. In young adult mice, approximately 8% of LT–HSCs arbitrarily enters into cell division per day [42], and half of their progeny are LT–HSCs to maintain the level of steady state [48]. LT–HSCs perform self-renewal perpetually without depleting the pool of stem cells, and the cells are in charge of producing proliferative short-term HSCs. LT–HSCs express the surface markers of Thy1.1^{low}Flk-2^{-}. The expression of Flk-2 is upregulated and the expression of Thy-1.1 is downregulated as self-renewal capacity of the cells diminishes [49].
2) Short-term HSCs (ST–HSCs): ST–HSCs engender the lineage-committed progenitors to produce the billions of differentiated hematopoietic cells in the peripheral blood daily. The self-renewal life span of ST–HSCs is 6–8 weeks, and afterward, the cells fade away from the bone marrow. ST–HSCs represent 0.01% of the cells in the bone marrow of young adult C57BL mice and have the phenotype of thy1.1^{low} Flk-2^{+}.
3) Multipotent progenitor cells (MPs): MPs have restricted self-renewal potential for less than 2 weeks. The expression of thy1.1^{-}Flk-2^{+} is also identified in MPs [49]. The offspring of HSCs have been characterized and lineage restricted oligopotent progenitor cells for *lymphoid*, common lymphoid progenitor (CLP), and *myeloid*, common myeloid progenitor (CMP), granulocyte-monocyte progenitor (GMP), and megakaryocyte-erythrocyte progenitor (MEP) lineages (Figure 11.3-2).

Comparable Phenotypic Markers of HSCs in Human and Mouse. CD34 was the first marker found in human hematopoietic progenitors [50]. Most human HSCs express CD 34, which is also expressed in the committed progenitors [51] and

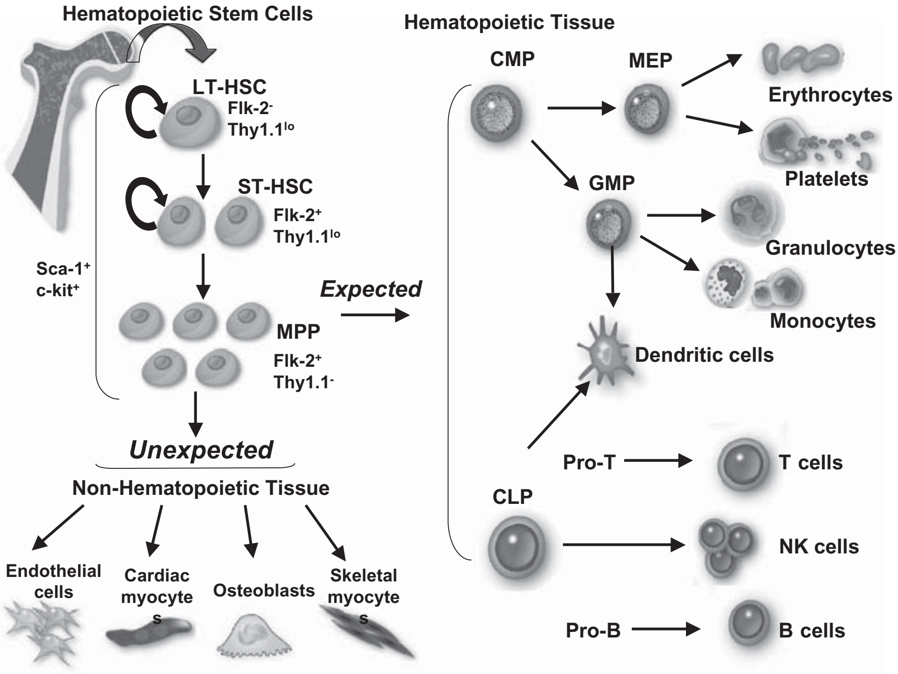

Figure 11.3-2. ***Model of hematopoietic stem cell lineage.*** Long-term hematopoietic stem cells (LT–HSCs) have the ability of unlimited self-renewal and of generating other precursors that give rise to population of the hematopoietic tissue cells (expected), including mature blood cells, CMPs (common myeloid progenitors), CLPs (common lymphoid progenitors), MEPs (megakaryocytes/erythrocyte progenitors), and GMPs (granulocytes/monocyte progenitosr). HSCs also generate a population of the non-hematopoietic tissue cells (unexpected), including ostoeblasts, skeletal myocytes, cardiac myocytes, and endothelial cells. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

nonhematopoietic progenitors [52, 53]. The characteristic phenotype of human HSCs includes the lack of expression of lineage markers (Lin-) and expression of Thy-1, c-Kit, and Sca-1, CD45 [54] without CD38 expression [51, 55, 56]. Nonetheless, some human HSCs can be found in the fraction of CD34-negative population [57, 58]. CD34- negative HSCs are a precursor fraction of CD34-positive HSCs. Human HSCs also express Bcrp, known also as ABCG2 transporter, which outflows particular molecules as Hoechst-33342 staining [40, 59]. Detection of CD34 expression in HSC could be performed by the use of HCC-1 antibody in CD59 family members [60] (the sca-1 [61] antibody for mouse detects CD59 family members). Recently CD133 has been identified and could be used as another marker for human HSCs instead of CD34 [62]. It is important to remember that the $CD34^+$ bone marrow population denotes 1–6% of the cells in bone marrow, whereas the HSC compartment corresponds to only 0.05% [38]. Hence the $CD34^+$ population includes HSCs and a small fraction of the non-HSC cell population. Most quiescent LT–HSCs are $CD34^+Thy^+Lin^-CD38$ [63] (Figure 11.3-3).

Mechanism of Activation Cycle of HSCs. During the late phase of embryonic development, HSCs are located in the fetal liver, where they undergo massive

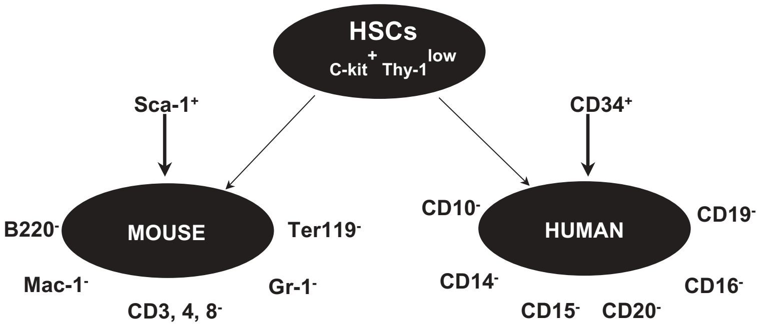

Figure 11.3-3. ***Marker profiles of HSCs in human and mouse.*** Human HSCs are positive for c-kit$^+$, Thy-1^{low}, and CD34$^+$, and mouse HSCs are positive for c-kit$^+$, Thy-1^{low}, and Sca-1$^+$. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

expansion before they enter into the bone marrow and express AA4.1 and Mac 1, which are usually absent in HSCs in a quiescent state [64]. It has been generally believed that the microenvironment affects the fate of the cells. When HSCs are unperturbed in their quiescence niche, the cells express receptors associated with metabolism and aging (IGF1R) and show the activity of tyrosine kinase Tie1, which allows the cells to respond to multiple mitogenic signals. HSCs also express high levels of transcription factors, such as c-fos and GATA-2, which enable quick activation of the cells. HSCs are ready to act in response to changes in their environment "state of readiness." Immediately encountering the stress, HSCs pause totally by remaining quiescent in their niche, while they prepare to proliferate. This phase is mediated by upregulation of TIMP and serine proteinase inhibitor A-3g and by antiproliferative genes, such as Tob1, p21, and Btg3. Interferon-induced genes are also upregulated, indicating that HSCs are responding to pro-inflammatory signals caused by the stress. The signals induce a proliferative status, which is divided into early and late proliferation phases. In the early phase, the expression of genes involved in the regulation of replication and repair of DNA is enhanced in HSCs [65]. In the late phase when most of HSCs are in cycle, other genes related to energy production are expressed, indicating an increase in the metabolic activity of HSCs. In this context, two proposed approaches are associated with the proliferation state, mobilization [66] and migration [67]. HSCs need to move out of their quiescence niches and enter into a proliferative zone. Downregulation of α-4 integrin is necessary for proliferation of HSCs, and downregulation of c-kit has been linked to mobilization of HSCs [68]. At the final phase, HSCs are required to return to their niches in order to stay at the initial state of bone marrow. This step usually starts the day when the damage is ameliorated, when several cells in cycle decrease, and is related with the expression of antiproliferative genes [69, 70].

Plasticity of HSCs. The hematopoietic tissues such as the bone marrow and peripheral blood have heterogeneous stem cell populations, including hematopoietic stem cells, mesenchymal stem cells, multipotent adult progenitor cells, and endothelial precursor cells. HSCs have been widely used to study the plasticity of adult stem cells [23]. Stem cell plasticity can be defined as a unique property of tissue-specific adult stem cells. Approximately more than 80% of studies reporting

plasticity of adult stem cells have been performed using the cells derived from the bone marrow or mobilized peripheral stem cells [23, 71, 72]. Although a previous concept was that differentiation of HSCs was restricted only to a hematopoietic lineage, current studies have reported that HSCs derived from bone marrow can give rise to hematopoetic precursors and multiple “unexpected” cell types, such as neural cells [73–75], hepatic cells [54, 76–78], cardiac muscle cells [79–81], and skeletal muscle cells [82, 83]. Many attempts have been proposed to define the mechanism for how stem cell plasticity occurs. Despite these efforts, there is still no clear evidence regarding whether stem cell plasticity really exists. Some investigators have suggested “trans-differentiation” as a possible cause of stem cell plasticity [84, 85], and others have proposed the cell fusion effect [86]. Even though many theories about plasticity have been proposed, nobody knows for certain whether stem cell plasticity is common or infrequent, whether it might be a vestige of the potential expression during embryonic development, or whether it has a physiologic role in the repair and homeostasis of the tissues. The plasticity of adult HSCs, even though it is rare, has suggested that the environment can reprogram the fate of the cells.

Potential Implications of HSCs. Studies on bone marrow cells differentiating into nonhematopoietic lineages have proposed that the cells are a representa-tive source of cell “replacement” in the treatment of numerous diseases. To amplify and generalize this issue for clinical translation, we should accumulate the useful processes of regeneration of blood formation by HSCs [36], skin replacement by putative epidermal stem cells [87], and the benefits reported in treating patients with myocardial infarction with bone marrow cells, mobilized peripheral HSCs, or hematopoietic progenitors [88, 89].

11.3.1.5 Mesenchymal Stem Cells (MSCs)

Characteristics. MSC is a wide population that exists in the niche of the bone marrow and has attracted the attention of researchers by their potential for self-renewal and differentiation into functional cell types in the intrinsic tissue where they reside. These cells have also been isolated from the fat tissues [90]. MSCs can be expanded in culture for several passages without losing their differentiation potential and have been widely accepted as stem cells due to their usefulness in the clinical treatment of osteogenesis imperfecta [91], bone tissue regeneration [92], and hematopoietic recovery [93].

Self-Renewal and Multilineage Differentiation Potential of MSCs. Characterization of MSCs is subject of active investigation, because diversities of techniques to isolate the cells and different ways to analyze the self-renewal ability of the cells have been documented. Considering the lack of reliable specific markers and locating site of MSCs, further experiments are needed to address these issues. To identify MSCs, a combination of several monoclonal antibodies has been tested [94]. As of now, markers for MSCs include SH-2 [95], SH-3, SH-4 [96], SB-10 [97], CD29, CD44, CD90, and STRO-1 [98]. In addition, MSCs are negative to hematopoietic markers CD34 and CD45 and the cells are human leukocyte antigen (HLA) class I-positive and HLA class II-negative [99]. The first experiment

supporting the presence of MSCs was conducted in the early 1960s [100, 101]. Aspirated bone marrow cells were cultured at low density. The resultant cells formed colonies of fibroblasts, and they were responsible for osteogenesis [102, 103]. Murine MSCs showed self-renewal activity, and the cells differentiated into many types of cell lineages, such as osteoblasts and chondroblasts [104–109], adipocytes [110], neuronal progenitors [111], and myocytes [83] with the stimulation of cytokines, growth factors, and chemicals *in vitro*. However, it is controversial whether such plasticity of MSCs is induced *in vivo* even after minimal injury. To address this issue, researchers have used animal models of injury [112, 113]. Such experiments have shown that MSCs contribute to the repair or regeneration of damaged bone, cartilage, and infracted myocardial tissues [114–116].

Isolation of MSCs. Since 1980 when the characterization of human bone marrow fibroblast colony-forming cells (CFU-Fs) was performed, which was the gold standard to identify MSCs, many researchers have attempted to develop different methods for isolation of MSCs [117]. Now MSCs can be identified by their ability to adhere to a static surface and their proliferat-ing potential. Approximately 30% of human bone marrow-aspirated cells adhering to plastic culture dishes are considered to be MSCs [110]. MSCs in the bone marrow are a heterogeneous population that contains not only putative cells but also tripotent (ability to differentiate into osteocyte, chondrocyte, and adipose lineage-osteo/chondro/adipo), bipotent (osteo/chondro), or unipotent cells (osteo) [118–121] (Figure 11.3-4).

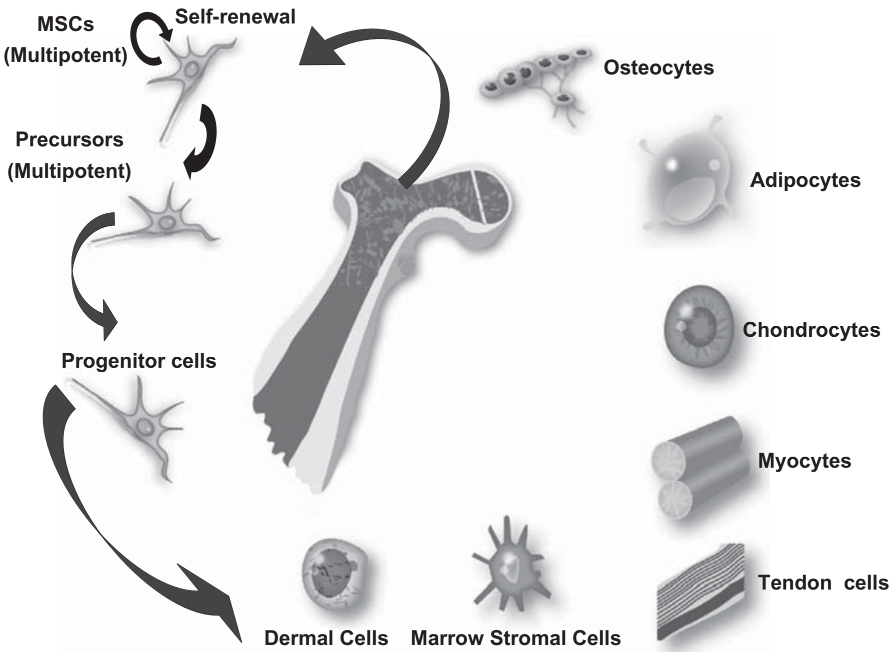

Figure 11.3-4. ***Multilineage differentiation of mesenchymal stem cells.*** Mesenchymal stem cells (MSCs) have the ability to differentiate into all types of cells of connective tissue. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

Future Prospectives of MSCs. Adult MSCs have shown great promise in cell therapy in humans due to their multipotentiality, capacity for extensive self-renewal, and lack of induction of immune response. MSCs may be a valuable source to introduce foreign genes and could be a useful tool for gene therapy for bone regeneration and tissue engineering [122]. Researchers have also proposed MSCs as a useful means to protect the brain tissue from ischemic damage [123, 124]. MSCs ameliorate functional deficits after stroke in rats probably by releasing protective cytokines by the cells. Another potential clinical application is the use of MSCs as a drug delivery vehicle for the treatment of invasive malignant tumors [125]. The behavior of MSCs has been exploited as a tumor-targeting gene therapy in gliomas. Many studies regarding genetically modified MSCs have revealed extraordinary antitumor effects of the cells in experimental models of gliomas [126–127]. MSCs have the advantage of easy propagation *in vitro*. Moreover, implantation of autologous MSCs into patients with malignant gliomas is ethically nonproblematic.

11.3.1.6 Multipotent Adult Progenitor Cells (MAPCs) MAPCs are bone marrow-derived stem cells with an extensive *in vitro* expansion ability, more than 80 population doublings, as well as a capacity to differentiate *in vivo* and *in vitro* into tissue cells of all three germinal layers; ectoderm, mesoderm, and endoderm. These cells have been isolated from three different species, including mouse, rat, and human [27].

Isolation and Culture of MAPCs. MAPCs of different species require different isolation and culture procedures. Human MAPCs are isolated after seeding bone marrow mononuclear cells (BMMNCs) of $CD45^-$ $GlyA^-$ at low densities ($1–3 \times 10^3/cm^2$) onto fibronectin-coated plastic dishes, with <2% FCS (fetal calf serum), EGF (epidermal growth factor), and PDGF-BB (platelet-derived growth factor). During the culture, depletion of the mono-nuclear cells is observed. The remnant clones that emerge over time are then harvested, and approximately 20% of the total cells seeded. The cells should be plated again at a density of $0.5–1 \times 10^3$ cells/cm^2. Maintenance of the stem cell phenotype is critically dependent on such low-density inoculation. The culture conditions of mouse MAPCs are similar to those described in human MAPC culture, except for the addition of the leukemia inhibitor factor (LIF).

Phenotypic Characteristics and Proliferation Capacity of MAPCs. Human MAPCs are characterized by the lack of hematopoietic markers such as CD34 and CD45 and the presence of the low expression of VCAM, CD44, MHC class I, and endoglin [29, 128]. The cells can be cultured *in vitro* for more than 50–80 population doublings, while preserving their normal karyotype. Mouse MAPCs are positive for CD34, CD45, CD44, c-Kit, CD3, Gr-1, Mac-1, and CD19 and negative for major histocompatibility complex (MHC) class I and class II. The cells express a lower level of Flk1 and Sca1 and a higher level of CD13 and SSEA-1 [129]. Mouse MAPCs express pluripotent markers of Oct-4, rex-1, and nanog, which were observed only in ES cells [129]. The cells can be cultured for more than 80–150 population doublings, but the karyotype of the cells becomes unstable.

In Vitro Differentiation of MAPCs. The differentiation of MAPCs to several lineages is achieved when the cells are re-plated at high density (1–2 $\times$ 10^4 cells/cm^2). The cells were cultured in the absence of the serum, but with lineage-specific cytokines required for the differentiation of the desired tissues.

1) ***Mesoderm.*** By the use of VEFG, the differentiation of MAPCs has been demonstrated into functional mature endothelial cells expressing endothelial markers such as CD31, flk-1, and vWF. Such MAPC-derived endothelial cells are capable of contributing to neoangionesis and wound healing *in vivo* [29, 130].
2) ***Ectoderm.*** Verfaille et al. have shown the potential characterization of MAPCs to differentiate into functional neuroectodermal cells, including astrocytes, oligodendrocytes, and neurons [27, 131, 132].
3) ***Endoderm.*** MAPCs can differentiate into hepatocyte-like cells by using FGF4 and HGF. Such cells expressed hepatic markers of CK19, AFP, CK18, albumin, HepPar-1, and CD26 and produced albumin, urea, and glycogen [30].

In vivo Differentiation of MAPCs. The potential of multipotency of MAPCs has also been examined *in vivo* [27] by intravenous transplantation of the cells into postnatal murine recipients treated either without radiation or with sublethal irradiation. The observation of chimaerism in many somatic tissues of the mice derived from blastocysts demonstrated the engraftment of MAPCs in various tissues, including hematopoietic, lung, gut, and liver. In these tissues, MAPCs have acquired phenotypic characteristics of the respective cells, indicating their multipotenty.

Future Prospectives of MAPCs. MAPCs have been compared with ES cells, for their similar *in vitro* potential to give rise to tissue cells of all three germ layers. MAPCs have shown the same ability as ES cells *in vivo* experiments, although MAPCs do not develop tumors. Due to the nontumorigenecity, MAPCs can serve as a source for the production of a wide spectrum of transplantable cells with an enormous promise for the treatment of many degenerative or inherited diseases. Taking it into account that MAPCs can be recovered from the patients themselves, the clinical use of the cells would be advantageous, avoiding the need for immunosuppressive therapy. MAPCs provide a prospectively beneficial tool to study developmental biology of the stem cells as well as drug discovery.

11.3.1.7 Side-Population Phenotype Cells (SPs) Purification of stem cells was reported based on an efflux of fluorescent dyes, such as Rhodamine 123 and Hoechst 33342 [133]. The purified cell population, referred to as SP, has been identified as a small fraction in the bone marrow in all species examined [45]. SP cells can yield about 0.05–0.1% from total bone marrow cells by the use of a flow cytometry cell sorting [40, 45, 59]. Despite being a small population, it possesses interesting capacities, including extensive proliferation and multipotential to generate the entire adult hematopoietic cell lineages [40]. Indeed, only a single transplantation of 200 SP cells can fully repopulate the bone marrow of lethally

irradiated mice [40, 134]. It has been reported that a successful expression of dystrophin is achieved in a mouse model of Duchenne's muscular dystrophy after transplantation of SP cells [82]. SP cells have contributed to regenerate the infarcted myocardium by developing cardiocytes and vascular endothelium cells [81]. SP cells have been identified in others several tissues, such as Posterior, by identifying the expression of the ABC transporter Bcrp1/ABCG2 [59]. Because of Hoechst 33342-related toxicity [46], other strategies have been proposed to recover SP cells by using monoclonal antibodies. Even though SP cells seem to be a small source for basic research and possible cell therapy, the cells have shown greater potential. Since SP cells were identified in the bone marrow, the cells have held great promise due to their plasticity and replicating capacity *in vivo* without any tumorigenic transformation [40, 45, 46, 81, 82]. *In vivo* differentiation of SP cells has succeeded in only mesoderm tissues (skeletal muscle, cardiocytes, and vascular cells) [81, 82]. Studies have shown that hematopoietic stem cells in the bone marrow are capable of trans-differentiating and giving rise to neuronal progenitor cells [73, 75, 135], but that such trans-differentiation has not occurred in SP cells [136].

Tissue-Specific SP Phenotype Cells from Different Compartments. For a period of time, the SP phenotype cells were identified in many other different tissues, including the brain [137, 138], pituitary gland [139], skin [140–143], corneal [144] and limbal epithelial ocular tissue [145], mammary glands [146], skeletal muscle [138, 143, 147, 148], lung [134, 138, 149–151], heart [138, 152, 153], liver [138, 154], spleen [138], pancreas [155], small intestine [138], kidney [138, 156–158], testis [159, 160], peripheral blood [138, 161], and in umbilical cord blood [45].

Main Characteristics of SP Cells from Diverse Compartments. A variable number of SP cells have been distributed in the different tissues of the body. The SP cells are a heterogeneous population that possesses the ability to give rise to their lineage-specific progenitor cells [138]. Some of these cells have been analyzed and found to be multipotent [139]. *In vitro* cultures of SP cells have shown differences in their propagation capacities and quiescent state [140, 145, 161].

11.3.1.8 Tissue-Specific Cell Progenitors (TSCPs)

Neural Cell Progenitor. The cells involving the development of mature central nervous system (CNS) are precisely regulated by both temporal and local patterns of differentiation, which determine the appropriate cell function. The role of niches shows plasticity coordinated by both the intrinsic factors and the extrinsic soluble signals. Therefore, the specific neural differentiation is affected by this regional patterning. Neurogenesis involves the opposing soluble signals that determine dorsal and ventral patterning: Sonic hedgehog (Shh), bone morphogenetic protein (BMP) antagonists, chordin, and noggin are secreted from the floor plate, whereas other signals originating from the roof plate result in the creation of the gradient of signal concentrations [162, 163]. Precise concentration and ratio of each independent signal derive the development of the specific neuronal phenotypes at different points in accordance with these gradients. Such phenomena cause the different expression patterns of the cells and create the groups of neurons with different patterns of cell division and differentiation [163]. At the beginning,

the CNS stem cells divide symmetrically to enrich their population pool, or asymmetrically to generate more differentiated progeny, which become mature cells of neuronal and glial lineages. The spinal cord can produce both oligodendrocytes and neurons from common precursors, and the final decision of the cell fate depends on extrinsic signals and specific patterns of transcriptional activation [164].

General Characteristics of Neural Progenitor Cells. In rodent models, neural progenitor cells have been identified in specific regions of adult CNS. The cells isolated from different sites of CNS are not identical and thus show different growth characteristics, trophic factor requirements, and specific patterns of differentiation [36, 165]. Growth factor requirements can define at least two major types of neural progenitor cells isolated from CNS. One cell type requires a high dose of EGF and can be expanded as floating neurospheres, while preserving their phenotype after many passages, and eventually they come to be FGF-responsive [166, 167]. In contrast, another cell type isolated from CNS is exclusively FGF-dependent. Such cells can be propagated, as adherent cultures with FGF-dependent and the cells do not respond to EGF. The cells do not express EGF receptor either *in vivo* or *in vitro*. As these cells have been isolated from multiple brain areas, it is likely that both of neural precursor cells coexist. Both cells can self-renew and differentiate into the three neural cell types *in vitro*. Differentiation of the cells in tissue culture can be induced by withdrawal of growth factors or by induction of specific signals [166–168]. It seems that distinct stem cell populations are programmed to differentiate into specific cell types during the CNS development based on their response to growth factors. Moreover, some of these phenotypes expressed in progenitor cells in CNS have been observed in progenitors isolated from the pancreas of adult mice, which can generate neural and pancreatic lineages [169].

Epidermal Progenitor Cells. Keratinocytic populations can be grown *in vitro*, while displaying clonal growth. Keratinocytes can generate normal epidermis when they are appropriately grafted [170, 171]. Furthermore, the proliferative heterogeneity of the keratinocytes reveals the presence of stem cells, that is, epidermal progenitor cells. β1 integrin seems to play a central role in the regulation of the progenitor cells. When β1 integrin binds its ligand of type IV collagen, the cells exhibit high proliferative capacity, while maintaining their undifferentiated state. Therefore, the number and patterning of progenitor cells *in vivo* are autoregulated by the stem cell niche and turnover of the cells provides regulatory feedback signals [172]. The differentiating potential of epidermal progenitor cells has totally denied the previous speculation, implying that the cells were not multipotent [173–175].

Progenitor Cells in the Respiratory Tract. The respiratory tract seems to have a local progenitor population, which gives rise to mature respiratory cells and preserves the native architecture along the tract. Consequently, tissue homeostasis is maintained by these cells, in which the trachea and bronchus segments, bronchiole, and alveolus are maintained by mucous secreting basal cells, by Clara cells, and by type II pneumocytes, respectively. These cells serve as structural and functional parenchyma and work for quick regeneration if any injury occurs in the respiratory tract [176]. In addition, the recent reports have demonstrated that progenitors

existing in the populations of basal cells, Clara cells, and type II pneumocytes are not only able to provide tissue function, but also possess renewal capacities [177, 178]. These progenitor cell populations contain both SP cells and hematopoietic markers-expressing cells and are capable of repopulating the bone marrow as HSCs do. These findings have sustained the theory that bone marrow stem cells serve as the whole postnatal stem cells and their own progenies to provide a common interchangeable cell source [23, 177, 178].

Skeletal Muscle Progenitor Cell or Satellite Cells. The embryonic mesoderm generates skeletal musculature. Satellite cells are skeletal muscle progenitor cells that are responsible for postnatal growth and repair [179, 180]. Injury in skeletal musculature results in detriment in skeletal muscle mass, but injury itself triggers muscle regeneration of muscle tissue, which is accomplished by differentiation of native progenitor cells [180]. The tissue-specific cell progenitors are so-called satellite cells [179–181]. Despite the replenishment of the satellite cell pool during muscle growth, the number of satellite cells, which is highest in postnatal muscle, declines with aging [181]. This unique population of the cells exists between the muscle fiber sarcolemma and its covering basement membrane. Anatomically, the satellite cells can be clearly defined. The cells are quiescent lying outside the myofibers but beneath the basement membranes [179, 180]. Quiescent muscle satellite cells are characterized by the expression of surface markers such as M-cadherin, syndecan 3 and 4, and CD34 [180]. Even using a standard dissociation technique of the muscle tissue, an efficient isolation of myogenic progentior cells has not been achieved [179, 180]. Many growth factors are implicated in the regulation, chemotaxis, proliferation, and differentiation of satellite cells [179, 181]. Basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF), transferring, and hepatocyte growth factor (HGF) have been identified as potent mitogens for satellite cells. HGF, bFGF, and IGF-1 and TGF-β can also promote chemotaxic activity of satellite cells in tissue culture [179, 182]. Based on their SP phenotype, Hoechst 33342 dye efflux-used FACS has become the easiest way to isolate skeletal muscle progenitor cells. This SP population can generate terminally differentiated skeletal muscle cells and completely repopulate the bone marrow after transplantation [179].

Hepatic Cell Progenitors. Hepatocytes possess the ability to rapidly respond to the parenchymal loss with turning on active mitosis. After massive loss of hepatocytes induced by two-thirds partial hepatectomy, the remaining hepatocytes make a cell-cycle progression at two to three times to restore preoperative cell volume. Such an enormous repopulating capacity is con-ducted by unknown potential and properties of hepatocytes [183]. These crucial properties that defines a stem cell are capable of generating a large progeny. This phenomenon can be observed at least in some hepatocytes [184–187]. Putative hepatic stem cells have been identified by the cell membrane markers, such as the lowered expression of the asialoglyco-protein receptor [188, 189]. Induction of a massive liver damage compromises the regeneration of hepatocytes, and then facultative hepatic progenitor cells distributed along the small branches of the intrahepatic biliary trees are activated to divide. Oval cells that express the same markers as HSCs (c-kit, flt-3, Thy-1, and CD34) transiently amplify the biliary population and then differentiate into hepatocytes

[19, 190, 191]. This particular phenomenon may provide information as to how the liver provides niches for facultative stem cells or offers an opportunity for cell fusion [19].

Progenitor Cells in the Gastrointestinal Tract. The presence of progenitor cells in the intestinal crypts has been observed [17]. Intestinal crypts and gastric glands are considered as specific niches that contain noncommitment and probably multipotent stem cells [17, 192–195]. The epithelial intestinal cells form the lining invaginates with numerous crypts and finger-shaped projections along the gastrointestinal tract and possess a rich population of neuroenteroendocrine cells disseminated throughout their epithelium. The plasticity of progenitor cells in the intestinal epithelium has been shown by differentiation of the cells to insulin-secreting cells using GLP-1 [196]. Intestinal crypts and gastric glands are enclosed by protective fenestrated intestinal subepithelial myofibroblasts and disperse in the lamina propria with merging blood vessels. The myofibroblasts secrete HGF, TGF-beta, and KGF to regulate the differentiation of the intestinal epithelial progenitor cells. Thus, myofibroblast cells play a central role in regulating the differentiation of the progenitor cells located in Lieberkühn crypts [197, 198].

Adult Pancreatic Progenitor Cells. The adult pancreatic tissue is composed of the exocrine and endocrine cells. During embryological development, the pancreatic tissue is generated from differentiation of the ductal epithelium. The exocrine tissue is first differentiated and then endocrine tissue is differentiated [199]. Islets of Langerhans under physiological conditions turn over continuously, but slowly. Terminally differentiated pancreatic beta cells have a life span of approximate 50 days [200, 201]. The cells have a balance of apoptosis and replacement, which is conducted by replication of differentiated beta cells [20]. The replicating capacity of the beta cells is limited [202]. The presence of pancreatic progenitor cells that can give rise to pancreatic and neuronal cell lineages has been demonstrated [169]. Ductal and acinar cells have been proven to have plasticity to differentiate into insulin-secreting cells or to trans-differentiate into hepatocytes [203–209]. The beta cells certainly replicate; however, the senescence of the cells still determines their potential [200, 202]. Otherwise, beta cells may be reprogrammed by cell fusion. *In vitro* culture human islets gradually lose their insulin expression, but they preserve the expression of PDX-1 [208, 210, 211]. Recent research has suggested that adult pancreatic islets contains progenitor cells [206]. Pancreatic progenitor cells may also exist in the non-endocrine tissue [208]. These progenitor cells are capable of generating terminally differentiated endocrine and exocrine progeny [155, 203–206, 212]. They are identified by the positive expression of nestin, referred as to nestin-positive progenitor cells (NIPs) [155, 206, 212], and are dispersed in the whole pancreatic tissue [213]. In addition, SP phenotype cells were observed in NIPs [155] and the cells can give rise to vascular and neuronal progenies [169, 214].

11.3.1.9 Umbilical Cord Blood-Derived Stem Cells (UCBSCs) Stem cells were isolated from umbilical cord blood (UCB) and cultured *in vitro* [215]. Umbilical cord blood-derived stem cells (UCBSCs) had been proposed as an alternative source of regeneration of hemopoietic tissue by allogeneic transplantation

[216]. The successful hematopoietic reconstitution in a patient with Fanconi's anemia has proved the potential of UCBSCs [217, 218]. Usually small cell fractions are recovered from the cord blood, but the primitive hematopoietic population possesses a high proliferative capacity. UCB cells contain a larger hematopoietic population of $CD34^-$ as well as a subset of $CD34^+$ and $CD38^-$, of which population ratio is about fourfold higher than that in bone marrow cells [219]. Moreover, the most primitive phenotype ($CD34^+CD38^-CD45RA^{low}CD71^{low}Thy\text{-}1^+c\text{-}kit^{low}Rh^{low}$)-expressing cells present in UCB at 0.003% of the entire population of nucleated cells [220]. Their proliferative capacity reach to a 50-fold expansion of colony forming cells [221, 222]. Successful *in vitro* expansion of the cells depends on the cytokines contained in the culture. Such cytokines include SCF, IL-1, IL-3, IL-6, GM-CSF, G-CSF, M-CSF, erythropoietin, and thrombopoietin [223]. The cells also possess multipotent characteristics and outstanding plasticity [220]. Therefore, there have been several approaches of differentiation of non-hematopoietic tissues ongoing in the clinical tissue regeneration settings [224–236] and *in vitro* toxicological studies [237].

11.3.1.10 Heterogeneous Populations of Stem Cells in Bone Marrow Bone marrow contains two main well-defined populations of stem cells, HSCs and MSCs. They renew by themselves and give rise to all of the terminally differentiated blood lineages. In addition, bone marrow possesses a small subset population of non-hematopoietic stem cells (NHSCs). This population of NHSCs is identified by the expression of $CXCR4^+$, $CD34^+$, $AC133^+$, lin^-, and $CD45^-$ [22, 23]. Moreover, there is evidence that tissue damage in the body itself is capable of triggering the bone marrow stem cells to get into the circulation [238–242]. Subsequently, the stem cells modify their phenotype in accordance with the tissue where they migrate. Specific activation of membrane surface receptors and subsequent activation of transcription factors determine a modulation of the phenotypes and migratory properties of the stem cells. Chemotactic or homing signaling is involved in the regulation of the migration. The bone marrow stem cells have an exceptional ability to adapt and survive in different microenvironments. The cells can respond to several cytokines and growth factor, such as HGF, VEGF, LIF, and bFGF. The axis SDF-1-$CXCR4^+$ seems to be the most crucial regulatory factor, which is involved in honing of the stem cells. Therefore, it may be considered that bone marrow stem cells can serve as the source of all adult somatic stem cells [23, 238–242]. UCBSCs are considered as HSCs because of their strong proliferative capacity. UCBSCs certainly display higher potentials compared with adult stem cells [217, 220] and have been proposed as the best candidate for regenerating the damaged tissues in the clinical setting among the stem cells [231, 232].

11.3.1.11 Uses and Applications of Stem Cells in Toxicology Besides the further clinical application of stem cells, utilization of the cells in the pharmacological field is also of great interest. As mentioned, stem cells are specialized cells found within many tissues of the body, in which they have the role to maintain homeostasis and repair of the damage tissue. The advantages of unlimited proliferation and subsequent differentiation of the stem cells can be of great use for *in vitro* screening of the newly developed drugs, allowing us to predict possible adverse effects without

the need to test them in animals. For example, hepatocytes derived from stem cells can be routinely screened for new drugs and chemicals to evaluate their liver toxicity.

11.4 ARTIFICIAL CELLS

11.4.1 Introduction

A major limitation to the clinical application of cell therapy and drug discovery is the current inability to isolate an adequate number of functional and transplantable cells [1]. Unfortunately, the number of human organs available for transplantation or cell isolation is severely limited. Considering the cost and difficulty in some cases of cell isolation and the need for immediate availability of consistent and functionally uniform cell preparations, human cells cannot be isolated on a scale sufficient to treat more than a fraction of the patients who need organ transplantation. The use of animal cells would result in additional concerns related to the transmission of infectious pathogens and immunologic and physiologic incompatibilities between donors and humans [2, 3]. Thus, other alternative cell sources, such as stem cells, have been explored. In particular, embryonic stem cells have unlimited proliferative capacity and theoretically can differentiate all kinds of cell types. In contrast, somatic stem cells have finite proliferation ability in the currently available culture system [4]. The cultivation of mammalian cells is an important experimental procedure that is a fundamental tool in biological studies [5]. Establishment of methods to control differentiation and proliferation in stem cells is not yet achieved. Thus, possible tumor development will be occurred after de-differentiated or trans-differentiated stem cells. To overcome this issue, great efforts have been made to construct immortalized human cell lines with an unlimited replicative potential.

However, despite the widespread use of the culture system, we have recently begun to understand the essential mechanisms that control cell growth and division. This section discusses recent advances in our understanding of the molecular mechanisms that regulate the life span of cell lineages *in vitro* and an approach to construct human cell lines with currently available genetic manipulation for cell therapy and the study of pharmacology and toxicology. The definition of cellular immortality is infinite survival with an unlimited proliferative potential [6]. In fact, primary human cells in tissue culture rarely undergo spontaneous immortalization process [7]. Thus, researchers tried to immortalize human cells by using x-ray [8] and chemical carcinogens [7], but it turned out to be very inefficient. Currently, human cells have been immortalized by an introduction of the transforming genes of DNA tumor viruses, such simian virus 40 large T antigen (SV40LT) [9], papillomaviruses [10], and the catalytic unit of the human telomerase reverse transcriptase [11].

11.4.1.1 Immortalization of Human Cells

Limited Proliferative Life Span or Senescence of Human Cells. Senescence is a terminally arrested growth state of the cells. It differs from the nonproliferative state of terminally differentiated cells. As senescent cells remain viable, senescence can be distinguished with cell death processes such as apoptosis or necrosis. Senescent cells are arrested at the G1/S phase of the cell cycle and are thus distinct from nondividing G0-arrested quiescent cells [5, 12]. Human cells are defined as senescent when they fail to respond to mitogens and the population of the cells does not divide in a certain period of time, for example, 30 days. Additional characteristics of senescent cells include (1) expression of β-galactosidase, (2) increased lysossomal biogenesis, (3) decreased rates of protein synthesis and degradation that are distinct from their pre-senescent ancestors, (4) increased cell size, (5) multinucleation, (6) cytoplasmic vacuolation, and (7) decreased membrane fluidity. The rate of protein, DNA, and RNA syntheses is reduced in senescent cells. Senescent cells accumulate altered macromolecules and exhibit DNA alterations such as shortened telomeres, decreased chromatin condensation, increased karyotypic abnormalities, and decreased methylation. Senescence does not lead directly to cell death, and senescent cells can persist in culture for up to 2 years if fed regularly [13].

Senescent cells may accumulate in aged tissue [14] and could compromise tissue function by both their altered pattern of gene expression and their nonproliferative state, resulting in aged phenotypes of the tissues [15]. A link between *in vitro* senescence and *in vivo* aging is suggested by the observation that the *in vitro* life span of cells from various mammalian species correlates with their *in vivo* life span and that the cells from individuals with premature ages suffering from disorders such as Werner's syndrome, Down's syndrome, and progeria have a shorter *in vitro* life span than that of the cells from normal individuals. However, evidence that the *in vitro* life span of normal human cells correlates with the donor age remains controversial [16].

Immortal or Extended Life Span of Human Cells. More than 30 years ago, it was demonstrated for the first time that SV40 [17], a DNA tumor virus of the papova

virus family isolated by Sweet and Hillman [18], can morphologically transform human fetal and adult skin fibroblast. The transformation of mammalian cells by SV40 is known to require expression of only the early region of the viral genomes, which encodes two proteins of large T-antigen (94 kd) and small t-antigen (17 kd) [18]. Transfer and expression of specific oncogenes, such as simian virus 40 large T antigen (SV40 LT), in primary human cells can generate cell populations that propagate for extended periods of time *in vitro*, presumably because they bypass the first senescence crisis through the inactivation of p53 and Rb, and thus extend their life span by about 20 population doubling (PD) [19]. This extended life span ends in M2 crisis stage (Figures 11.4-1 and 11.4-2), which typically coincides with

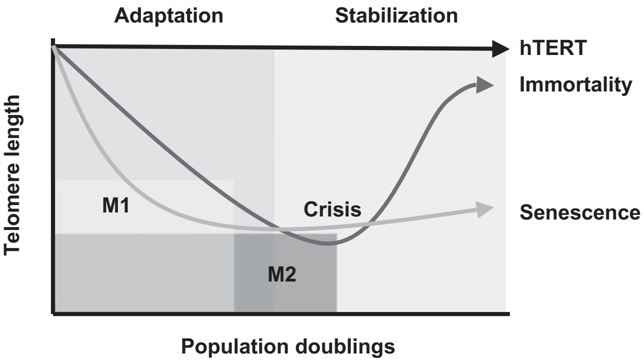

Figure 11.4-1. ***Cellular senescence and immortalization.*** Telomere length is maintained by telomerase, and most human somatic cells have lower levels of telomerase. The cells are telomerase-negative and experience telomere shortening with each cell division. Shortened telomeres may start the cells to enter senescence at the Hayflick limit, or M1. This proliferative checkpoint can be overcome by an inactivation of pRB/p16 or p53, for example, by the use of SV40 or human papilloma virus oncoproteins. Such cells continue to suffer telomere erosion and ultimately enter crisis, or M2, characterized by cell death. Quite a few surviving cells acquire stabilization of telomere length and unlimited proliferative potential, mostly due to activation of telomerase. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

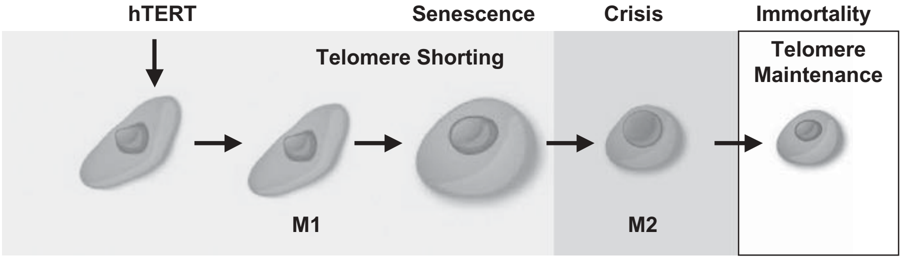

Figure 11.4-2. ***Immortalization of cells with hTERT.*** Ectopic expression of hTERT allows cells to bypass proliferation barriers and become immortal. Telomeres are very important in booth senescence (M1) and crisis (M2) as hTERT introduction either before or after M1 results in cell immortalization. If introduction of hTERT does not result in immortalization in the cells, another type of growth arrest called “premature senescence” or “cell culture shock” will be occurred, which is telomere-independent. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

dangerously shortened telomeres, and every mitosis is accompanied by enormous chromosomal instability in the cells. Most of the cells fail to survive crisis, and the frequency rate of the cells that overcome the crisis is very low in humans. The *in vitro* spontaneous immortalization of human cells using SV40T is approximately 10^6–10^7 and is believed to result from activation of the endogenous telomerase [20]. Such cells are infrequently tumorogenic, and tumorigenicity occurs only after long periods of continuous culture of the cells [10]. These phenomena have suggested that establishment of permanent cell lines in culture involves two distinct processes: (1) an initial adaptation of cells to grow in the unnatural environment of culture dish, and (2) an acquired ability of these adapted cells to proliferate indefinitely in tissue culture (Figure 11.4-1). The life span of cells is measured in cell divisions [5]; thus, cells must possess a molecular "clock" that counts the number of times they have divided. In a telomere model of senescence, telomere length acts as this counting mechanism. Nucleoprotein structures that constitute the ends of linear chromosomes became the primary candidates to fulfill this role in human cells. It was for the first time described molecularly in 1981 [21]; telomeres serve to protect the ends of chromosomes from illegitimate fusions and other damage and shield the ends of chromosomes from recognition by the cellular DNA repair machinery [22]. Telomeric DNA is maintained at a constant length, and telomeres shorten at a constant rate with progressive cell divisions in human cells (Figure 11.4-3). Telomere shortening occurs for at least two reasons: (1) Telomeres shorten with successive replication because the polymerases involved in conventional DNA replication cannot fully copy telomeric DNA [23] and (2) telomerase, an enzyme responsible for telomere maintenance, is tightly repressed in most human somatic cells [24]. Most immortalized human cells express telomerase [24], and telomere length is stable. These observations have suggested that some elements of telomere structures monitor cell proliferation and order a signal of the onset of replicative senescence. The ectopic expression of telomerase in pre-senescent cells halts telomere shortening and permits cells to avoid replicative senescence. Telomerase is a ribonucleoprotein composed of an RNA subunit, *hTERC*, that is ubiquitously expressed [25] and a reverse transcriptase protein catalytic subunit, *hTERT*, whose expression correlates with telomerase activity in immortal cells [26].

hTERT is indeed undetectable in most types of normal human cells, but it is readily detectable in most immortal cell lines, cells derived from human cancers, and human tumor samples. Expression of *hTERT* in pre-senescent human cells confers telomerase activity [10], resulting in telomere lengthening or stabilization, and it allows the cells to bypass replicative senescence. Cells expressing *hTERT* maintain the normal karyotype and continue to respond in the same manner as pre-senescent, nonimmortalized cells [27]. Thus, activation of telomerase by expression of *hTERT* permits the cells to bypass senescence and become immortalized in a single step. Although maintenance of telomere plays an important role in replicative senescence, it has been proved that both pRB and p53 tumor suppressor pathways also play a prominent role in regulating the onset of replicative senescence (Figure 11.4-4). When cells expressing SV40LT continue to repress hTERT expression and lack a detectable telomerase activity, the telomere length of the cells gradually shortens with continued cell proliferation. Eventually such cells enter the second period of diminished growth, which referred is to as crisis or M2 [28]. Telomere shortening may be one signal that activates the pRB or p53 pathway and initiates replicative senescence. These observations have suggested that both pRB

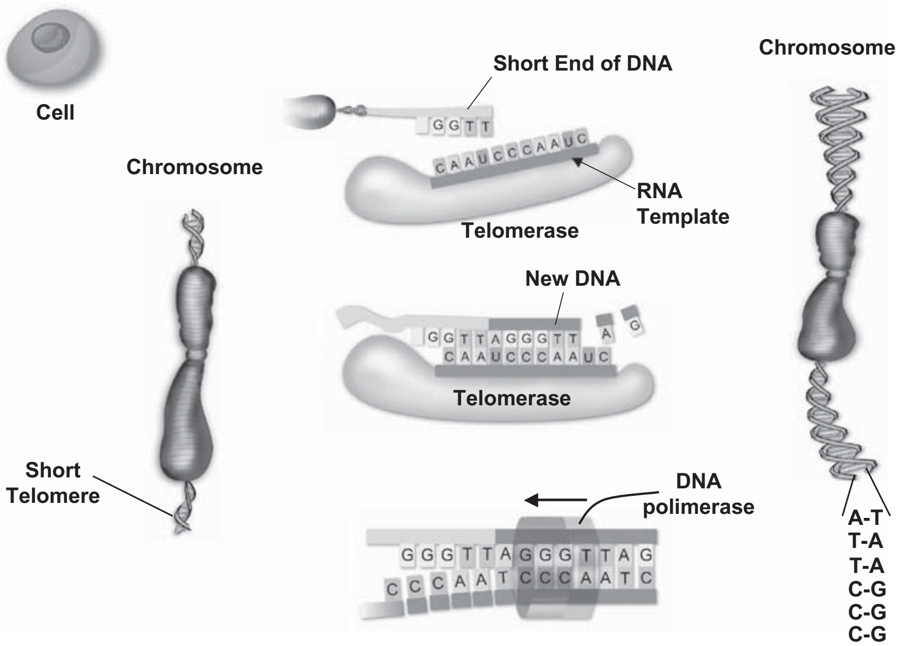

Figure 11.4-3. ***Telomeres and telomerase.*** Telomere is a repeating sequence of double-stranded DNA located at the ends of chromosomes. Long telomere length is associated with immortalized cell lines, cancer cells, and embryonic stem cells. Cells experience telomere shortening with each cell division. Telomerase is an enzyme that lengthens telomeres by adding on repeating sequences of DNA. Telomerase binds the ends of the telomere via an RNA template that is used for the attachment of a new strand of DNA. Telomerase adds several repeated DNA sequences, then releases to a second enzyme, DNA polymerase, and attaches the opposite or complementary strand of DNA, completing the double-stranded extension of the chromosome ends. The function of telomere and telomerase seem to be important in cell division, normal development, and cancer research. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

and p53 pathways in conjunction with telo-mere shortening play significant roles in governing replicative senescence (Figure 11.4-1).

Crisis stage. Crisis (M2) is distinguished from senescence by cell death in the presence of ongoing cell division [29]. Although most cells that enter crisis die by apoptosis, a few cells overcome crisis and become immortal [30]. Immortal cells that have survived crisis typically exhibit aneuploidy and extensive nonreciprocal chromosomal translocations, which suggests that substantial genomic rearrangements accompany the selection of these rare surviving cells. These observations indicate that crisis is precipitated by critically shortened telomeres that have lost their ability to protect chromosomes in the setting of p53 loss. Immortal cells that emerge from crisis show the stabilized telomere lengths with extended passage, which suggests that only those cells that acquire the ability to maintain stable telomere lengths survive. It is important to note that, in general, immortal cells fail to form tumors in immunodeficient animals [31]. Experimentally, the introduction of *hTERT* in post-senescent, pre-crisis cells confers telomerase activity, stabilizes telomere

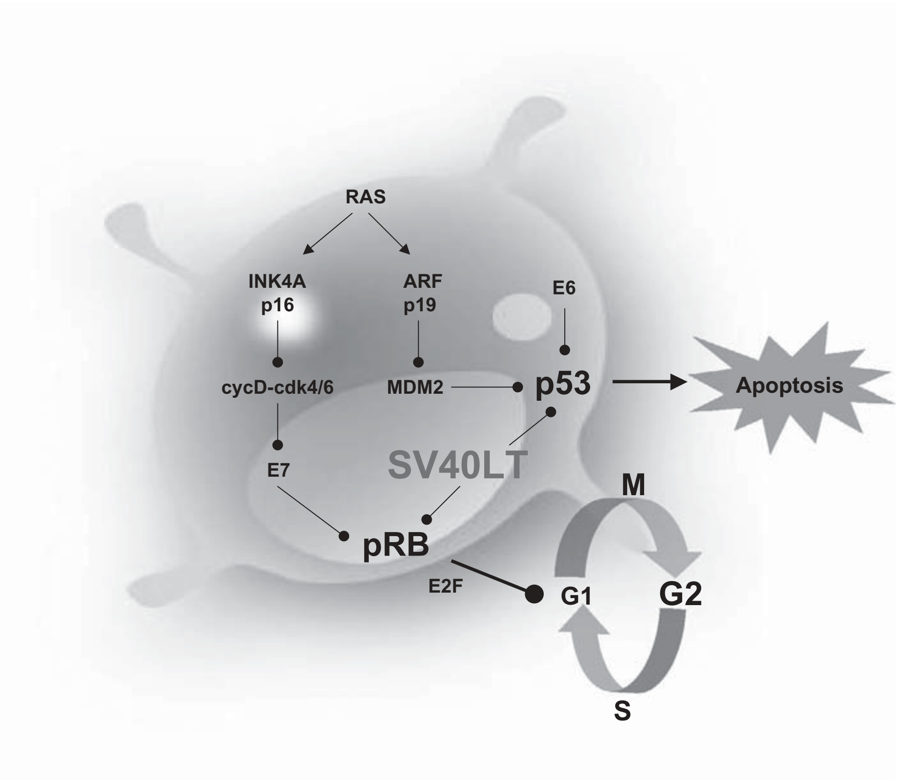

Figure 11.4-4. ***pRB and p53 tumor suppressors pathways.*** These pathways play critical roles in the cell physiology and mutations. Their affectation is found in most human cancers. The viral oncoprotein SV40 LT targets pRB and p53 pathways. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

length, and permits these telomerase-expressing cells to become immortal [10, 27, 32–35]. Human cells immortalized in this manner often exhibit near-diploid karyotypes, which strongly suggests that critical telomere shortening in the absence of pRB and p53 functions initiates crisis. Two barriers limit proliferative lifespan in human cells: (1) replicative senescence and (2) crisis. Furthermore, it is obvious that telomerase, pRB, and p53 play critical roles in regulating an entry of human cells into these two states.

Immortality. Several groups have demonstrated that the introduction of pairs of cooperating oncogenes, such as myc and ras [36], or the adenoviral E1A protein and ras [37] into the primary rodent cells leads to direct transformation of the cells. However, several laboratories have now shown that telomere biology differs in important ways between human and murine cells [38]. Unlike most human cells in which telomerase is tightly repressed, most murine cells express detectable telomerase activity. In addition, telomeres are maintained at much longer lengths in cells derived from inbred mice than are observed in human cells [38]. These observations have suggested that the replicative life span of murine cells is not limited by telomere length. With extended cell division, telomere shortening

activates either replicative senescence or crisis and telomeres play in protecting chromosomal integrity, which suggests that telomeres play an important role in repressing tumor formation. In contrast, the maintenance of telomere length confers cell immortality. These observations also indicate that telomeres serve as a factor that restricts and/or promotes malignant transformation. Under most circumstances, short telomeres limit the life span of the cells, depending on the status of the pRB and p53 pathways, to greatly reduce the pool of premalignant cells (Figure 11.4-2).

To address cellular immortality, researchers have made great efforts to establish an immortalized human cell lines. Such cell lines provide the advantage of uniformity and sterility, grow in unlimited quantity, and are far less costly than isolating the primary cells. One approach to construct clonal cell lines is transduction of the primary cells with genes from DNA tumor viruses, such as SV40, human papillomavirus, and Epstein–Barr virus [39]. Transformation of normal cells with early region genes of SV40, typically by transfection with expression plasmids, remains a common immortalization technique. For example, human fetal hepatopcytes were successfully transduced with pSV3neo DNA containing both large and small T antigens of the early region of SV40 and bacterial neomycin phosphotransferase gene (Figure 11.4-3). After G418 treatment, one line of the surviving clones, OUMS-29, grew well in the chemically defined serum-free medium without any crisis and showed liver-specific functions [40]. When transplanted into immunodeficient mice, OUMS-29 cells were not tumorigenic. The potential risk of malignant formation of OUMS-29 cells cannot be precluded in humans. Safeguards, including the introduction of suicide genes, should be considered in immortalized cells for human application.

In parallel, cells are recovered from surgically resected tumor specimens and cultured. Cell lines have been established for the study of different pathophysiologies. These cell lines grow indefinitely in tissue culture and have been widely used all over the world. However, genetic constitution and alterations of such cells are often observed, and several important specific functions, including several receptors and transporters, have been unfortunately deregulated [41].

11.4.1.2 Tightly Immortalized Human Cell Lines Transduction of immortalized cell lines with these suicide genes would provide a way to eliminate the cells after transplantation. Cells modified to express a herpes simplex virus–thymidine kinase (HSV–TK) gene become sensitive to ganciclovir (GCV) [42]. Thus, researchers have introduced the HSV–TK gene into cell lines. For example, OUMS-29/TK cells, immortalized human fetal hepatocytes expressing HSV–TK, were more than 100 times sensitive to GCV treatment than unmodified parental OUMS-29 cells. OUMS-29/TK cells stopped proliferation in the presence of 5-μM GCV [40].

11.4.1.3 Conditionally Immortalized Cell Lines An approach to create a conditionally immortalized cell line is the use of a transforming gene containing a temperature-sensitive mutation. Primary rat hepatocytes were successfully immortalized with a thermolabile mutant SV40T (encoded by the early region mutant tsA58) and functioned as well as primary hepatocytes after transplantation [43–45]. However, the continued presence of SV40T in the transplanted cells may increase the risk of malignant transformation of the cells after transplantation in the recipients.

11.4.1.4 Ultra-Transform Immortalized Transgenic Cell Lines This approach has proven to be successful because the resulting cell lines showed stability in culture and sensitivity to chemical exposure. The strategy implicates the development of a bi-transgenic hepatocyte cell line to evaluate the ability of various organic and inorganic chemicals to induce the expression of the HSP70-driven reporter gene. Development of two types of transgenic mice is necessary in advance. One is a transgenic mice (Hsp70/hGH) [46] secreting high levels of human growth hormone (hGH), and another is transgenic model (AT/cytoMet) [46] allowing the reproducible immortalization of untransformed hepatocytes retaining liver functions. Both strains are crossed, and the resulting transgenic strain permits a reproducible immortalization of untransformed hepatocytes. Several stable hepatic cell lines (MMH–GH) showing highly differentiated phenotypes have been generated from the double transgenic animals. This strategy is valuable in the field of toxicology and in the development of chemical and physical xenobiotics. The technology provides a simple biological system that reduces the need for animal experimentation and/or continuously isolating fresh hepatocytes [46].

11.4.1.5 Reversibly Immortalized Cell Lines To generate an immortalized hepatocyte cell line more suitable for clinical use, a more tightly regulated system for cell growth should be considered. An attractive system using site-specific recombination has been documented [47]. DNA sequences intervened by loxP recombination targets can be excised after expression of Cre recombinase [47]. A Cre/loxP system allows the construction of reversibly immortalized cell lines. To provide more stringent control over the expression of transforming genes, human hepatocytes were transduced with a retro-viral vector SSR#69 expressing SV40T and selectable positive (hygromycin resistance gene) and negative (HSV-TK) markers that were intervened by a pair of loxP recombination targets and subsequently excised by Cre/loxP recombination [31, 48]. One emerging clone after SSR#69-transduction, NKNT-3, was a highly differentiated hepatocyte cell line. NKNT-3 cells were sensitive to 5-μM GCV. Adenovirus-mediated Cre recombinase expression was efficiently performed to remove SV40T from NKNT-3 cells. Intrasplenic transplantation of such reverted NKNT-3 cells significantly improved the survival of 90% hepatectomized rats [31]. Cre/loxP-based reversible immortalization has been achieved in several types of human cells [31, 48, 49]. In our studies, SV40T-transduced normal human endothelial cells (ECs) acquired an extensive proliferation capacity to population doubling level (PDL) 65 to 80, but complete immortalization was not achieved [49]. This was explained by the absence of spontaneous activation of endogenous telomerase, which is known as one of the essential participants in cellular immortalization processes in SV40T-transduced ECs [50–52]. To achieve immortalization of normal human ECs, a retroviral vector SSR#197 expressing hTERT and GFP cDNAs flanked by a pair of loxB target sequences was constructed. Cotransduction of human ECs with retroviral vectors SSR#69 and SSR#197 facilitated establishment of a completely immortalized cell line TMNK-1 that expresses a differentiated endothelial phenotype. Feasibility of reversible immortalization in TMNK-1 cells was demonstrated by using TAT-derived HIV-mediated Cre/loxP recombination followed by GFP-negative cell sorting and drug selection [27]. Lately, the system has been applied to establish hepatic stellate cell lines [33], cholangiocyte cell lines [10], hepatic progenitor cell lines [53], bone marrow-derived human cells [54], and human pancreatic beta cell lines [32]. To

establish immortalized human pancreatic beta cell lines, freshly isolated human pancreatic islet cells were transduced with SSR#69, followed by hygromycin selection. Then, the resultant cells were super-infected with SSR#197 for immortalization (Figure 11.4-5). At the first screening, tumorigenic assay of the resulting cell lines was performed in immunodeficient mice. Then, gene expression analysis was conducted in nontumorigenic clones. Based on these findings, NAKT-15 turned out to be highly differentiated. To obtain the reverted form of NAKT-15 cells, the cells were infected with a recombinant adevovirus virus vector (AxCANCre) expressing Cre recombinase tagged with a nuclear localization signal (NLS) expressing the recombinant adenovirus vector. After AxCANCre infection, GFP-

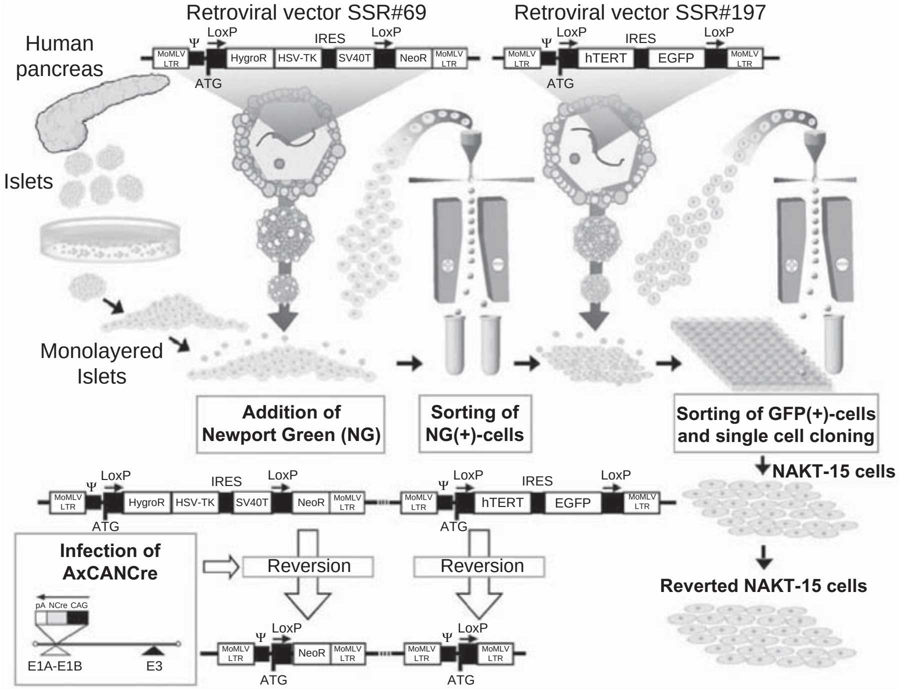

Figure 11.4-5. ***Scheme for the establishment of reversibly immortalized human β-cell lines.*** Freshly isolated human islets were cultured in monolayer and transduced with the retroviral vector SSR#69. After hygromycin selection of SSR#69-transduced cells, Newport Green dye was added and Newport Green-positive cells were sorted. After transduction with SSR#197, EGFP-positive cells were sorted and subjected to single-cell cloning, yielding the clone NAKT-15. Transient expression of Cre recombinase was induced by infecting cells with a recombinant adenovirus expressing Cre recombinase (AxCANCre), which removed the SV40T and TERT genes that were flanked by loxP sites. Neomycin (G418) selection and EGFP-negative cell sorting resulted in the collection of reverted NAKT-15 cells. CAG, promoter consisting of cytomegalovirus IE enhancer, chicken b-actin promoter, and rabbit b-globin polyadenylation signal; HSV-TK, herpes simplex virus thymidine kinase; HygroR, hygromycin-resistance gene; IRES, internal ribosomal entry site; MoMLV LTR, long terminal repeat of Moloney murine leukemia virus leader sequence; NCre, nuclear localizing signal-tagged Cre recombinase; pA, polyadenylation signal; j, packaging signal. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

negative cell populations were recovered by a MoFlo cell sorter and then cultured in the presence of neomycin analog G418 [32]. These procedures are well illustrated in Figure 11.4-5. This strategy can be applicable to various types of human cells.

11.4.1.6 Applications Numerous genomics-based technologies are now routinely applied to drug discovery. The central role for these technologies is validating the next generation of therapeutics from novel targets identified through genomics. The aim of such technologies is to accurately identify the next generation of targets that demonstrate therapeutic efficiency and safety. Immortal human cell lines will have unique attributes that can be used for drug discovery, and if cell therapy is the goal of such cells, the addition of redundant safeguards into the cells and accumulation of experimental data will be required before clinical trials. The ultimate goal of cell transplantation is an autologous setting in which the patient's own cells are genetically modified *ex vivo* with a reversible immortalization method, and then a reverted form of the cells can be transplanted back to the patient. Immortalized or reversibly immortalized cells offer continuous availability, uniformity, and sterility, and the cells can be functionally cryopreserved for the future use. Production of such cell lines may overcome the shortage of donors, and thus, the established human cell clones may be considered as a potential cell source for the treatment of diabetic patients or liver failure patients with transplantation. We anticipate that the production of artificial cells will be useful not only to provide carcinogenesis models, but also to develop drug discovery and possible cell therapy in the future. Reversible immortalization of human cells has important applications in biological research, biotechnology, and medicine.

11.4.2 Conclusions

The ethical issue of transplanting immortalized cells is still controversial, but clinical approval of a protocol involving transplantation of these cells depends on the balance of risks and benefits. If patients with high risk were to receive such transplants with considerable benefits, approval would be obtained after reliable accumulation of data regarding the safety and efficacy of immortalized cells. We here represent an important step in the development of a useful strategy for resolving the organ shortage that now limits the use of normal human cells for cell therapies. Such technology can be applicable to a variety of somatic cells and would potentially be used to treat a large number of patients with clinically significant pathologic conditions.

12.1.1 HISTORICAL PERSPECTIVE ON REGULATION

Regulation is the logical consequence of the search from health institutions and governments to ensure public protection from unsafe products.

The regulation of drugs emerged first in developed countries. The first initiatives of regulation appeared in 1862 with the Bureau of Chemistry in the Department of Agriculture of the United States, lead by Harvey Wiley, trying to regulate food,

drug, and biological products. At that time, adulterated food and drugs as The Great Blood Purifier System (Peter's specific) and Mrs. Winslow's Soothing Syrup for teething and colicky babies (which was related with morphine, without a label indication) were the main targets of regulation [1].

The Bureau of Chemistry enforced a 1906 law until 1927, when it was reorganized to form the Food, Drug and Insecticide Administration, later renamed, in 1931, as the Food and Drug Administration [1]. The 1906 Act prohibited the sale of adulterated or misbranded drugs and prohibited interstate transport of disallowed food and drugs. It also mandated that a variety of information be stated on the drug package. Changes to labeling requirements and a provision to label certain dangerous ingredients led many patent medicine makers to reformulate their products because many of the products contained harmful chemicals [1].

After an event in 1937, when a marketed anti-infective called Elixir Sulfanimide caused over 100 deaths regulators were forced to change the law to require that drugs meet certain safety requirements before being marketed. A new 1938 Act called for evidence of drug safety, prohibited false therapeutic drug claims, and also included cosmetics and therapeutic devices under FDA regulation. The 1938 Act established a listing of active ingredients on the drug label and required that drugs be labeled with adequate directions for safe use [1].

Even after all these efforts to ensure the safety of drugs were implemented, many incidents (included the thalidomide tragedy) occurred and the U.S. Congress had to pass major amendments to the Act in 1962. In addition to safety issues, for the first time drug manufacturers were required to prove the effectiveness of their drug products before marketing.

In parallel with the development of drug regulations, biological regulations were historically developed in connection to safety concerns. The 1902 Biologics Control Act enacted by the U.S. Congress established the initial concepts used for the regulation of biologicals. These provisions were revised in 1944 and expanded in the 1950s. Attention to regulation of vaccines and toxins was enforced until a major tragedy occurred in the United States, and only then were actions taken by the federal government to ensure public protection from unsafe products. The incident occurred in 1901, in St. Louis, Missouri, when 20 children became ill and 14 died after administration of an equine-derived diphtheria antitoxin (prepared from horse serum) contaminated with tetanus toxin. The serum had been manufactured in local establishments designed without any of the current knowledge of Good Manufacturing Practices, particularly without procedures that guarantee the product's safety and potency. This event forced legislation to regulate the sale of biologicals. In July 1902, Congress passed the Biologics Control Act also known as the "Virus-Toxin" law [2], which is the first time that the United States' government took control over biologicals' production, consequently with the responsibility to ensure their safety for the public. In this act, the need to include the control of the manufacturing establishments and facilities was recognized, as assurance of purity could not be demonstrated if control was limited to inspection and testing of a final product. This act settled the essential concepts for ensuring the safety of biologicals. These ideas are used as the basis for ensuring safety and effectiveness of biologicals throughout the world [3].

The history of vaccine control and regulation in developed nations has been one of increasing complexity. By 1955, many biologicals, including blood products and

vaccines, had been licensed and the need for appropriate regulation was evident. In the United States, the use of inactivated polio vaccines from different manufacturers, licensed in the country, provoked a number of children to develop poliomyelitis, and some of the children died. The reason was incompletely inactivated vaccines [3]. This incident led to the expansion of the biologicals control function to the establishment of the Division of Biological Standards (DBS) within the National Institutes of Health. Later, in 1972, the DBS was transferred to FDA and became the Bureau of Biologics. In 1982, the Bureau of Biologics was renamed the Office of Biologics Research and Review (OBRR) and combined with the Office of Drugs Research and Review (ODRR) formed the Center for Drugs and Biologics. In 1987, the OBRR was separated and renamed the Center for Biologics Evaluation and Research (CBER) [4].

The need to develop and institute an independent evaluation of medicinal products before they are allowed into the market for public consumption was reached at different times in different regions, generally associated with the level of technological development. In Japan, government regulations requiring all medicinal products to be registered for sale started in the 1950s. In many countries in Europe, the thalidomide tragedy of the 1960s was the trigger. This tragedy revealed that the new generation of synthetic drugs, which were revolutionizing medicine at the time, had the potential to harm as well as to cure [5].

Between 1960 and 1970, important developments transpired regarding laws, regulations, and guidelines for reporting and evaluation of data on safety, quality, and efficacy of new medicinal products. At the same time, the industry was becoming more international and seeking new global markets, but still the registration of medicines remained a national responsibility.

The urgent need to rationalize and harmonize regulation has been forced by the need of countries to have access to drugs and biologicals to cure, treat, and prevent diseases according to the development of important technological advances in science and responding to the effort of manufacturers to gain access to more and new markets.

For the purpose of this review, drugs will be classified as small molecules, biologicals, and biotech products:

- Small molecules are most medicines or drugs chemically synthesized with molecular weights of typically less than 500 Da applicable to prevention, treatment, or cure of diseases or injuries in man.
- Biologicals are any virus, therapeutic serum, toxin, antitoxin, vaccine, blood component or derivative, allergenic extract, or analogous product applicable to the prevention, treatment, or cure of diseases or injuries in man, generally with molecular weights larger than thousands of Daltons.
- Biotechnological products are any biological or pharmaceutical product made using recombinant DNA techniques and intended to prevent, treat, or cure diseases or injuries in man. This group includes mainly proteins of high molecular weight.

Drugs or small molecules of natural origin that are not produced through chemical synthesis are not considered in this review.

12.1.2 ISSUES RELATED TO REGULATION FOR BIOLOGICALS (VACCINES) COMPARED WITH REGULATION FOR OTHER MEDICINAL PRODUCTS

WHO has established that effective drug regulation promotes and protects public health by ensuring that [6]:

- medicines are of the required quality, safety, and efficacy;
- health professionals and patients have the necessary information to enable them to use the medicines rationally;
- all premises, persons, and practices engaged in the development, manufacture, importation, exportation, wholesale, supply, dispensing, and promotion of drugs comply with approved standards, norms, procedures, and requirements;
- product information is unbiased, accurate, and appropriate;
- illegal manufacturing and trade are detected and adequately sanctioned;
- promotion and advertising are fair, balanced, and aimed at rational drug use; and
- access to medicines is not hindered by unjustified regulatory work.

National drug budgets, as a proportion of total health budgets, currently range from 7% to 66% worldwide. The proportion is higher in developing countries (24–66%) than in developed countries (7–30%) [7]. People and governments willingly spend money on drugs because of the role they can play in saving lives, restoring health, preventing diseases, and stopping epidemics. However, to accomplish these goals, drugs must be safe, effective, and of good quality and used appropriately, which means, in turn, that their development, production, importation, exportation, and subsequent distribution must be regulated to ensure that they meet prescribed standards.

In the search of implementing regulations for drugs, biologicals, and all medicines to guarantee the protection and benefit of the users, governments have established the national drug regulatory authorities (DRAs). These institutions must be developed with a clear mission, solid legal basis, realistic objectives, appropriate organizational structure, adequate number of qualified staff, sustainable financing, access to technical literature and information, and with the capacity to exert effective market control. DRAs must be accountable to both the government and the public and their decision-making processes should be transparent. Monitoring and evaluating mechanisms should be built into the regulatory system to assess attainment of established objectives [6].

Regulatory authority is generally based on laws, which represent policy choices. This authority is assigned to designated organizations, generally part of the bureaucratic institutions, with the mission to carry out drug regulation. Several factors regarding the authority and the capacity for exercising such authority affect the operation and drug regulatory activities [7]. Among the most important are:

- availability of standards, procedures, and guidelines to be used as guidance in performing the authorized functions;

- consideration of strategies to overcome structural and resources constraints, including financial adequacy and sustainability;
- establishment of clear strategies for planning, monitoring, and evaluation;
- availability of appropriate human resources including number, qualifications, remuneration, and human resources development; and
- definition of the scope of regulatory authority, in relation to type and extent of the activities carried out to implement legal provisions, including sanctions for noncompliance.

The value of drug regulatory activities depends on whether they produce the intended outcomes in terms of the following [7]:

- the quality of pharmaceutical products marketed;
- the proportion of licensed pharmaceutical facilities meeting international standards in Good Manufacturing Practices, Good Laboratory Practices, Good Clinical Practices, and so on;
- the number of illegal products on the market; and
- the number of illegal facilities marketing pharmaceutical products.

In addition to effectiveness, policy makers must also address regulatory efficiency, transparency, and accountability when evaluating regulatory policies. The cost effectiveness of drug regulation; the cost for pharmaceutical businesses and consumers of regulatory delays; political and commercial influence over regulatory decisions, public access to regulatory procedures and decision-making criteria; communication among the regulatory authority, its clients, and the consumer; and the accountability for the results of regulatory actions are performance indicators that must be assessed in the evaluation of regulatory agencies.

12.1.2.1 Regulation of Small Molecules

Since the mid-1930s, many new pharmaceutical products have emerged, and trade in the pharmaceutical industry has taken on international dimensions. At the same time, however, the circulation of toxic, substandard, and counterfeit drugs on the markets has increased, mainly because of ineffective regulation of production and trade of pharmaceutical products in exporting and importing countries. Problems relating to drug safety and efficacy are generally caused by the use of drugs containing toxic substances or impurities, drugs whose claims have not been verified or that have unknown severe adverse reactions, as well as substandard preparations or counterfeits drugs. All these problems can be tackled effectively only by establishing an effective drug regulatory system.

The development process stages for a small molecule drug that are relevant to the regulatory scrutiny are as follows:

- drug discovery,
- drug purification,
- preclinical research, and
- clinical trials (phase I, II, and III).

When the dossier of a drug is submitted to the DRA, an exhaustive review of the medical/clinical, chemistry/manufacture, pharmacology/toxicology aspects, and their statistical validity is conducted. The main element of the evaluation is to certify its safety (clinical trials phase I or II) and, during this stage of the approval, the manufacturer can be required to submit additional information to ensure the safety of the product. When safety is acceptable, the DRA proceeds with complete reviews to ensure efficacy, stability, and all other specifications that guarantee the product complies with the required norms. At any stage of the trial, the DRA of the country where the trial is being conducted should have the authority to put it on hold if deficiencies or safety issues appear and until they are resolved. If results of clinical trials demonstrate that the drug is safe and efficacious over existing treatment drugs, an application is made in most of the regulatory agencies to seek approval for marketing the drug.

As part of the new drug approval process, the DRA conducts inspection for Good Manufacturing Practices (GMP inspection) of the facilities where the drug is being manufactured. GMP is a quality concept and consists of a set of policies and procedures for manufacturing processes to guarantee that drugs are pure, consistent, safe, and effective. These policies and procedures describe the facilities, equipment, methods, and controls for producing drugs with the intended quality. The guiding principle for GMP is that quality cannot be tested in a product, but must be designed and built into each batch of the drug product throughout all aspects of its manufacturing processes [8].

12.1.2.2 Regulation of Classic Vaccines and Biologicals

Well-managed programs of vaccination have brought about profound reductions in the impact of diseases in terms of morbidity and mortality in the majority of countries of the world. One major disease, smallpox, has been totally eradicated largely as a result of vaccination and another, poliomyelitis, is absent from large areas of the world and on target for eradication during the next few years, and the incidence of measles has been greatly reduced. Vaccines provide one of the most cost-effective public health interventions and are among the safest medicinal products [9] (Table 12.1-1).

These enormous achievements have been possible in part because internationally agreed principles and procedures are in place to secure high levels of safety, efficacy, and quality of vaccines. Vaccines differ from therapeutic medicines first because of the biological and thus inherently variable nature of the products themselves, the raw material used in their production, and the biological methods used to test them. Thus, special expertise and procedures are needed for their manufacture, control, and regulation. The use of appropriate standard materials and reference preparations, whenever they exist, is fundamental to the standardization and control of vaccines [9].

Vaccines are unique in the fact that they are usually administered to very large numbers of healthy people, mostly infants, in national immunization programs. Thus, safety and quality are of high relevance. Although vaccines have a key role in preventive medicine, recent history of their use has shown a general high level of safety compared with their benefit. In most cases, minor adverse reactions may occur, but these reactions do not challenge the risk-benefit advantage of vaccina-

TABLE 12.1-1. Classification and Characteristics of Vaccines

- **Classic vaccines:** products of a whole or part (subunit) of a microorganism. They can be attenuated or inactivated vaccines, subunits, or toxoids products of the microorganism's metabolism, for instance, Diphtheria-Tetanus-Pertussis (DTP), Measles–Mumps–Rubella (MMR), oral polio vaccine (OPV), inactivated polio vaccine (IPV), smallpox, rotavirus, and so on.
- **Recombinant vaccines:** obtained as products of gene modification of different organisms (yeast or bacteria) with posterior purification to get the immunogenic protein (example Hepatitis B vaccine).
- **Synthetic vaccines:** Part or the whole antigen is a product of chemical synthesis, proteic nature (peptides and oligopeptides), or carbohydrates (saccharides and oligosaccharides) (polyribosylribitol phosphate (PRP) synthetic antigen conjugated to tetanus toxoid).
- **Combined vaccines**: including different combination of classic, recombinant, or synthetic vaccines (DTP-HepB-Hib).
- New approach of vaccines: DNA vaccines and plant-derived vaccines, under development but still not licensed.

tion. A number of potential and theoretical risks are implicit in their use. They include, in particular, the presence of adventitious agents derived from the source materials or introduced during manufacture or, as is the case of live vaccines, the presence of virulent organisms caused by reversions of the vaccine virus or bacteria to its virulent form. In these cases, a possible risk to the community at large may exist in addition to the vaccinees [9].

A remarkable difference between vaccines and biologicals and other synthetic pharmaceutical drugs consists of the difficulty of evaluating the activity for those biological products, and thus the differences among them in their control and regulation. In general, for synthetic drugs and medicinal products, the active ingredient is totally defined and the activity can be evaluated by quantitative methods. They are synthesized in the laboratory in a precisely controlled way by a defined sequence of chemical reactions, and the nature of these molecules is such that, once they are made, their exact structure and composition can be determined by laboratory tests. Today, technology allows the modeling of small drug-receptor interactions that can be studied using computational chemistry (*in silico*) methods and extraction of valuable data and information from databases (bioinformatics). The modeled drug is then synthesized using combinatorial chemistry. The application of technologies such as X-ray crystallography and Nuclear Magnetic Resonance [8] are standard procedures for the 3D structural determinations and drug-receptor interactions.

For biologicals, the biological activity and its consequences must be evaluated in an integrated way before starting clinical trials. The complexity and challenge that regulators face with vaccines can be exemplified with the case of combined vaccines, where different epitopes are being introduced in the human body, inducing different responses to the regulatory mechanisms of the immune system, while not causing interference in the responses between them. New vaccines challenge regulators with the development of novel procedures for the proper evaluation of their efficacy and safety.

It is important that the standardization and control of vaccines by the national regulatory authority and the manufacturer are continually reviewed and modified

so as to reflect the current state of science and technology incorporating an improved understanding of quality and safety issues. Regulatory authorities must thus be proactive and maintain an acute awareness of scientific developments in the vaccine field [9].

12.1.2.3 Regulation of Biotechnology Products

Recombinant insulin was the first biotechnology product, which emerged in 1982. Today, biopharmaceutical products have diverged to encompass not only recombinant forms of natural proteins and biologicals derived from natural sources, including recombinant plant-derived pharmaceutical proteins, but also monoclonal antibody (mAb)-based therapeutics. All these products require special consideration from a regulatory point of view.

In the past, microbial and animal cell culture was the most common method of producing recombinant proteins. Currently, the interest is focusing increasingly on transgenic animals because of their apparent ability to produce complex proteins at a high volume and a low cost [6]. Many of these products are now in different phases of clinical trials, although some of them without encouraging results [10].

During 2002 and 2003, regulators in North America and Europe approved a total of 64 biopharmaceuticals for human use. These approved drugs included hormones, blood factors, thrombolytics, vaccines, interferons, monoclonal antibodies, and therapeutic enzymes (not including new indications for products already approved) [11]. Data published by Walsh [11] suggest that during the past three years, over a quarter of all new drug approvals were biopharmaceuticals, taking into account that these numbers do not reflect duplication for products with different formulations and different commercial names for the same active ingredient. All of the new biopharmacuticals approved in United States in 2003 are protein-based drugs (rather than nucleic acid-based drugs). According to estimates at that time, around 500 biopharmaceuticals were undergoing clinical trials [11].

To date, no gene therapy drug has gained marketing approval as a direct consequence of the technical, manufacturing, and regulatory difficulty that still beset this class of therapeutic compounds. Besides, it is important to consider that a bad reputation on these products exists as a consequence of reported incidents of adverse reactions after their use [11]. Monoclonal antibody therapeutics have been hit particularly hard regarding warnings mainly related to hypersensitivity or anaphylactic reactions or cytokine storms [12].

The major target indications of biopharmaceuticals currently undergoing clinical trials include cancer, cardiovascular, and infectious diseases, the major killers within the developed world. Although in excess of 30 nucleic acid-based drugs are currently being evaluated for gene therapy, vaccines, and other applications, the majority remain in the early stages of clinical development (phase I/II) [11].

Another kind of biotechnological product that is acquiring interest as a therapeutic agent is the biopharmaceuticals derived from plants. As a result of the limited production capacity of many pharmaceutical products, the production in plants represents an innovative tool that can expand the yields of active principles because the large volume of biomass that can be developed at the fields. An extra advantage is that these products are free of human diseases and mammalian viral vectors. In products derived from bacteria, the bacterial endotoxin content of the

final product has always been of concern, which is not an issue in products derived from plants.

To date, only proteins have been developed through genetically modified plant, including mammalian antibodies, blood components, coagulation factors, vaccines (edible vaccines), hormones (insulin, somatotropin, and erythropoietin), various interferons, and other therapeutics agents such as enzymes and interleukins [13].

Monoclonal antibodies for therapeutic and diagnostic use seem to be the best potential successful products produced in plants, but they currently have not reached the marketplace. Tobacco plants are the most commonly used plant in these developments. Hepatitis B surface protein and rabies virus glycoprotein are examples of advances in edible vaccines.

In the production of biopharmaceuticals derived from genetically modified plants, several steps are part of the process, and they commonly include:

- selection of host plant;
- selection of the gene expression system;
- location of gene expression within the plant (green matter, the seed, or other tissues);
- production of biomass; and
- implementation of purification systems for the protein.

Several of these steps will require new and special regulatory developments. The products obtained from genetically modified plants must be carefully studied by regulators focusing on some main issues such as the development of Good Manufacturing Practices appropriate for the use in the fields that can guarantee the consistency of production during the manufacturing process. Environmental issues also exist that must be taken into account. Potential effects on nontarget species such as butterflies, honeybees, and other wildlife at or near the growing sites are important to be considered [13]. The possible transgene escape through pollen or seed dispersal, the potential for recombinant molecules to enter the food chain [14], and the proper evaluation of the impact that the introduction of virus from plants into the human body can cause are issues that have to be resolved for the success of this modern biotechnology tool.

Table 12.1-2 summarizes some of the main differential issues regarding small molecules, biologicals, and biotechnological products.

12.1.3 MAIN REGULATORY AGENCIES

12.1.3.1 Food and Drug Administration (FDA)

FDA is recognized as the strongest regulatory agency in the world. Although the agency has limited its regulatory functions to products to be used in the United States, this agency has been the pioneer in the development of the regulation for drugs, including vaccines, blood products, and a lot of new biotechnology products emerging in the field that are used worldwide by other regulatory agencies.

Since 1962, the key elements of product safety and efficacy have not changed, although the agency's level of participation, collaboration, and transparency has

TABLE 12.1-2. Major Differences that Impact the Regulation of Small Products versus Biologicals versus Biotech Products

Activity or issue	Small molecules	Biologicals	Biotech products
Control of starting materials	Generally purified and well-characterized chemicals	Most of culture media for fermentation processes are not totally synthetic. Use of animal-derived additives (fetal calf serum) is requested	Requirements for: Baseline data on the host and the gene (vector) used for production; stability of the host-vector expression system under storage and recovery conditions
Control of the manufacturing process	In general, well-established procedures are available for synthesis and purification of drugs and medicines	Great diversity of production and purification procedures, depending on strain of origin. Procedures developed case by case	Great diversity of production processes depending on the host and gene used. Requirements for control at genetic, post-transcriptional, post-translational level or during production and purification
Quality control tests	Well-established qualitative and quantitative control tests are available to measure the activity of medicines and drugs. Mainly required for final product	Difficulties in the evaluation of biological activity. In many cases, “in process” quality control tests are requested to ensure the safety and effectiveness of the final product. It is very important that the correlation of biological activity with efficacy is shown in clinical trials. Need to show absence of potentially hazardous contaminants from animal origin, cell substrates, or additives	Similar to biologicals, “in process” quality control tests are requested to ensure the safety and effectiveness of the product. Need to show absence of potentially hazardous contaminants mainly oncogenic DNA

increased as demonstrated with review goal dates, meetings with industry, guidance documents, and public and private partnerships. Today, according to FDA estimates, 10,510 approved drugs and more than 100,000 over-the-counter drugs are on the market [15].

As discussed by Ray and Stein [16], "the current regulatory process does not have systematic provisions for obtaining important data needed to guide clinical practice. Planned data collection happens almost exclusively during pre-marketing testing. The FDA approves medications on the basis of studies of limited duration that include relatively small numbers of patients who are often healthier than the target populations for the new drug. Although many important effects of a new medication almost certainly will be unknown at the time of licensing, there are no systematic provisions for post-marketing studies."

This problem is common for regulatory agencies around the world. The lack of information presented by manufacturers regarding the safety during the use by populations at large, the identification of the best indicators for efficacy, and the differentiation that manufacturers try to obtain between products with the same active ingredient, frequently make the regulation function difficult to perform. In addition, in developing countries, the lack of expertise in the different areas of regulation, particularly on clinical trial evaluation and interpretation of statistical results, increases the high uncertainty of the regulatory agencies' results.

12.1.3.2 European Medicines Agency (EMEA)

The European Medicines Agency (EMEA) is a decentralized body of the European Union created with the objective to harmonize regulatory activities in Europe. EMEA began its activities in 1995, when the European system for authorizing medicinal products was introduced, providing for a centralized and a mutual recognition procedure. Its main responsibility is the protection and promotion of public and animal health through the evaluation and supervision of medicines for human and veterinary use.

Before 1995, the legal framework in Europe for drugs was 25 independent national regulatory authorities and thus 25 parallel national review processes, with the same number of independent marketing authorizations. The consequence was poor resource utilization, divergent scientific opinions, and confusion by physicians, nurses, and health workers in general when decisions had to be made. At the present time, EMEA coordinates the evaluation and supervision of medicinal products throughout the European Union. The Agency brings together the scientific expertise of the 25 European Union Member States in a network of 42 national competent authorities. It cooperates closely with the international partners, reinforcing the European Union contribution to global harmonization [17].

At the beginning, the EMEA set up two procedures for product authorization in Europe, the centralized and decentralized procedures.

The centralized procedure is as follows [17]:

- submission of the marketing authorization application to EMEA;
- a unique evaluation is carried out through the Committee for Medicinal Products for Human Use (CHMP);

- if the committee concludes that the product has proven its quality, safety, and efficacy, it adopts a positive opinion; and
- the positive opinion is sent to the commission to be transformed into a single market authorization valid for the whole of the European Union.

The decentralized procedure establishes a mutual recognition between Member States. Briefly, this procedure is based on:

- a marketing license application is submitted to one Member State;
- if the national regulatory authority concludes that the product has proven its quality, safety, and efficacy, it grants a marketing authorization to the product; and
- the marketing authorization is extended to one or more additional Member States.

Today, EMEA uses both procedures, but is primarily involved in the centralized procedure [17]. The regulation 2309/93 has defined a mandatory centralized procedure for medicinal products developed by means of one of the following biotechnological processes: recombinant DNA, controlled expression of genes coding, hybridoma, and monoclonal antibody methods. In addition, after 2005, the regulation establishes the mandatory centralized procedure for medicinal products containing new active substances for AIDS, cancer, diabetes, and neurodegenerative diseases, including orphan designated medicinal products. The regulation still allows the mutual recognition procedure for generic centralized products or for medicinal products with a significant therapeutic benefit, products of scientific or technical innovation, or products answering the interest of patients or animal health at the community level.

The fact that more and more products are being included in the mandatory centralized procedure is indicative of a general reliance on this procedure more than on the mutual recognition procedure; it can also reflect that not all national regulatory authorities have developed the same regulatory capabilities to authorize the marketing of new products for the whole European Community.

Although European countries have faced many challenges in the establishment of regulatory activities of the agency, mainly because the diverse conflicting priorities between the Member States, the centralized procedure has generated harmonization in the scientific opinion in Europe, getting one marketing authorization valid in the European Community, one common name, and, most important for the impact on health professionals and users (potentially 370 million), one common product information.

After 10 years of been established, EMEA is a good example of harmonization, with both centralized and mutual recognition procedures, that can be extrapolated to other regions of the world, mainly in the developing world where the few countries that have developed strong regulatory systems can share technical knowledge and expertise in the different areas of regulations with those countries in the corresponding regions with limited resources to the benefit of the whole region.

12.1.3.3 International Committee for Harmonization (ICH)

The ICH is not a regulatory agency, it is a unique project that brings together the regulatory authorities of Europe, Japan, and the United States and experts from the pharmaceutical industry in the three regions to discuss scientific and technical aspects of product registration.

The purpose is to make recommendations on ways to achieve greater harmonization in the interpretation and application of technical guidelines and requirements for product registration to reduce or obviate the need to duplicate the testing carried out during the research and development of new medicines. The objective of such harmonization is a more economical use of human, animal, and material resources and the elimination of unnecessary delay in the global development and availability of new medicines while maintaining safeguards on quality, safety, and efficacy and meeting regulatory obligations to protect public health. The guidelines established by ICH are followed by many countries around the world, sometimes as the only guide available to establish harmonized standards on quality, safety, and efficacy for their products. However, its impact in classic vaccine regulation is limited, being more developed regarding biotechnological products.

Six founding members of ICH are directly involved in the decision-making process. They represent the regulatory bodies and the industry in the European Union, Japan, and the United States. They are the European Commission and the European Federation of Pharmaceutical Industries and Associations (EFPIA) in Europe; the Ministry of Health Labor and Welfare and the Japan Pharmaceutical Manufacturers Association (JPMA) in Japan; the FDA and the Pharmaceutical Research and Manufacturers of America (PhRMA); and a group of observers including WHO, The European Free Trade Area (EFTA represented at ICH by Swissmedic Switzerland), and Canada represented by Health Canada.

12.1.4 GLOBAL ROLE OF WHO IN DRUGS AND BIOLOGICALS REGULATION

Although WHO is not a regulatory agency, it provides guidelines for acceptability of products taking in consideration the specifications needed in regions where the regulatory institutions have not fully developed. With the responsibility to guarantee the quality, safety, and efficacy of products all around the world, WHO develops guidelines joining efforts from experts in the most diverse regions, getting a generalized opinion about the best way to establish technical guidelines. WHO provides relevant expertise ant technical assistance through such activities as guidelines development; workshops and training courses; coordination and promotion of anti-counterfeiting measures; prequalification of medicines for priority diseases; pharmacovigilance for global medicine safety, regulatory, and other information exchange; and review of narcotic and psychotropic substances for scheduling within the 1961 Convention on Narcotic Drugs and the 1971 Convention on Psychotropic Substances.

12.1.4.1 WHO Procedure for Assessing Drug Regulatory Authorities

As WHO establishes [9], the overall objective of a DRA is to ensure that medicinal products (pharmaceuticals, biologicals including vaccines, blood products, and other biologicals) are of acceptable quality, safety, and efficacy and that they are manufactured and distributed in ways that ensure their quality until they reach the patient/consumer and their commercial promotion is accurate.

According to WHO [9], the main functions of a DRA are as follows:

- registration (licensing) of products,
- inspection and licensing of manufacturers,
- inspection and licensing of distributors,
- post-marketing surveillance, and
- regulation of claims that can be made for commercial promotion of products as well as authorization of clinical trials.

A DRA can be effective only if it has the following:

- a legal basis for all its functions in legislation and regulations,
- sufficient human and financial resources,
- access to appropriate scientific expertise, and
- access to a quality control laboratory.

Particularly for vaccines and biologicals, in comparison with medicines, because the inherent variability of these products caused by the biological nature of their starting materials, their manufacturing processes, and their test methods, WHO has identified six essential regulatory functions to evaluate a regulatory system as effective [9]. These functions are as follows:

- a published set of clear requirements for licensing,
- surveillance of vaccine field performance (safety and efficacy),
- system of lot release,
- use of laboratory when needed,
- regular inspections of manufacturer for Good Manufacturing Practices compliance, and
- evaluation of clinical performance in clinical trials.

An extra function not included in the six established by WHO must be considered during the evaluation of regulatory authority for vaccines. This function must include the distribution and vaccine's shipment mechanisms; it must be able to guarantee the delivery of vaccines to all points of use with an acceptable level of quality.

Finally, research in the regulatory agencies, looking to have experts in each function updated in all relevant aspects involved in the regulation activities, is an aspect that must be considered during the implementation of regulatory systems in the countries.

The difference of the regulatory activities that WHO performs in comparison with the activities of other regulatory institutions is the impact that WHO guidelines, norms, and procedures have all over the world. The documents are developed looking for consensus with globally recognized experts. They are a reflection of the activities that are being developed in the world, and it facilitates their implementation.

12.1.5 OTHER INITIATIVES FOR HARMONIZED REGULATION

The Pan American Network for Drug Regulatory Harmonization (PANDRHA) is an initiative to support the process of drug regulatory harmonization throughout the Americas, with the mission to promote drug regulatory harmonization for all aspects of quality, safety, and efficacy of pharmaceutical products as a contribution to the quality of life and health care of the citizens of the member countries of the Americas. It includes the participation of all regulatory authorities in the region along with representatives of academia, industries, and other experts. The main forum for developing the PANDRHA activities is the Pan-American Conference on Drug Regulatory Harmonization, where there is also participation from other organizations such as the Caribbean Common Market (CARICOM), the Southern Countries Common Market (Mercado Comun del Sur, MERCOSUR), the North American Free Trade Agreement (NAFTA), and the Central American Integration System (Sistema de Integracion Centro Americano, SICA) and constitutes a way to disseminate the decision on drug regulatory harmonization of global initiatives such as the ICH. The network functions through working groups assigned to different areas including: good manufacturing practices, bioequivalence, good clinical practices, combat to drug counterfeiting, pharmacopoeia, drug classification, medicinal plants, pharmacovigilance, good laboratory practices, vaccines, and drug registration.

Other initiatives around the world exist that are incorporating, among many objectives, the harmonization of drug regulation. Although not all of these organizations have been developed exclusively for regulation, such initiatives can be found in the Association of South-East Asian Nations (ASEAN) [18], Andean Community of Nations (CAN), the Collaboration Agreement of Drug Regulatory Authorities in European Union Associated Countries (CADREAC), the European Union, the Gulf Central Committee for Drug Registration (GCC-DR), the Southern Common Market (MERCOSUR), and the Southern African Development Community (SADC).

12.1.6 FUTURE PERSPECTIVE OF REGULATION

Regulators must be prepared to face challenges resulting from the fast scientific, technological, and methodological development of drugs, biologicals, and biotechnological products. This effort will require that DRAs establish stronger alliances with the research community, universities, and academia in general so as to have available experts in all fields. Still, much remains to be done in the development of clinical trials with products derived from new technologies, mainly focusing on

those that target the immune system's natural control mechanisms, including therapeutic monoclonal antibodies, interleukins, and some vaccine's adjuvant, to avoid the recent disastrous example in Europe with the use of a monoclonal antibody [10].

Regulatory authorities have been receiving important pressure from industry to decrease approval times. Some agencies are trying to reduce approval times by making changes to the review system such as: improving communication and consultation by applicants [19], which leads to better preparation of dossiers; eliminating unnecessary administrative time loss; interacting with similar regulatory agencies; and increasing the number of employed reviewers with appropriate expertise. The latter has impacted through the accumulation of experience, know-how, and proficiency within the regulatory agency. However, it must be clear that from the point of view of society and improving public health, approval times alone are not the only goal. It is more critical to make the best decision to secure safety, efficacy, and effectiveness of the new drugs.

At the same time, for product developers, the recommendation to integrate regulation in the very early stages of their research and development work exist. This strategy can contribute as a success factor instead of a bottleneck at the later stages of licensing and market authorization. Incorporating a regulatory perspective will have a positive effect on the cost and time frame of product development. Furthermore, having a good understanding of regulatory requirements will also assist the developer in identifying nonviable projects at an early stage, thus reducing the risk of the loss of investment.

Regulation of drugs must balance the extreme efforts to regulate and control the presence of adverse effects while trying to address health care needs of the population in general. New products are costly to develop and produce. To guarantee their safety, specifically for possible rare events associated to its use, the need of designing and conducting large clinical trials to show statistical significance exist. This cost will be included in the product's price. As a recent example, in the vaccine area, large clinical trials had to be conducted to demonstrate safety for two new rotavirus vaccines. Over 60,000 children were involved in trials for each vaccine. These regulatory requirements add not only onto the cost of development but also onto the timing for the products to access the markets.

Post-marketing surveillance activities follow programs based in passive collection of spontaneous reports for ensuring safety using voluntary reporting of adverse reactions from physicians and other health workers is a common practice in developed countries, in many cases without or with poor participation from the regulatory agencies. This procedure shows deficiencies such as underreporting, difficulty in calculating rates because incomplete numerator data along with unreliable denominators, and limited ability to establish cause and effect [20, 21].

Recent withdrawals from the market of high-profile drugs are more often being carried out by the manufacturer who proceeds to withdraw the product before the regulatory agency does so, in principle to protect the public from further harm, but, at the same time, the manufacturer avoids the drastic consequences of penalties that the law establishes if the recall is done by the regulatory agency. Although much has been done to strengthen quality and safety during the development and production processes, post-marketing surveillance involvement by the regulatory authorities is still a pending issue.

The strongest regulatory agencies are still looking for reforms on drug regulation [16, 22] focused to improve the current regulatory process. Modifications proposed for the regulation in developed countries generally are focused on solving the particular problems in terms of the country or region that is involved, and, in general, are not applicable to regulation in developing countries. To be able to address the enormous challenges faced by regulation of new products, regulatory agencies in developing countries will have to urgently strengthen their networks and establish new harmonized regulatory and methodological procedures.

12.2.1 INTRODUCTION

Intellectual property laws and regulations govern the creation, use, and exploitation of intellectual activity in the industrial, scientific, literary, or artistic fields within national boundaries [1, 2]. They establish property protection over intangible items such as inventions, signs, and information. In theory, intellectual property protection provides incentives for the production and distribution of new knowledge that may benefit society by establishing a mechanism for the creator of that knowledge to obtain compensation for the use of protected works.

Intellectual property laws and regulations are designed to manage the competing interests of those who produce new knowledge, those who want to make use of new knowledge, and those who want simply to buy the products and services made through the use of new knowledge. It is becoming increasingly difficult to balance these competing desires in light of rapid advances in fields such as biotechnology and information technology. More broadly, designing sets of laws and regulations, along with the governmental institutions and practices that administer them in keeping with business practices and public interests, is becoming increasingly difficult, which is especially so given the lack of empirical data on how the entire intellectual property system works for innovation in emerging technological fields [3, 4]. The central issue is the appropriate balance to be struck between setting intellectual property rights that encourage and reward innovators while still permitting affordable and ready access to the public and other users. The latter concern is paramount in the context of health biotechnology.

This chapter provides an overview of intellectual property rights available for biotechnological innovation and the national and international laws and regulations governing those rights. The focus is on patent rights, the most widely sought intellectual property right in the field of biotechnology. We compare the national patent laws of the United States, Europe, Japan, and Canada.

Unfortunately, most patent laws and regulations were designed for inanimate matter. Significant difficulties develop in the application of arcane laws to technological innovation involving biological material, especially self-replicating life forms. Patent rights have become a flash point for many of the social and ethical concerns that derive in the context of biotechnology. Although the controversy centers on patenting of biotechnological innovation, the underlying concern is the increasing commercialization of biotechnological research. We conclude with widely raised policy reforms designed to address issues of balance, access, and public support for research and innovation in health biotechnology.

12.2.2 OVERVIEW OF INTELLECTUAL PROPERTY RIGHTS FOR BIOTECHNOLOGY

12.2.2.1 Patents

Patents, the focus of this chapter, are the most prevalent form of intellectual property right (IPR) sought for biotechnological innovation [5]. Patent rights are nega-

tive rights because they confer upon the holder the right to prevent others from selling, using, importing, and making the invention for a set period of time [6–8]. In effect, patent rights grant a holder exclusive control over an invention—a monopoly right. This broad exclusionary right is an important and valuable tool for industry as it can translate into the ability to limit entry by others into a market sector and to set the market price for an invention.

Patent rights may be granted over several aspects of an invention including the product itself and the process to manufacture the product. Several formal steps exist that must be completed to obtain a patent. The two most important are: (1) submission of a patent application, drafted to meet legislated format and content requirements; and (2) a successful review of the patent application by a national patent office based on the patent criteria. The most crucial aspect of the patent application is the claims; only those elements of the invention included in the claims will be granted patent protection. Nonclaimed elements will not be granted patent protection [9, 10]. The patent criteria, with some variation between national patent systems, are that the invention be new, useful, and involve an inventive step. An invention that fails to meet any of the criteria, or any other requirements set out in national patent laws, will not be granted a patent.

As patent rights are national in scope, inventors who want to secure patent rights in more than one nation must submit a patent application and comply with the patent legislation in each country individually. Patent rights granted by one country will not be respected in any other country. For example, if an inventor is granted a patent in the United States but fails to seek patent protection in Canada, the inventor's patent rights will end at the U.S./Canadian border and Canadians will be free to make use of the invention. Moreover, if an inventor is granted a first patent in the United States and a second patent in Canada for the same invention, the U.S. legislation will govern the use of the patent rights granted in the United States and the Canadian legislation will govern the use of the patent rights granted in Canada. Generally, no overlap of patent legislation exists between nations.

The modern version of patent rights has evolved and changed significantly from its historical role. For example, in Europe, patents were originally granted as letters patent, which were intended to reward inventors for their industrial activities. The original letters patent were different from today's patents in that they granted privileges rather than property rights. The sovereign had the right to grant a privilege to an inventor, and in so doing, encourage the development of new industries within a nation [11]. Letters patent were not necessarily granted for inventions that were absolutely new but for those that were newly introduced to the nation [11]. Copying a foreign invention and introducing it to a new country was an entirely permissible and desired outcome. For example, a patent was granted in France by the French crown "for glassware according to the manner of Venice" [11], although it was common knowledge that the glassware technique was not novel but was previously practiced in Venice. The fact that it was new to France was sufficient to garner a patent right.

The modern patent system is largely a creation of the nineteenth century and is popularly understood to respond to the argument that inventors have a natural, inherent property right in their inventions that the state has an obligation to protect [11]. This argument is directly related to the realization that innovation can repre-

sent significant commercial value. Accordingly, the state agrees to protect the inventor's natural property right in an innovation, but considers public benefit by requiring the inventor to disclose publicly the details of the invention. Disclosure allows for the generation and circulation of technical information, which is known as the "information function" of the patent system [2].

The second main justification for patents is that they provide an incentive for the production of new innovation and improvements on old innovations. The key incentive is the 20-year patent term. The establishment of 20 years as a firm and unbending time period during which inventions may be exploited solely by the inventor has many benefits. In particular, it offers certainty in the length of the right, a major factor in attracting investment for research and development.

Modern patent legislation, which emerged in the United States and the United Kingdom in the 1970s, formalized the information function of patent law. It requires an inventor to describe the invention in such a way that it can be put into practice by a person skilled in the art. Modern-day patent law also rationalizes the procedural component of patent examination by establishing set criteria that must be met for an invention to merit a grant of patent rights [11]. The outcome of these changes is that skilled examiners are now required to evaluate whether a patent application is complete and ultimately whether an invention is patentable.

12.2.2.2 Other Intellectual Property Rights

A number of other forms of IPRs, besides patent rights, may also apply to protect elements of biotechnological innovations. Here, we present a brief overview of these IPRs, which include trade secret, plant breeders' rights, copyright, database rights, and trade mark.

Trade Secret. Trade secret grants a right over information that is treated as confidential by a corporation or other organization. The right translates into the ability to sue for a breach of confidentiality if someone, for example, a key employee, discloses confidential information to a competitor. The wronged party is entitled to a remedy usually in the form of monetary compensation for the harm caused by the wrongful disclosure of the secret information.

Trade secret provides a necessary supplement to other IPRs because it can be used to protect technical information and know how during research, development, and testing stages of a biotechnology project. Unlike other IPRs, trade secret is rarely rooted in statute, but is usually established by the collective history of judgments from litigated cases known as jurisprudence [12, 13].

Trade secret protection is acknowledged when information is treated as confidential, which usually means those to whom it is properly disclosed realize that it is secret and agree to protect the confidentiality of the information. In many cases, companies establish secrecy through the use of confidentiality agreements with employees and other customers or partners. As the right relies on absolute secrecy, trade secret protection is fragile; the right can be lost immediately upon nonconfidential disclosure of the secret information. Companies therefore usually opt to seek patent protection once a product is introduced to the market and only rely on trade secret during the research and development stages. It is particularly true for

innovations that can be easily reversed-engineered. Such inventions cannot be adequately protected by way of trade secret because they are subject to copying.

However, in some cases, trade secret protection may constitute a competitive advantage by sustaining marketplace confidentiality [14]. If the technical details of an innovation remain secret, it is often difficult for competitors to recreate a product, invent around it, or improve on it, especially if the innovation is complex. These latter types of activities are commonly known as competitor piggy-backing. If adequate confidentiality measures are put in place and enforced, trade secret can be an effective method of protecting information from the public and securing a market sector monopoly [15].

Plant Breeders' Rights. Generally, plant breeders' rights are granted to a person who breeds a new plant variety and for this reason are helpful tools for many biotechnology projects. Like patents, plant breeders' rights require a formal application and review process, which is undertaken nationally. The strength of plant breeders' rights varies greatly between nations. The rights granted may extend to the plant, as in the United States where plant rights are a subset of the patent system, or may only include the propagating material and not the plant, as set out by Canadian legislation. It is argued that strong plant breeders' rights negatively affect farmers because plant breeders may exercise their right to limit the subsequent uses of their plants. For example, a farmer who grows a crop from protected seeds may be prevented from saving the seeds from that crop for the purpose of cultivating a subsequent crop [16, 17]. Concerns over farmers' rights vary globally resulting in an international collection of plant breeders' rights statutes that are inconsistent in strength and scope.

Copyright. Copyright regulates the creation and use of a range of original works such as books, songs, films, and computer programs. Copyright protects the expression of an idea, not the idea itself. Thus, it protects the work that is produced but, unlike a patent, cannot prevent the making, use, or sale of an identical work by an independent originator [18]. Copyright differs from patent and trade mark in another important way—it arises automatically and confers upon the owner the right to prohibit copying or performance of a work. For example, a researcher has a copyright in the scientific papers they seek to publish, although he or she generally transfers or assigns those rights to the journal before publication. Copyright is granted by national statutes for the lifetime of the author plus anywhere from 50 to 70 years after the death of the author, depending on the country. However, because of international treaties, the national foundation of copyright law is less oppressive than for patent rights. Copyright can cross borders—a work created in the United States will be acknowledged as a copyright protected work in Canada as well [19]. Copyright is of limited use for the products and processes of biotechnology, even in the area of collections of biological data, gene sequences, and plants.

Database & Material Deposit Rights. One emerging area of biotechnology that is testing the limits of intellectual property regimes is the production of academic data collections, especially biological and genetic data linked to long-term health of the individuals who provided the data. Such databases require substantial

intellectual investment. Traditional IPRs, however, such as patents and copyright, do not protect mere collections of data. Indeed, the prevailing thought in legal discourse over IPRs and data is that data *per se* should not be protected based on the public nature of many large data collection efforts [20]. However, there may be need for some form of property right to prevent misappropriation and misuse of data. One such model exists, namely the European Database Directive, which was introduced in 1996 by the European Union. The directive vests an exclusive right in the producer of a database to grant permission to extract and reuse the contents of the database [11]. The debate about the appropriateness of database rights in the context of biological data is ongoing [20].

It should be noted that some national patent laws require the deposit of biological and genetic materials to supplement the disclosure of an invention. Materials are submitted to authorized depositaries that eventually find themselves in possession of a collection of biological samples. Biological material depositaries are governed at the international level by the Budapest Treaty on the International Recognition of the Deposit of Microorganisms for the Purpose of Patent [21], as established in 1977 (discussed in more detail below). The treaty and national patent rules cooperatively establish authorized depositories and sets rules for the deposit as well as the availability to the public of the material.

Trade Mark. National trade mark legislation grants protection for certain words or symbols, usually trade names such as Microsoft or pictures such as the Nike swoosh, when the words or symbols are used in connection with specific marketplace goods or services [2]. Trade mark holders are granted the right to prevent others from using the protected words or symbols to represent the same or similar goods or services. Generally, trade marks must be registered at a national office to be effective, although some jurisdictions acknowledge that a right can be established through consistent long-term use.

12.2.3 BIOTECHNOLOGY PATENTS, PUBLIC POLICY, PUBLIC OPINION, AND MORALITY

The patent system is traditionally viewed as a tool for promoting economic goals [22]. It is understood to work by encouraging the advancement of new industries, research and development, or innovation. In contrast, noneconomic factors such as health, human rights, environment, or ethics have historically been viewed as extrinsic to the activities regulated by the patent system or as undesirable side effects that require mitigation. Accordingly, patent law has been largely unconcerned with moral arguments. A few notable exceptions exist including medical treatments and inventions designed for purely criminal applications.

With the advent of the patenting of the products and processes of biotechnology, moral arguments have entered the patent arena with more force than ever, especially in Europe [23]. Indeed, the commercialization and patenting of biotechnological innovation has become a focal point for opposition to biotechnology *per se*. The core objection is that some applications of biotechnology, such as the genetic manipulation of higher organisms or embryonic stem cell research, are in them-

selves wrong because they are against God, nature, or human dignity. The patenting of human genes also draws special criticism as establishing property rights over the common heritage of humankind.

Intuitively, biotechnological inventions do not fit neatly into the customary model of patentable subject matter because the original law was developed for mechanical inventions. Two reasons why the patent system is not necessarily a neat fit with biological matter are the ability of living organisms to self-replicate, which has significant implications for the exclusive rights patents grant over the use and manufacture of a product, and because many biological products, such as genes, may be seen more as discoveries than as new inventions. But, despite the ill fit, patents have been issued over life forms since the mid-1800s and biological inventions have been patented since the 1970s [5]. That said, some forms of biotechnology remain unpatentable; for example, genes and gene fragments are not patentable in their natural state, but only in isolated form.

In the field of biotechnology, policy makers must achieve a delicate balance between the advancement of research and biomedical innovation and the many social, legal, and ethical challenges raised by this field of science. The latter, coupled with the fast pace of advances in biomedical research, makes it essential that there be an ongoing public review accompanied by appropriate legislative and regulatory responses [23]. Unfortunately, legislative and regulatory responses generally lag behind research and corresponding moral and ethical dilemmas. It is therefore necessary to keep law making and regulatory processes flexible and responsive to scientific advances, including those in the realm of IPRs.

There is considerable debate about the appropriateness of using the patent system to regulate innovation on the basis of public morality [3]. Those opposed state that the patent system is ethically neutral, concerning itself only with the technical requirements for patentability spelled out in national laws and influenced by international standards. Historically, patents are concerned primarily with economics and innovation while other regulatory mechanisms are both more flexible and better at optimizing health, safety, and environmental outcomes. However, others argue that the balance has shifted too far toward granting property rights over biotechnological innovation at the expense of the beneficial social outcomes of information diffusion and access to new innovation [3]. Globally, opposition to the patenting of living organisms, genes, and gene fragments may be viewed as broad opposition to the commercialization or commodification of biological matter [24]. Public unease may be augmented by distorted media reporting of sensitive issues, or these reports may merely reflect public perceptions. Either way, such reports may lead to a general public mistrust of government regulators and politicians [25].

Although such concerns may seem unfounded, it is not wise simply to discard public sentiment that opposes biotechnology. It is overly simplistic to state that public opinion, particularly public concern, is based on a combination of ignorance and misinformation. Proponents of genetic technologies and products use this argument to delegitimize public opposition. Media sensationalism is "blamed for amplifying and exploiting that public ignorance" [26]. Indeed, public opinion does not necessarily show a correlation between a level of education and support for biotechnology but depends, instead, on the segment of the public and on the specific genetic technology or product [25].

On the whole, polling studies have shown that the public is largely supportive of biomedical research [27], especially when that research is perceived to be independent of industry and conducted at publicly funded research institutions [24, 28]. Public support for agricultural biotechnology, on the other hand, is lower, especially in Europe, partly because the public has not been convinced of the utility of the applications of agricultural biotechnology, which translates into a higher level of risk tolerance by the public for health biotechnology. That said, the scientific community must be willing to accept that some research avenues are simply not acceptable to the majority of the public, and should potentially be reconsidered. Rather than blaming the media and other information conduits that are generally presenting a pro-science position, especially in the biomedical research, scientists need to demonstrate the utility of their research along with a fair assessment of the risk [29, 30].

In a democratic society, it is important to maintain public trust and confidence because the lay public can exert substantial influence on their public representatives who in turn fund or regulate scientific research and the use of science-based technologies [27]. One substantial set of studies estimates that public opinion, as measured by polling, becomes functioning law about two-thirds of the time [31]. Public representatives may also ban or criminalize scientific research that is perceived as immoral, dangerous, or unjust. Indeed, such steps have been taken in Canada with the recent enactment of the *Assisted Human Reproduction Act*, which has criminalized a range of research endeavors such as human cloning, somatic cell nuclear transfer, and germ-line alteration [32].

One factor that may significantly influence public opinion and public support for health biotechnology is the increasing trend toward commercialization of publicly funded research. Many major public funding agencies and research institutions, including publicly funded universities, now set commercialization of research activities as an explicit goal. Indeed, the rise of modern biotechnology is often explained by two events: First, the United States Supreme Court allowed the first patent of a genetically modified bacterium in 1980 [33], giving industry an incentive to invest and engage in biotechnological research; and second, the United States Congress passed the Bayh–Dole Act in 1980, providing universities with the right to obtain patents in the results of federally funded research and encouraging universities to transfer technology to industry. The success of technology transfer between universities and industry is measured by the annual survey of the Association of University Technology Managers [34].

However, evidence exists that the public is becoming increasingly suspicious of the ties between industry and researchers, at a time when academic biomedical research receives unprecedented levels of funding from industry and research institutions are increasingly focused on policies aimed at commercialization [35–38]. Survey data show that a perceived connection with commercial forces has an adverse impact on the perceived credibility of researchers. If there is a perception that funding comes from less independent sources, credibility deteriorates. For example, one recent survey of the Canadian and U.S. public on biotechnology issues found that publicly funded university researchers are highly trusted and credible. Only the World Health Organization (WHO) and peer-reviewed scientific journals were rated higher. In contrast, scientists working for biotechnology com-

panies and university researchers funded by industry were not considered credible [39]. A 2000 focus group study done on behalf of the Canadian government came to a similar conclusion, finding that "many people say university scientists are much more credible than other scientists because it is assumed they are free from funding pressures and therefore more 'independent'" [40].

Some of the most highly publicized controversies in science policy have been a direct result of the growing ties between biomedical science and commerce. For example, in the United States, the death of Jesse Gelsinger raised concerns about whether financial considerations had had an inappropriate impact on the running of the gene therapy research trial [41]. Other concerns about commercialization are directly related to the patenting process, the Myriad Genetics controversy being the most obvious. As described by Professor Caulfield, "the decision by Myriad, a Utah based company, to enforce its patents over the BRCA1/2 genes was, arguably, the most significant recent catalyst of national policy-making activity, media coverage, and public outrage on the topic of gene patents. In 2001, the company sent a 'cease-and-desist' letter to most Canadian provinces that used the test as part of the publicly funded health care system. The case was viewed, rightly or not, as a harbinger of the policy challenges created by gene patents" [42].

Other high-profile biotechnology patent stories exist, such as Harvard College's attempts to patent a mouse, genetically modified to be susceptible to cancer, known as the "onco-mouse." A patent was granted both for the method of making the mouse and the mouse itself by the United States Patent and Trademark Office (USPTO) in 1989, but the application for the mouse patent was initially rejected by the European Patent Office (EPO). Unlike the United States, Europe allows for the rejection of patents considered to be contrary to public morality or the *ordre public*. The patent was eventually granted, but the EPO developed a statement on the patenting of transgenic animals. The analysis developed by the EPO requires an evaluation of the risks, including moral risks, and benefits of a new technology, with the recognition that every new technology is accompanied by some risk. In the case of the onco-mouse, the benefits to humankind of the mouse model for cancer research outweighed the public morality concerns about protecting the environment and the suffering of the experimental animals. The risks were further allayed by the lack of research alternatives to mouse models and the additional efficiency of using the onco-mouse in reducing the number of mice required for experimentation. The primary importance of this analysis is that biotechnology is to be treated the same as any other new technology in evaluating risks and benefits, and genetically modified organisms are not excluded out of hand from patentability on the basis of immorality.

The Canadian courts have taken a different stance on the patentability of higher life forms in a number of high-profile cases. In *Harvard College v. Canada (Commissioner of Patents)*, the Supreme Court of Canada (SCC), in a slim majority, concluded that the onco-mouse was not patentable subject matter under Canadian patent law. The SCC held that the drafters of the Patent Act had not intended higher life forms to fit within the definition of patentable subject matter [43]. To confuse the issue further, the patentability of higher life forms was addressed again only two years later in the 2004 case of *Monsanto Canada Inc. v. Schmeiser* [44]. In that case, a farmer had grown a crop of Monsanto's genetically modified canola

without authorization from Monsanto. In its patent, Monsanto had claimed all products and processes related to the genetically modified canola except for the canola plant itself, because higher life forms are not patentable in Canada. The SCC did not explicitly overturn its decision that higher life forms are not patentable, but ruled that if a nonclaimed element, in this case the canola plant, is determined to have an "important role in production," then patent protection will extend to that element as well as the claimed elements [44]. In other words, having a patent over a gene inserted into a higher life form grants patent protection over the higher life form as a whole, even though technically the higher life form cannot be claimed as an invention in Canada.

The effect of the decision was to grant patent protection to a nonpatentable plant (a higher life form) because its bioengineered cells are patentable [44]. In application, this doctrine means that patent scope can be understood to cover both the claimed invention as well as any broader structure that encapsulates or incorporates the invention [44]. These Canadian decisions have been referred to as "the most significant decisions in the area of biotech patent law anywhere in the world," and the esteem attributed to them makes their inconsistencies that much more disconcerting [45].

These examples in Canada and Europe have generated a high degree of public and policy-making interest. Indeed, in these regions, a high level of public discomfort exists with the patenting of higher life forms and human genes, which is augmented by the morally contentious nature of much biotechnology research, for example, the ongoing debates about embryonic stem cell research. In controversial areas, public trust is fragile. Professor Caulfield summarizes the dilemma as follows: "The public may be setting aside moral concerns based on the belief that the research is being done in the public's interest. If the public comes to believe that commercial interests are dominating the research process, trust could easily be lost. And, it should not be forgotten that many in the public are already suspicious of the motivations behind biotechnology innovation" [42].

In addition, numerous other policy challenges exist that stem back to the social benefit side of the patent bargain. Significant concerns exist that a commercialization agenda for biomedical research will skew the research agenda away from basic research and that new biotechnological innovations will drive up the cost of health care in publicly funded systems, such as Europe and Canada, and increase the disparity between patients or regions that can afford new technologies and those who cannot. These concerns may partially be addressed by a well-formulated and well-balanced patent system and government regulation.

12.2.4 INTERNATIONAL INITIATIVES

As a result of the national scope of many intellectual property laws, problems sometimes develop where inventions, such as biopharmaceuticals, are traded internationally. International trade can bring divergent national legislation into conflict. Countries that are net exporters of innovations protected by IPRs, such as the United States, the European Union, and Japan, advocate strongly in the international arena for the strengthening of national intellectual property laws and international harmonization of these laws [46]. Although international harmonization

has not been achieved, intercountry trade has lead to a number of international initiatives that significantly impact the intersection between IPRs and biotechnological innovation.

Here, we review the main international treaties relating to either IPRs or biotechnology and the institutions that administer them. The treaties range from attempts to coordinate the filing of patents at an international level to guidelines for the sharing of benefits derived from biologic resources. Depending on the form of a biotechnological innovation, several of these treaties may be applicable to a single invention. Thus, simultaneous compliance with several treaties may be required. As the treaties have not been drafted to reflect and consider each other, but do in some instances overlap, compliance can be difficult in some areas of biotechnological research and commercialization.

12.2.4.1 The World Trade Organization (WTO)

The function of the WTO, to establish trade standards at an international level, is particularly important in today's era of globalization. The WTO engages in "analysis and debate about the relationship between international trade and investment, and its implications for economic growth and development" [47]. It promotes trade and eliminates inefficiencies [47] by imposing obligations on members to accept common rules and arbitration methods. The WTO addresses trade issues in a number of different categories, one of which is the protection of IPRs and trade.

The WTO membership includes countries at varying levels of development, and from divergent political and legal systems, which are differentially impacted by globalization. This breadth of input lends credibility to both the organization and the standards created by WTO membership [48]. Despite criticism, the membership of the WTO causes its principles to be adopted widely around the world.

Trade-Related Aspects of Intellectual Property Rights (TRIPs). TRIPs, the most influential multilateral agreement on IPRs, was created by the WTO at its 1986–1994 Uruguay Round of negotiations [49]. TRIPs regulates trade exchanges through uniform transnational rules and encompasses issues related to biotechnology within its framework. The TRIPs negotiations were instigated by the realization in the 1970s of the negative effect of counterfeiting of trade-marked products on international trade [50]. Although there was opposition to the WTO assuming a role in global intellectual property issues, a move that was thought to usurp the authority of the World Intellectual Property Organization (WIPO), a General Agreement on Tariffs and Trade decision of January 28, 1987 established guidelines for the negotiation process that eventually produced TRIPs [50].

The official goal of TRIPs is to "reduce distortions and impediments to international trade" posed by divergent national IPRs [49]. It presents a common minimum standard of IPRs for the adoption within national intellectual property laws of each WTO member country. The common standards are enforced by the WTO, which adjudicates disagreements between nations [50]. Each WTO member country retains the right to legislate more stringent IPR regimes [50].

TRIPs sets standards for many forms of IPRs—copyright, plant breeders' rights, and trade marks—but the provisions relevant to patent rights are particularly significant for biotechnological innovations. To be eligible for patent protection,

TRIPs requires an invention to be new, to have an industrial application, and to have an inventive step [49]. Inventions that meet these criteria are protected against use, offer for sale, and sale and importation by anyone who is not the rights-holder for a minimum term of 20 years [49]. Moreover, TRIPs requires nations to grant patent rights for all fields of technology without discrimination and for both inventive products and processes [49].

Despite the harmonizing nature of TRIPs, a number of controversies have developed over the implementation of provisions related to biotechnological innovation and higher life forms. Article 27.3(b) states that "plants and animals other than microorganisms, and essentially biological processes for the production of plants or animals other than non-biological and microbiological processes" may be excluded from patent protection. However, plant varieties must be protected within national legislation through patents, *sui generis* protection, or a combination of both. Patents are well understood and *sui generis* protection is commonly provided as plant variety protection or plant breeders' rights legislation, compliant with UPOV, discussed below. The correct blend of these methods of protection has been subject to varying interpretations, particularly in the field of biotechnological invention. The issue of integrating the protection of traditional knowledge about genetic resources and benefit sharing with traditional knowledge holders and plant variety protection is particularly controversial.

Another controversial aspect of TRIPs is the compulsory licensing provisions in Article 31, which allow a government to override the rights to exclusive use and manufacture of a product or process granted by a patent. National IPR regimes may allow for compulsory licensing under limited circumstances. Conditions for granting a compulsory license include a national emergency and public noncommercial use for public health, national defense, or environmental protection. The provisions of a compulsory license may likewise be limited by national IPR laws. For example, negotiations with the holder of patent rights must start before the granting of a license, the scope and duration of the license must be limited, the rights holder must be compensated, and the license must be nonexclusive. However, these strictures have not quelled the debate, which is fueled by the characterization of the compulsory license issue as a struggle between developed nations, who support very limited compulsory licensing, and developing nations, who are interested in the extension of broad compulsory licensing rights to combat public health crises such as the HIV/AIDS pandemic [50].

TRIPs does address some concerns specific to developing countries. Article 66 exempts developing countries from compliance with most provisions of TRIPs for a term of 10 years because of "their economic, financial, and administrative constraints, and their need for flexibility to create a viable technological base" [49]. A further extension may be granted on request. Moreover, TRIPs admonishes developed nations to engage in technology transfer initiatives with less-developed countries to facilitate the establishment of a sound and viable technological base in those countries [49].

TRIPs also establishes minimum standards and definitions for undisclosed information or trade secrets.

Sanitary and Phytosanitary Agreement (SPS). The SPS is a multilateral mechanism formulated to protect human, animal, and plant health in WTO member

countries. The SPS details how governments can apply food safety and animal and plant health measures. These measures are based on standards articulated by a number of international organizations including the food safety standards formulated by Codex Alimentarius Commission, the animal health and disease control measures drafted by the International Office of Epizootics, and the steps for plant quarantine and phytosanitary certificate regulation articulated by the International Plant Protection Convention. SPS measures are based on a risk assessment—risks should be evaluated and the measures adopted should be commensurate with the risk. The SPS recognizes the sovereignty of nations and acknowledges that a country may maintain measures that are stricter than the SPS measures. Each nation has a right to determine its appropriate level of risk. Set standards will only be questioned if they result in discrimination or a disguised restriction on trade [51].

12.2.4.2 World Intellectual Property Office (WIPO)

WIPO is a specialized agency of the United Nations (UN) system of organizations, with a mandate to administer intellectual property matters recognized by the member states of the UN [52]. It administers 23 treaties and various programs that aim to harmonize national intellectual property legislation and procedures, provide services for international applications for industrial property rights, exchange intellectual property information, provide legal and technical assistance to developing and other countries, facilitate the resolution of private intellectual property disputes, and marshal information technology as a tool for storing, accessing, and using valuable intellectual property information.

Patent Cooperation Treaty (PCT). The Patent Cooperation Treaty (PCT) makes it possible to reserve the right to seek patent protection for an invention simultaneously in each of a large number of countries by filing an "international" patent application [53]. Such an application may be filed by anyone who is a national or resident of a contracting state. It may be filed in the applicant's national or regional patent office. Copies of a filed application are then forwarded to the International Bureau and an International Search Authority for processing and review.

The aim of the PCT system is to consolidate and streamline patenting procedures. A PCT application reserves the right to file patent applications in all of the member states at a future date. It gives the applicant more time to submit patent applications to national offices than is allotted under national patent systems. This additional period of time (up to 42 months depending on the residence of the applicant and whether a priority filing has been made) gives an applicant more time to decide where to continue with national patent applications. The PCT process also provides the applicant with valuable information about the potential patentability of the invention through an international search report and the optional international preliminary examination report.

The PCT system is expanding rapidly: the number of member states, including many European countries, Japan, and Canada, has more than doubled in the last eight years, to 125, and the number of international applications has grown from 2600 in 1979 to about 110,065 in 2003.

Budapest Treaty on the International Recognition of the Deposit of Microorganisms for the Purposes of Patent Procedure (Budapest Treaty) [21]. Patents require the disclosure of the invention, usually in writing, with sufficient detail that a person skilled in the art can reproduce the invention, which raises difficulties when the invention involves a microorganism or the use of a microorganism. The Budapest Treaty allows for disclosure to be made by depositing a sample of the microorganism with a specialized institution [54]. In practice, the term "microorganism" is interpreted in a broad sense, covering a range of biological material the deposit of which is necessary for the purposes of disclosure, in particular regarding inventions relating to the food and pharmaceutical fields.

An "international depositary authority" (IDA) is a scientific institution—typically a "culture collection"—that is capable of storing microorganisms. Such institutions have been formally nominated by the contracting state within which they reside and have agreed to abide by the treaty provisions. Under the treaty, the deposit with any IDA satisfies disclosure requirements of national patent offices of contracting states if those states allow or require deposits of microorganisms in their national patent legislation. The regional offices of The African Regional Intellectual Property Organization (ARIPO), the Eurasian Patent Organization (EAPO), and the European Patent Office (EPO) have recognized this method of disclosure, as have the United States, the United Kingdom, Japan, and Canada.

12.2.4.3 The World Health Organization (WHO)

The WHO is the UN specialized agency for health. Although it does not administer any intellectual property treaties, it is involved in intellectual property issues in the field of health. Indeed, the independent Commission on Intellectual Property Rights, Innovation and Public Health, established by the World Health Assembly in 2003 has recently completed a report entitled, *Public Health, Innovation and Intellectual Property Rights* [55]. This report considers "intellectual property rights, innovation, and public health, including the question of appropriate funding and incentive mechanisms for the creation of new medicines and other products against diseases that disproportionately affect developing countries . . ." [56].

12.2.4.4 Union for the Protection of New Varieties of Plants (UPOV)

UPOV is an intergovernmental organization with headquarters in Geneva, Switzerland [57]. It administers the UPOV System of Protection of Plant Varieties, established in Paris in 1961, with the adoption of the International Convention for the Protection of New Varieties of Plants [58]. The goal of the UPOV Act is to encourage the development of new plant varieties and to benefit society through the grant of a *sui generis* IPR to plant breeders.

Members of UPOV are required to grant and protect plant breeders' rights, including exclusive rights for the production, reproduction, and conditioning, for the purpose of propagation, offering for sale, selling or marketing, importing, exporting, and stocking, of plant varieties. The UPOV Act also sets criteria for plant variety protection, namely novelty, distinctness, uniformity, and stability [59].

The impetus behind plant breeders' rights varies globally, and, thus, the rights granted vary from nation to nation, despite the harmonizing role of UPOV. For example, countries that allow for plant patents offer broader, stronger enforcement options than countries with *sui generis* plant breeders' rights. The extent of rights granted to plant breeders reflects issues of national concern, such as the rights of farmers to save and reuse seeds, among others. The stronger rights for plants provided by patents are favored by multi-national agribusiness and countries such as the United States.

Recent changes to the UPOV Act have resulted in significant controversy about the appropriate scope of plant variety protection. Specifically, the act was extended to provide protection to an "essentially derived variety" of plant, which has left confusion about exactly which plants are now covered by UPOV. Moreover, debate rages about provisions that allow a breeder to impose royalty payments on farmers who save seeds for the purpose of reusing them in the future [17]. Royalty payments may be a significant hurdle for some farmers, particularly those in developing countries, and the provisions may augment food insecurity issues [60].

Another controversial modification to the act allows for *ordre public* considerations to supersede infringement if equitable remuneration is offered, which opens the door to a system in which *ordre public* may be invoked to avoid seeking the consent of a rights-holder to use a protected plant variety. Together, these changes to the UPOV Act are worrisome to those who perceive it to be unjust and those who consider the act to offer insufficient solutions for the problems facing farmers in developing countries [61].

12.2.4.5 Convention on Biological Diversity (CBD)

The CBD, established in 1992, provides a coordinated international framework for the commercialization and sustainable use of genetic resources [62]. It forms the basis for a fair and equitable means of sharing benefits derived from the commercial use of genetic resources. The CBD tries to balance the sovereign rights of states to draft legislation regarding the natural environment within their borders with obligations states owe to other nations. For example, Article 3 of the CBD acknowledges a state's right to exploit its own resources, but simultaneously asserts the responsibility of a state to refrain from harming areas lying outside its borders. Article 15 addresses genetic resources specifically. It permits states to regulate access to genetic resources. However, at the same time, that access must be subject to prior informed consent obtained from the party providing the resources. This provision is intended to ensure benefits flow to indigenous or other marginalized communities, which are often the custodians of traditional knowledge and rich biodiversity within their territories. The CBD is binding for its signatories, which presently include 188 parties. However, it does not include the United States.

The CBD is not formally recognized by the WTO and, consequently, is considered to lack significant legal weight. Developing countries in particular continue to advocate for the adoption of the CBD by the WTO. They argue that the CBD promotes fair and equitable use of genetic resources and, therefore, its integration with the WTO is necessary to formulate balanced international standards for genetic resources. The CBD standards may also complement and enhance the

TRIPs provisions, which promote technology transfer between developed and developing countries.

Parties attending the conference that adopted the CBD have also accepted a supplementary agreement known as the Cartagena Protocol on Biosafety as of January 29, 2000 [63]. The Protocol protects biological diversity from potential risks posed by genetically modified organisms (GMOs). One initiative is for an advance informed agreement procedure that will ensure all relevant information is provided to a country before the importation of GMOs. The protocol also establishes a biosafety clearinghouse, intended to facilitate an exchange of information on GMOs and aid the implementation of the protocol.

12.2.4.6 Food and Agricultural Organization (FAO)

The FAO administers the International Treaty on Plant Genetic Resources for Food and Agriculture (FAO Treaty), in force as of June 29, 2004, which encompasses all plant genetic resources that fall within the categories of food or agriculture [64]. It sets out access and benefit sharing rules for these resources. The provisions of the FAO Treaty accord with the CBD, although its subject matter is limited in comparison. The FAO Treaty sets up a multilateral system to facilitate access to plant genetic resources for food and agriculture, allowing countries that have ratified the treaty to work together to create equitable material transfer agreements, in compliance with the treaty. It also coordinates a pool of crop resources, collected from the members, which facilitates sharing of information among farmers and breeders. In general, the FAO Treaty aims to protect genetic resources relating to specific plants and is one of the first treaties to propose an operational system of plant genetic resource distribution at an international level.

12.2.5 NATIONAL PATENT LAWS

In this section, we compare patent rules and patent criteria for biotechnological innovation in the United States, Europe, Japan, and Canada. Although attempts have been made to harmonize patent laws globally, so far it has been impossible to achieve international consensus. TRIPs sets minimum standards that must be included in national patent legislation enforced by all WTO members, but it has not had the effect of creating consistent national patent laws.

Some attempts at regional harmonization of patent rules have been implemented. The European Patent Convention (EPC) guides the granting of patents in European countries by offering an alternative means of filing a patent in several European jurisdictions simultaneously [65]. A party seeking a patent in Europe has two options: file an application in national offices or file with the European Patent Office (EPO). An application filed with the EPO, upon grant of patent, is equivalent to having a patent in each member state of the EPC [not necessarily the same as the member states of the European Union (EU)]. All patent applications filed under the EPO system are required to submit to EPC rules. However, the jurisdiction and activities of the EPC are limited to the granting of patents. The EPC does not deal with issues developing after the grant of a patent such as infringement. Thus, the EPC governs the adjudication of the granting of patens, but national laws govern post-grant challenges.

Regional filing initiatives aside, patent laws are generally national in scope and apply only to the use of patented inventions within national borders. A patent application must, therefore, be filed in each country where patent protection is sought. The problem is that the patent law of each country is slightly different. TRIPs has created consistency in some aspects of patenting such as the patent term, which must be at least 20 years from the filing date. However, national variation may affect the subject matter that can be patented, the criteria used to judge whether a patent may be awarded, and the scope of the right granted.

It is tempting to formulate judgments about the relative strength of national patent laws based solely on patentable subject matter and the scope of the right to exclusivity. However, it is important to note that patent laws have many elements. Subject matter and scope are only two aspects of any bundle of patent rights. Patent subject matter, criteria, permissible invalidity and infringement challenges, claims construction tests, and drafting rules all play important roles in patent law as well.

12.2.5.1 Substantive Patent Law

Patentable Subject Matter. A threshold issue for patentability is whether the subject matter of the patent falls within the categories of patentable subject matter set by national patent law. In some jurisdictions, such as the United States, what is considered patentable subject matter is broadly interpreted. In the 1980 United States Supreme Court decision of *Diamond v. Chakrobarty*, which revolved around the patentability of a genetically modified bacterium capable of metabolizing oil, the Supreme Court noted that U.S. patent law embodies Thomas Jefferson's philosophy that "ingenuity should receive a liberal encouragement." [33]. The court made the famous observation that an inventor should be able to patent "anything under the sun that is made by man." Based on this justification, the United States has gone on to grant patent rights over innovations that are excluded from patentability in other countries. One such category is plant patents. The USPTO also grants patents over culture methods, differentiated cells derived from human embryonic stem cells, and the human embryonic stem cells themselves [66], subject matter that is considered not to be patentable in other jurisdiction because of moral concerns.

Adopting a narrower definition of patentable subject matter, other countries have drawn lists, of varying lengths, of inventions explicitly excluded from patentability. In Europe, the EU adopted Directive 98/44/EC of the European Parliament on the legal protection of biotechnological inventions as a standard to be adopted by all its member states and complied with by the EPO [67]. The provisions of the directive outline a restrictive approach to patenting biotechnological inventions, stating in Article 6 that inventions, including "(1) processes for cloning human beings; (2) processes for modifying the germ line genetic identity of human beings; (3) uses of embryos for industrial or commercial purposes; processes for modifying the genetic identity of animals which are likely to cause them suffering without any substantial medical benefit to man or animal, and also (4) animals resulting from such processes," and "where their commercial exploitation would be contrary to *ordre public* or morality" are not patentable. Recital 38 of the

directive confirms that this list is not exhaustive and that any process whose application offends against human dignity is also excluded from patentability.

The EPC specifically limits patentable subject matter for patent applications filed with the EPO, excluding inventions that are contrary to *ordre public* or morality, as do many national European patent systems [65, 67]. The EPC further identifies discoveries, scientific theories, mathematical methods, aesthetic creations, games, business methods, computer programs, presentations of information, and methods for treatment of the human or animal body by surgery or therapy and diagnostic methods as unpatentable [65]. Furthermore, the human body, at the various stages of its formation and development, and the simple discovery of one of its elements, including the sequence or partial sequence of a gene, cannot constitute patentable inventions. However, an element isolated from the human body or otherwise produced by means of a technical process may constitute a patentable invention, even if the structure of that element is identical to a natural element. Plant and animal varieties and essential biological processes for production of plants and animals are also explicitly excluded from protection [65]. In keeping with the requirements of TRIPs, however, microbiological processes and their resultant products are patentable [65]. In compliance with Article 6 of the directive, the EPO has amended the EPC to include Rule 23d, which states that the list of exclusions included in Article 6 of the directive will likewise be unpatentable under the EPC.

In practice, genetically modified mice have been found to be patentable because they provide research platforms with significant benefits for research into human diseases [43]. Human embryonic stem cells, on the other hand, are not patentable on moral grounds because of the constraints imposed by Rule 23d(c) of the EPC, which prohibits the patenting of the "human embryo"[66]. The EPO, in two leading rulings now under appeal, has interpreted Rule 23(d) to exclude not only process patents for creating stem cell lines, thereby destroying the embryo, but also patents derived from already existing stem cell lines. Adult stem cells are not caught within the moral exclusion of subject matter from patentability.

The national patent laws of European nations have not been as well tested as the EPC provisions and the application of the directive within jurisdictions is open to interpretation and therefore can be adjudicated in variant manners. For example, the United Kingdom has interpreted the legal prohibition of patenting human embryos more narrowly than the EPO [66]. The United Kingdom Patent Office has issued a Practice Notice stating that although patents will not be granted for processes of obtaining stem cells from human embryos, nor for human totipotent cells because these have the potential to develop into a human being, patents will be granted for pluripotent stem cells, which develop from further division of totipotent cells and no longer have the ability to develop into a human being. Both the United Kingdom and Sweden have issued stem cell patents filed by the Wisconsin Alumni Research Foundation. The U.K. practice has not yet been challenged on moral grounds in the national courts.

Japanese patent laws are different still from those of either the United States, EPO, or individual European nations. Japan identifies a broad range of inventions as patentable. It does, however, impose two limits on patentability; those innovations that contravene public order or morality are deemed unpatentable [68].

The Canadian Patent Act identifies several innovations as nonpatentable subject matter, including games, medical treatments, scientific principles, and abstract

theorems. As has been discussed earlier, officially higher life forms are not patentable in Canada [43], although recent case law suggests that the rights associated with patent protection are extended to genetically modified higher life forms, such as plants, that are made up of patented genes [44].

There is a lack of clarity on the patentability of biotechnological innovation, which can have a number of unwanted outcomes. The scope of the right over some biotechnology inventions, such as genetically modified plants, can be difficult to determine. Such uncertainty may lead to increased litigation for lucrative inventions. The ethical and moral boundaries of patent rights are unknown and are differentially applied, which can create problems for international technology transfer. The same invention can receive very different treatment as patentable subject matter depending on the region or nation where an application is filed.

Patent Criteria. Patent criteria are applied to determine whether a product or process described in a patent application is an invention. If the product or process fails to meet the criteria, the innovation is not patentable. The deliberation on whether an invention meets the patent criteria is distinct from whether the invention falls within the category of patentable subject matter. An invention may meet all the patent criteria, but its subject matter may fall into a category that *a priori* cannot receive patent protection.

Most countries have three criteria that must be met for patent protection to be granted. Among countries, the criteria are often similar in nature and intent, but not identical. These differences can have a significant effect for biotechnological innovations. In the United States and Canada, the criteria are utility, novelty, and non-obviousness. The EPC defines the criteria as industrial application, novelty, and inventive step. In Japan, the criteria are industrial application, novelty, and inventive step.

Utility or Industrial Application. Utility and industrial application are similar, but not identical, criteria. In the United States, the definition of utility is not mere functionality but, rather, whether the invention is useful for its described purposes. For inventions involving DNA sequences, utility is considered to be established if a substantial, credible, and specific use is demonstrated in the patent application. In Canada, utility is understood to mean whether the invention works [69]. It does not have to work well or for a prolonged period of time, nor does a model or prototype have to be presented. Simple evidence that the invention, as it is claimed in the patent application, will work is sufficient.

Industrial application, the standard applied by the EPO and several European countries, is a narrower criterion than utility because it requires an invention to be applicable for use in industry. However, the interpretation of what constitutes an industrial application varies among national patent laws. For example, in the United Kingdom, an invention must be capable of being made or used in some kind of industry, which is broadly defined as anything that is distinct from a purely intellectual or aesthetic activity. Industry does not mean commercial use *per se*, and it includes agriculture [70]. In France, industrial application is more narrowly defined than in the United Kingdom, as industry is interpreted to mean an endeavor that turns a profit. Sweden applies an interpretation similar to the United Kingdom: An invention having industrial application must be of a technical nature, have technical effect, and be reproducible [71]. In Germany, an invention has industrial

application if it can be made or used in any kind of industry, including agriculture. The German definition is similarly worded to the provisions of the United Kingdom and France, but it is much more narrowly interpreted so that manufacture or use must occur in an industrial enterprise.

The European Biotechnology Directive, which must be adhered to by all EU member states and the EPO, sets out specific requirements for the industrial application of DNA patents. The directive states that an invention involving DNA must indicate the function of the DNA and "in order to comply with the industrial application criterion, it is necessary in cases where a sequence or partial sequence of a gene is used to produce a protein or part of a protein, to specify which protein or part of a protein is produced or what function it performs" [67].

The definition of industrial application included in the Japanese patent law is similar to that imposed by the EPO in the EPC [72]. However, the fact that Japanese patent applications are rarely refused for lack of industrial application suggests that Japan's application of this criterion may be less stringent than that of the EPO.

Novelty. The novelty criterion simply identifies whether the innovation is truly new, meaning it is not previously known or existing. To determine novelty, patent offices conduct a search for prior disclosure, including prior art materials that describe the invention and were available publicly before the date the patent application was filed. Patent offices in different countries conduct searches with varying degrees of diligence.

One factor that determines the breadth of the search undertaken is the definition of what constitutes disclosure as spelled out in national patent law. The United States considers use of the invention, printed publications, or patents from any country that pre-date the day when the applicant created the invention [73]. The EPO criterion includes use as well as both oral descriptions and written descriptions of an invention pre-dating the filing of the patent application [65]. Oral disclosure is a hot issue in the debate over the patentability of traditional knowledge, as traditional knowledge is often passed down orally rather than in written form, and, accordingly, patent laws that only recognize written disclosure do not consider oral information to represent a barrier to patentability. Japan encompasses public knowledge or public working of inventions and printed publications that precede the filing date of the patent application [68]. In Canada, written descriptions of the invention as well as public disclosure, which may include oral disclosure, pre-dating the filing of the patent application all constitute disclosure [74].

Some prior disclosure of an invention is permissible. In the United States and Canada, the inventor is granted a one-year grace period during which he can disclose the invention before filing a patent application without the disclosure barring the right to a patent [73, 74]. Without this grace period, as soon as an invention is disclosed, it can no longer be considered novel, and therefore is unpatentable. Japan and the EPO allow only a six-month grace period [65]. The conditions for the grace period under the EPC are very stringent; only disclosures because of inclusion in an officially recognized international exhibition or that is caused by an "evident abuse" (e.g., breach of a confidentiality agreement) are permissible. Some European national patent laws, such as those in force in the United Kingdom, do not permit a patent application to be filed after any public disclosure of an inven-

tion [75]. A prudent inventor will delay disclosure of an invention until he is certain of rules in the jurisdictions where patent rights will be sought or until after an application is filed.

Another factor affecting the scope of prior art searches is the amount of time that examiners have to devote to a search, which is directly related to the staffing levels and expertise of examiners working in national patent offices. For some examiners, searching time is short and prior art searches are consequently limited [76, 77], which has implications if a patent is later challenged on the ground of novelty. A search for prior art conducted by an examiner that is limited in scope because of time constraints may fail to discover prior art, which may later be discovered by persons wishing to oppose the patent. Any prior art can be used to challenge a patent and ultimately render the patent invalid for lack of novelty.

The novelty criterion further identifies a distinction that is particularly relevant to biotechnological innovation—the difference between an invention and a discovery. An invention is a product or process that did not exist previously, whereas a discovery refers to something that already exists and is a product of nature [78]. In practice, albeit somewhat counterintuitively, the discovery/invention distinction means that a gene sequence that exists *in situ* is not patentable, whereas an isolated gene sequence, with further restrictions in some countries, is patentable [79]. When a patent is sought for a gene, it is, in fact, sought for the complementary DNA (cDNA) sequence. That molecule is a manmade product derived from nature. Thus, although patentability of human body parts is controversial, isolated human genes, proteins, and cell lines are patentable.

Non-Obviousness or Inventive Step. Non-obviousness or inventive step is the third criterion applied to establish whether an innovation meets the definition of an invention set by patent legislation. Non-obviousness invokes the expertise of a person skilled in the art and asks whether such a person would have considered the invention to be obvious in light of the ordinary knowledge of the art [80]. The date of the relevant knowledge of the art differs between countries. The United States requires a consideration of knowledge existing when the invention was made, whereas Canada requires it as of the claim date of the patent application. Canadian jurisprudence distinguishes obviousness and novelty in the following manner: saying that an invention is obvious if a person skilled in the art sees it and says, “any fool could have done that,” whereas novelty invokes a reaction of “your invention, though clever, was already known” [81].

Inventive step is a similar criterion to non-obviousness. The EPO actually defines inventive step as existing if an invention is non-obviousness in regard to the state of the art. Japan’s test states that there is no inventive step if the invention could have been easily made before the filing date by a person skilled in the art on the basis of pre-existing inventions [68].

As is true of utility/industrial application and novelty as well, each of the provisions for non-obviousness and inventive step are similar. It is, therefore, the wording and interpretation of each nation’s criterion that is critical because it ultimately determines if an invention is patentable within that jurisdiction. These variations in national patent criteria may cause an invention to be denied patent protection in one country while being granted such protection in another.

12.2.5.2 Procedural Patent Law

The Patent Application. A patent is a legal and technical document generally drafted by a patent agent. It at once discloses information about the invention and establishes the boundary around the rights given to the patent holder and is intended to give fair warning about infringing activities. To this end, the drafting of patents is a highly technical art, controlled by strict rules and procedural requirements [82]. For example, patents must be drafted clearly and completely so that the invention can be directly performed by a person skilled in the art. However, a patent rarely results in such clear and compre-hensible disclosure. Key details of the optimum manufacture or working of an invention are often withheld to preserve marketplace advantage because patent documents are available for public perusal.

Patents are generally made up of four parts: an abstract, a description of the invention, one or more claims, and any drawing or technical illustrations referred to in the description or claims. The exact nature of these components may vary from nation to nation. The abstract is a concise summary of the invention and generally identifies the field of art and the technical problem the invention addresses. In some jurisdictions, a word limit is imposed on the abstract [83]. The drawings provide a representation of embodiments of the invention. Generally, elements of the invention that are depicted are numbered for the ease of reference. The description, also known as the specification, provides background information about the field of art of the invention and prior art, addresses why the invention overcomes a technical problem not addressed by the prior art, and offers a complete description of the invention in its various embodiments. The description may reference the drawings for the purpose of better describing the invention. As has been discussed, if an invention involves biological material that cannot be adequately described, the applicant may deposit a sample of this biological material at a recognized institution or depository, depending on the rules of the jurisdiction where the patent is filed [21]. Special rules also exist in some jurisdictions for applications relating to nucleotide and amino acid sequences [65]. Above all else, the description is intended to support the claims. To fulfill this role, the description may be relied on to offer insight into the intention of the inventor for the purpose of any interpretation of the claims.

The claims are the most important element of a patent because only the elements of an invention that are claimed are granted patent protection. Claims are highly technical and challenging to draft because of the strict rules governing their formulation and organization.

Claims can describe various types of inventions or embodiments of the same invention. The most common types of claims are product claims and process claims. Product claims confer protection over any aspects of a product specified, regardless of how that product was derived. Process claims describe a particular means of making a product, and it is the described process that is granted patent protection. Also relevant for biotechnology patents are Markush claims, which are used where embodiments of the invention can include a class of compounds (e.g., chemicals or DNA sequences). By opting to use a Markush claim, the applicant need not spell out every possible combination individually, instead he can claim a range of products that may be used in an embodiment of the invention. This range is compiled on the basis of a limited number of representative samples.

Every patent application must include all of the sections prescribed by national patent law. A patent right may be refused on the basis of an application that is deficient. However, a well-drafted patent application can result in a grant of significant patent rights and great economic value for an owner.

Patent Filing

First-to-File versus First-to-Invent. The United States applies a "first-to-invent" patent system, which means that if two different patent applications describe the same invention, the patent right will be issued to the invention that can be proven to have been invented first [84]. By contrast, the patent law of Canada, the EPO, and Japan, impose a "first-to-file" system, meaning that if two patent applications for the same invention are filed, the patent right will be granted to the applicant who filed an application at the earliest date [85], which is true even if the two identical inventions were arrived at independently. For this reason, first-to-file systems are often referred to as creating a "high stakes race" [86].

When to File. The first step toward obtaining patent protection for an invention is to file a patent application. The date the patent application is filed is a key reference point for the patent examination and establishes the beginning of the patent term. In accordance with TRIPs, most countries now grant patent rights for 20 years beginning on the earliest filing date [49]. Considerations of the desired patent term and the possibility of being usurped by competitors should dictate when a patent application is filed. Patent term is important because an invention that is in early-stage development and will not reach the market for many years may benefit from a decision to delay filing. A later filing date will ensure that a greater period of the patent term will occur while the invention is marketable (e.g., if the invention takes 15 years post-filing to complete research and development, it will only be on the market during 5 years of the patent term, so waiting to file can extend the period of patent protection while the product is on the market). The position of competitors is important because a delay in filing a patent means that a competitor working on an identical or similar invention may file an application first, and thereby extinguish patent rights for others in the future.

The decision of when to file a patent application can be tricky for complex biotechnological inventions that involve a long research and development period. In the case of the NF-κB patent application, it took 16 years to complete the review at the USPTO before the patent was issued [87]. This significant review period was, at least in part, caused by the large number of claims that were required because of the complexity of the invention.

How to File. There are three possible ways to file a patent application, as a national patent, a regional patent, or a Patent Cooperation Treaty (PCT) filing. The decision of which type of patent filing to pursue will depend on commercial, strategic, and cost considerations. For example, the cost of filing a PCT patent is greater than filing in a national patent office. Strategic considerations may relate to the speed of the grant of a patent under each type of application, which is often related to the type of patent review employed. The PCT includes an extended review period of 30 months pre-national filing, the EPO requires a full examination of the patent, whereas some national patent offices require no examination (e.g., Belgium, the Netherlands, Switzerland, and Ireland).

National patent offices act within the boundaries of the country they exist within and apply that country's patent law. Patent applicants may file applications directly with national patent offices in each country where patent protection is required. The decision of where to file an application is generally based on the predicted potential markets for the invention. For example, a crop plant genetically modified to be resistant to frost may only be marketable in countries with colder climates and with markets open to genetically modified foods. Another consideration is the patentable subject matter allowed in each jurisdiction. For this product, an inventor can seek patent protection for a plant in the United States, but not Canada or Europe. The most cost-effective strategy for an invention that is only marketable in a small number of countries is to file patent applications directly with individual national patent offices.

A further consideration is the differences in disclosure rules set by different countries, as discussed above under "novelty." As has been discussed, if an invention is publicly disclosed before an application is filed, it may limit the countries in which patent protection may be sought. For example, once disclosure is made, an inventor may be barred from obtaining a patent in the United Kingdom. For this reason, disclosure should never occur before the decision about where patent rights will be sought, as patent applications themselves are a form of disclosure.

In some circumstances, patent filings can rely on each other for the purpose of establishing an early filing date. The Paris Convention allows for priority filings among signatory nations. A priority filing is one that relies on the filing date of a previously filed patent application. For example, if on April 19, 2006 an inventor files a patent application for protein A in the United States, a Paris Convention signatory, a second patent application for protein A can be filed in Canada, also a Paris Convention signatory, up to 12 months later. If the Canadian application is identified as a priority filing based on the U.S. application, then the priority date granted to the Canadian application will be the filing date of the U.S. filing—April 19, 2006—which takes off some of the pressure of deciding exactly what type of patent to file immediately while holding an early filing date for subsequent filings to rely on, which is crucial in a first-to-file patent system.

Inventors who wish to obtain patent rights in multiple countries represented by a region may file applications with a regional office, if such an office exists. The EPO is a regional patent office serving several European countries, and ARIPO accepts applications for multiple African nations. Regional patent offices allow for a filing process that reserves rights in all nations within the region simultaneously. For example, once an inventor files a patent application with the EPO, the right to national patent protection in each of the participating European nations is reserved, so that after a successful examination, the inventor is granted a patent right in each of the individual nations represented by the EPO.

Regional patent offices are distinct from national patent offices. National patent offices not only undertake the filing of patents, they also administer the national patent laws. Regional patent offices are limited to undertaking the grant of patents. Post-grant patent rights will be dealt with in accordance with the national patent laws of individual nations. For example, an infringement dispute erupting in France over a patent application that was filed with the EPO will be resolved in accordance with the national patent laws of France.

Regional offices, in developing nations in particular, play another key role besides granting patent applications. They allow for the integration of services and free flow of information. ARIPO was mainly established to pool the resources of its member countries in industrial property matters to avoid duplication of financial and human resources [88].

The PCT system facilitates the filing of a patent application on a even broader scale, globally [53]. Upon filing, a PCT patent application reserves for an inventor the right to seek patent protection in all countries that are signatories to the PCT at the time of filing. This option is generally chosen by an inventor for two reasons, first, because the inventor is unsure of the scope of the market for the invention, but believes it could be global, and second, because the inventor needs time to raise investor funds. The time advantage is achieved because the process of PCT examination of a patent application can add several months (at least 30 months) to the filing process, a significant period of time to be able to put off a final determination about where patent rights are required internationally for an invention, especially considering the pressure to file patent applications as soon as possible imposed by investors and competitors, and the expense that is incurred to seek patent protection in multiple countries. A PCT filing offers some breathing space to an inventor. Moreover, an additional time advantage can be achieved if a PCT filing is made as a priority filing based on a previous foreign filing. For example, a filing made in the United States on April 19, 2006 for a widget can be identified as the priority filing for a subsequent PCT application for the widget, so that the PCT filing would be granted the priority date of April 19, 2006. Through this process, the 30-month lapse during which an inventor can decide which countries to pursue patent rights in is increased to 42 months.

It is important to remember that the PCT is not a patent-granting system but only a patent-filing system [89]. Once a PCT patent application has been examined and deemed patentable, the inventor is then required to file national applications in each of the countries where patent rights are desired. The initial PCT filing merely reserves the right to file in each of these nations (so that applications will not be refused because they missed disclosure deadlines, etc.), it does not take the place of national filings—the PCT is a preliminary step to national filings. However, as the patent application has already been examined by PCT examiners, the expectation is that the national patent filing will be a simple and straightforward process, devoid of extensive discussion between the inventor and the examiner. The drawback of a PCT filing is that it is slightly more expensive than normal national filings; a fee is charged for the PCT filing in addition to the filing fees that must be paid in each country where patent applications are subsequently sought. However, for inventions with a truly global appeal, such as with some types of biotechnology, PCT filing may be worth the added cost.

The determination of how a patent application will be filed—nationally, regionally, or PCT—can greatly affect the ultimate scope of the freedom to operate (FTO) achieved for a commercial patent owner. Evidence exists that for biotech start-up companies, FTO considerations are surpassing the previous focus on exclusion of competition [90]. Issues such as freedom from third-party contracts and properly timed disclosure can also affect FTO; but, ultimately, securing the right to seek patent rights in key marketplaces will ensure significant FTO success.

12.2.5.3 Legal Challenges: Infringement, Exemptions to Infringement, and Validity

The Scope of Patent Protection. The scope of patent protection granted to an invention defines the breadth of the patent right, sometimes referred to as the fence around the invention [80, 91]. Only when armed with an understanding of patent scope can a party know which activities will constitute infringement of the patent. The interpretation of patent protection differs by jurisdiction. In some countries, patent protection is limited to commercial activities involving the invention whereas in other jurisdictions the range of activity is broader. For example, in the United States and Canada, patent legislation does not limit patent protection to the commercial working of the invention. In contrast, in Japan, the patent holder's right is limited to the commercial application of the patented invention. For patents granted by the EPO, the applicable patent protection applied in an infringement proceeding is prescribed by the national patent law in the jurisdiction in which the alleged infringement occurred; but, generally, most European states impose a level of industrial application as a boundary for patent protection. The infringement test and specific details of infringement may also differ from one jurisdiction to the next.

Infringement. The test for infringement varies by jurisdiction. A U.S. patent is infringed when an unauthorized person makes, uses, offers to sell, or sells any patented invention within the United States or imports a patented invention into the United States [73]. Those who actively induce infringement or who sell or import critical components of inventions, knowing the sale will aid others to infringe the patent, may also be found liable for contributory infringement.

Infringement proceedings occur before a national court in the United States. The test for patent infringement asks whether the patent has been either literally or substantively infringed. The test determines the scope of the invention claimed in the patent and decides whether the patent has been infringed as a related consideration. Literal infringement means that the product or process of the invention has been duplicated as it was claimed. Substantive infringement, on the other hand, also known as the doctrine of equivalents, considers the "spirit of the invention" [82]. The question here is whether the alleged infringing product or process copies aspects of the invention that, although not being expressly included in the text of the patent, should nevertheless be considered part of the invention as it was conceived of or intended by the inventor. Thus, the substantive test is not limited to the text of the patent, but can be read into the document.

A further aspect of the U.S. infringement test that is unique is the doctrine of prosecution history estoppel. The doctrine prevents a patent holder from alleging substantive infringement based on a claim, or portion of a claim, that formed part of the original patent application but was removed during the office action stage [92]. The office action stage is the examination process when the patent applicant and patent examiner enter into discussion about a filed patent application. Generally, during the office action stage, the patent examiner will refuse claims included in the patent application on the basis of prior art; the patent applicant will either agree or disagree with the challenge. As a result of this process, the claims of the patent application will be modified at the behest of the patent examiner. The result

is that the claims included in the filed patent application are often entirely different from those included in the granted patent, as claims are often reduced in scope or removed altogether during this process. Prosecution history estoppel holds that any element of an invention removed during the office action stage cannot later be considered protected by the patent as a result of any interpretation of the claims.

The remedies for infringement available in the United States include an injunction (court order to stop the infringing activity or to destroy the infringing product) or damages (monetary or other compensation calculated to reimburse the patent holder for the losses suffered) [73]. Attorney fees may also be claimed.

As has been stated, infringement of patents granted by the EPO will be evaluated in accordance with the national patent law of the jurisdiction where infringement is alleged to occur. As an example, infringement occurs in the United Kingdom if there is disposal of, offer to dispose of, use, or importation of a patented product or a product created using a patented process or unauthorized use of a patented process in the United Kingdom [93]. Both substantive and contributory infringement are prohibited. Proceedings may occur before a court or comptroller, and possible infringement claims include an injunction, an order to deliver or destroy the patented product, damages, an accounting of profits (a calculation of the profits of the infringer derived from the infringement), and a declaration that a patent is valid and has been infringed. The test applied to infringement is the Catnic test [94], which first establishes patent scope by reducing the invention into essential and nonessential elements. Only the essential elements are then considered in the subsequent evaluation as to whether infringement occurred. The considerations of patent scope and infringement are distinct steps in the test, and scope is determined in a manner that takes no account of the infringement allegation.

Japan applies a literal/substantive test, similar to that used in the United States and has adopted the doctrine of equivalents [95]. The Japanese version of the test, however, also takes into account the weight or importance of the claimed elements of the invention in a manner similar to the United Kingdom [96, 97]. Infringement proceedings occur within the courts but rarely rely on oral arguments as the majority of the proceedings are presented in the form of written briefs. Damages may be claimed as a remedy for infringement, as can lost profits. Infringement awards were low for a long period in Japan, but evidence exists that these have been rising steadily since 2002 [98]. The burden of proof is considered to be higher in Japanese infringement proceedings than in U.S. cases (i.e., it is more difficult to prove infringement in Japan than in the United States).

In Canada, anyone who makes, constructs, uses, or sells a patented invention without authorization to do so can be found guilty of infringement. An infringement action may proceed in the higher courts in each province or in the more specialized federal court [74]. Remedies include damages, injunction, and accounting of profits. In Canada, as is true in most jurisdictions, an infringement allegation can only be raised after a patent is granted; however, Canada is unique in that the damages claimed can include a period of time between the date when the patent application was disclosed to the public and the patent was granted, in addition to the post-grant period [74].

The test applied to determine infringement in Canada is the purposive construction test [99, 100]. This test is based on the U.K. Catnic test, although the tests are not absolutely identical. The first step of the test is a determination of the scope of

a patent, which involves the break down of the claims into essential and nonessential elements. As is true of the U.K. test, this step is undertaken without any consideration of the infringement allegation. An important distinction between the Canadian test and that of the United States is that it is limited to the "four corners" of the patent document, whereas the U.S. test allows for consideration of extrinsic documents, such as the prosecution history, otherwise known as the file wrapper information. Once patent scope is determined, the Canadian test compares the alleged infringing innovation to the essential elements of the patented invention. No infringement occurred if an essential element is different or omitted in the alleged infringing device; but infringement may have occurred if nonessential elements are substituted or omitted.

Infringement is a common challenge raised in the biotechnology patent world against competitors. Myriad Genetics, as described above, applied the threat of an infringement suit to great advantage. Ariad Pharmaceuticals, owner of the NF-κB patent, likewise has "gone to extraordinary lengths to ensure that anything that comes within so much as a whiff of NF-κB will be drawn into the '516' patent's black hole" [87].

Exemptions to Infringement: Exemptions for Research and Generic Drug Manufacturing. Certain activities are exempt from patent infringement challenges, and, again, these vary according to national patent laws. Exemptions may be raised to defend against allegations of infringement. The most pertinent exemption for biopharmaceuticals and biotechnology is the research exemption. The research or experimental use exemption curtails a patent holder's rights by permitting researchers and research institutions to make certain uses of a patented invention without compensating the patent holder. Many policy documents argue that the research exemption for free access to basic research materials should be strengthened (see discussion below) [101]. However, it is becoming increasingly difficult to justify a research exemption as the lines between private-sector and public-sector research blur and the commercialization activities of public-sector research institutions increase.

In the United States, no statutory research exemption exists; instead, a very narrow experimental use exemption has been carved out by judges and exists in the common law [102, 103]. Previously, the exemption did not apply if the research has "the slightest commercial implication" [104]. However, the decision of the United States Court of Appeals for the Federal Circuit in *Madey v. Duke University* [105] has further narrowed the exemption. Now, any conduct by a research institution that is in keeping with its legitimate business, regardless of the commercial implications of the research, cannot rely on the research exemption. In the case of *Madey*, Duke University was using patented equipment for teaching and research. The court characterized both of these activities as part of the legitimate business activities of the university and therefore decided that Duke University could not be exempted from patent infringement. The result is that the research exemption has been restricted only to the most exceptional circumstances [102].

Most importantly, for biopharmaceuticals, however, and the eventual entry of generic products of biotechnological research into the marketplace (see discussion below) is the Restoration Act or Hatch–Waxman Amendments to the Drug Price Competition and Patent Term Restoration Act of 1984 [106]. This act creates an

exemption to the normal rules governing infringement for parties seeking Food and Drug Administration (FDA) approval for generic drugs. Section 271(e) of the U.S. Patent Act now states that "use of a patented invention solely for purposes reasonably related to gathering data to support an FDA application for generic versions of [patented] drugs" does not constitute infringement. However, the generic drug manufacturer, although having the ability to do research to show that their drug is equivalent to the patented original, must still wait until the patent expires before it can seek FDA approval.

In Europe, the issue of infringement is still largely determined by national patent law. Article 31 of the Community Patent Convention creates an exemption for acts "done for experimental purposes relating to the subject matter of the patented invention" [107]. All members of the EU except Austria have introduced a similar provision into their national patent laws [102]. However, the interpretation of the scope of the exemption still varies between countries. For example, in Germany, the scope of the experimental use exemption is broad and applies to activities that test the viability and potential for development of patented inventions. In the United Kingdom, however, the exemption is narrower. It does not apply for experimentation in the context of regulatory approval in contrast to Canada, the United States and other countries of the EU [102].

Infringement exceptions in Japan's patent law include some research uses [68]. Further exemptions include, in the United States patented inventions in use upon vessels, aircraft, or vehicles that are in the Unites States on a temporary basis (and will be used solely aboard the vessel, aircraft, or vehicle); and if a person other than the patent holder reduced the invention to practice at least one year before the filing date of the patent, that person can continue to use the invention [73].

The United Kingdom also exempts patented inventions used on an aircraft that is temporarily landing in or crossing over the United Kingdom [93]. Canada offers a similar exemption for ships, vessels, aircraft, or land vehicles within Canada, allowing temporary use of patented inventions solely for their needs and upon the craft; and they also acknowledge that any prior holder (meaning a person who had the patented product in their possession before the claim date of the patent) has a right to continue to use the product [74].

Challenging the Validity of a Patent. The validity of the claims made in a patent is likely to be challenged in one of two situations: directly in a post-grant opposition or validity challenge proceeding, depending on the jurisdiction; or alternatively, as a defense to an action for infringement. The latter use of a validity challenge may be formulated in a variety of ways, but will most likely argue that the invention is not patentable subject matter, that the patent criteria is not met (e.g., prior art exists that establishes that the invention is not new), or that claims are invalid (e.g., claims are not supported by the description or are affected by a technical deficiency). In some countries, pre-grant validity challenges may be raised as well; for example, in Canada, a prior art filing process can be invoked [74]. This challenge involves the delivery of prior art that proves that the invention was not novel at the date of filing to the patent office by a person wishing to thwart the grant of a patent. In Canada, such challenges are unpopular because the person filing the prior art has no right to involvement in the proceedings after delivery to the patent office and is bound by the decision. Canadian validity challenges are normally only raised

after a patent has been granted, at which point the challenger can have full involvement in the proceedings and a right of appeal.

An opposition proceeding is a form of post-grant validity challenge available for EPO patents [65]. As the EPO is solely a patent-granting organization, the effect of the issuance of an EPO patent is effectively to create multiple patents from a single application, one patent in each of the European countries designated by the applicant during the patent prosecution stage. However, if an EPO opposition proceeding is launched within nine months of the granting of the EPO patent, it has the effect of pulling back each of the national patents, so that a single EPO patent exists [108]. It is the validity of this single EPO patent that is challenged. The benefit of the opposition proceeding is that only one challenge needs to be made; this option is more cost-effective than pursuing multiple proceedings in each individual European nation where the patent exists post-grant. An opposition proceeding may be brought by any person and is based on three grounds.

(1) that the subject matter is not patentable under European law;
(2) that the European patent does not disclose the invention so that it could be carried out by a person skilled in the art; and
(3) that the subject matter of the European patent extends beyond the content.

In the United States, post-grant oppositions are under discussion as a major feature of proposed patent reform [109–111]. Advocates of opposition proceedings hope that allowing an opposition to be filed in the USPTO within a limited time window, immediately after the patent issues, would help weed out invalid patents in a procedurally simple, relatively inexpensive forum. Presently, a re-examination process is set out in the U.S. patent law, which is a challenge to the validity of a patent based on the presentation of prior art [73]. However, the outcome of the re-examination is binding and no right to appeal is granted, and, like the Canadian filing of prior art process, the re-examination process is rarely used [108].

In Japan, the opposition procedure after an examiner's decision to grant a patent was abandoned in 2005. The alternative is a trial for the invalidation of the patent [112].

Canada does not offer an opposition procedure, but includes a reexamination procedure in its patent law. Re-examination may be requested for any claim or claims at any time during the term of the patent, but the evaluation is undertaken solely on the basis of prior art [74]. The Commissioner of Patents appoints a three-person re-examination board to undertake the review. Unlike the re-examination process in the United States, the board's decision is not the end, and an appeal can be launched within three months.

12.2.6 THE EFFECT OF THE REGULATORY ENVIRONMENT

Biotechnological innovations that are eligible for patent or other IPR protection can simultaneously be regulated by relevant IPR laws and other legislation or regulation. For example, an overlap between patent law and legislation directed specifi-

cally at biologic products may affect biopharmaceuticals. Biologics, as defined by the FDA, “in contrast to drugs that are chemically synthesized, are derived from living sources (such as humans, animals, and microorganisms). Most biologics are complex mixtures that are not easily identified or characterized, and many biologics are manufactured using biotechnology. Biological products often represent the cutting-edge of biomedical research and, in time, may offer the most effective means to treat a variety of medical illnesses and conditions that presently have no other treatments available” [113]. A biotechnological innovation that meets the definition of biologic and is granted patent rights will need to comply with food and drug legislation as well as patent law.

Simultaneous compliance with two sources of legislation has the potential to affect the scope of patent rights. For example, the parameters for the introduction of generic versions of the patented drug into the marketplace are set not only by patent law but also by food and drug legislation. In Canada, the patent regime has been tied to the food and drug legislation to address concerns that patent rights over drugs may negatively affect public health by limiting access to drugs. Cooperation between the food and drug regime and the patent regime also ensures that the term of a patented drug is respected. Specifically, legislation prohibits generic drug manufacturers from introducing an equivalent drug into the marketplace during the patent term, thereby introducing patent considerations into the regulatory approval system.

12.2.6.1 Biosimilars

An emerging issue in the field of biopharmaceuticals is the issue of biogenerics and how these may be introduced into the marketplace. Biogenerics are the generic version of the original, usually patented, biologic product; the same relationship is found between the original pharmaceutical and its generic counterpart. The primary distinguishing feature between biologics and traditional pharmaceuticals is the former uses recombinant DNA technology to produce macromolecules whereas the latter conforms to a “chemical synthesis/small molecule paradigm” [114]. Diverse biotechnological products include hormones, cellular growth factors, enzymes, clotting and anticlotting factors, monoclonal antibodies, and fusion proteins. The very diversity and complexity of biologics leads to problems in setting the regulatory environment.

To date, no specific regulations or universally applicable guidelines exist governing biogenerics. Each product is reviewed on a case-by-case basis according to existing regulations governing generic pharmaceuticals. Such regulations exist in most jurisdictions and provide a simplified approval process based on the proof of “essential similarity” or product equivalence of the generic pharmaceutical compared with the patented pharmaceutical already available in the marketplace. Equivalency may be in terms of chemical composition, pharmaceutical equivalence or dosage forms, and thera-peutic equivalence. Generic pharmaceuticals are almost identical to the original product or even contain an active ingredient for which the patent has expired.

The problem with biopharmaceuticals is that these are generally characterized by properties that may complicate the demonstration of equivalence because of the difficulty of characterizing the physico-chemical makeup [115]. The product

properties, such as the impurity profile, glycosylation, and protein folding, may be highly dependent on the process by which they are manufactured, adding to the complexity of a determination of equivalency [115].

A further problem is the issue of the patent thicket that surrounds much biotechnological innovation. There may be multiple patents held by multiple parties for constituent ingredients, processes required for the development of biopharmaceuticals, and the products involved in those processes (e.g., gene and protein patents). Navigating the thicket to ensure that a biogeneric violates no extant patents may be quite challenging. Thickets greatly impede FTO.

These problems will become increasingly significant as the patents for top-selling biopharmaceuticals expire. Several of the top-15 selling biopharmaceuticals come off patent in the next five years and a number of large generic manufacturers have begun development of biogenerics [115]. Indeed, if a similar market penetration is assumed for biogenerics as for generic pharmaceuticals (10–15%), the worldwide market for biogenerics will be $2–3B U.S. [114, 115].

Some hope exists that the regulatory framework will become responsive to the emergence of biogenerics. The shift will require a move from essential similarity (or demonstration that the generic is almost identical to the origi-nal pharmaceutical) to product comparability [115] and clearer working definitions for different classes of biologics [114]. These issues are under consideration by the FDA, and the European Commission has passed legislation for the approval of “similar biological medicinal products” [116].

12.2.7 REFORM PROPOSALS FOR INNOVATION GOVERNANCE IN BIOTECHNOLOGY

The rapidly changing area of biotechnology innovation does not necessarily fit comfortably within the confines of traditional intellectual property laws. Some reforms have been made at national and international levels to adapt intellectual property law, particularly patent laws, to biotechnology. These reforms generally take the form of specific provisions and adjunct statutes, regulations, and practice guidelines within patent offices designed to address patent rights in biotechnology. Many of the reforms are driven by moral and ethical concerns that develop from the research *per se* and discomfort with the commodification of products and processes that are perceived to belong to nature or life. However, some more pragmatic concerns exist, developing from considerations of the appropriate balance to be struck between the rights of innovators in biotechnology and access to the innovation by the public, by government, and by researchers, among others. In this final section, we explore some of the reforms that have been proposed as solutions or compromises to moral and ethical dilemmas and to the issue of striking the right balance for patent protection of biotechnology innovation.

12.2.7.1 Strengthening Research Exemptions

Many jurisdictions are currently considering reform proposals for a broad research exemption from patent infringement [117, 118]. The concerns prompting the call for policy reform are set against a backdrop of rapid growth of DNA-related

patents, particularly in the United States with growth of about 5% per annum [119]. It is estimated that over 3000 new DNA-related patents per year have been issued in the United States since 1998 and more than 40,000 such patents have been granted [120]. On the human front, at least 20% of the human genes are associated with at least one U.S. patent, and many have multiple patents [121].

The first concern, raised by Heller and Eisenberg, is the plethora of overlapping patents that may result, in the research context, in a "tragedy of the anti-commons" [122]. That is, the large number and diversity of ownership of gene patents may make it difficult to acquire all of the rights necessary for products and processes required for research (e.g., a patent thicket), resulting in the underuse of valuable technologies and the abandonment of promising avenues of research. Second, concern exists that patent holders will exercise their right of exclusivity in an overly restrictive manner that prevents others from developing or accessing a particular technology, for example, by refusing to license the technology for use by others [123]. The case of Myriad Genetics' zealous enforcement of its BRCA1/2 gene patents to prevent government-run diagnostic laboratories in Ontario from testing for genetic predisposition to breast cancer was such an example. Denial of access to patented genes and other biological products raises particular concerns because of the likely inability to invent around product patents because of the unique role these molecules play in biological processes. Third, the increasing focus on commercialization of public-sector research institutions will undermine norms of open scientific collaboration, especially the sharing of research results and materials [124, 125]. Increasing levels of industry funding will augment this effect and contribute to delays in the publication and dissemination of scientific research.

To date, the empirical evidence indicates that most of these concerns have not materialized [126]. However, real worries exist about the sharing of research materials, resulting in an increasingly competitive environment, which is likely tied to the commercialization ethos, industry funding, and the practical difficulties, such as time limitations, of transferring research materials [126].

12.2.7.2 Patent Pooling

A combination of the controversial nature of some areas of biotechnological innovation and a general distrust of commercially driven research are two factors that will influence public support and policy setting for both the private research sector and the public research sector. Patent pools may be a potential solution for maintaining public confidence in the research enterprise [42].

A patent pool is an arrangement in which "two or more patent owners agree to license certain of their patents to one another and/or third parties" [127, 128]. Patent pools bring together patent holders in a specific area of innovation, such as a viral genome, to facilitate the efficient use and development of a technology. The patents are "pooled" in the sense that the arrangement allows inventors in the pool to use all patented invention under favorable licensing terms. Any benefits that may materialize are then shared among the group. Patent pools have been used successfully in the motion picture industry, in aeronautics, and in the development of video and DVD technology [129].

As commercial interests are part of the problem, patent pools could be set up as independent, nonprofit corporations with an independent governance structure

in which researchers are removed from direct involvement with industry and commercial forces [42, 130]. The governing body of the patent pool would make decisions about commercialization, access, and licensing. These decisions would be open to public scrutiny to ensure that research is in the public interest and not solely concerned with the profit motive. Such a structure is being considered for the Canadian Stem Cell Network and research related to the SARS genome, for example.

Of course, many challenges face the setting up of a patent pool. Patent pools may trigger anticompetition laws [127]. Researchers may not join in the patent pool because, although patent pools lower research transaction costs and spread risk, they also decrease the potential for the attainment of large profits from an invention. In the end, "the major incentive for all parties is economic benefit. In order for a patent pool to be an effective solution, the right balance has to be achieved between the cost of creating a pool and the prospect of adequate revenue generated by royalties on the endproduct" [131].

12.2.7.3 Open Source Patents

Another governance model designed to improve access to information and biotechnological research is open source patents. Open source patent systems share the goal of promoting free dissemination of biotechnological research. The aim is to foster an environment of sharing between inventors and the public rather than marketplace monopolies. Open source systems can be directed at endproducts or research tools used to develop products. Some consider open source to represent a grassroots movement to return to precommercialization sensibilities about scientific research and development, where there was a greater ethos of freely sharing scientific information among members of the scientific community [132].

The concept of open source rights as an alternative to IPRs originated with copyright. The rights granted by copyright arise automatically with the creation of a work. Copyright holders are then free to decide who may use the work. Open source systems, often found to protect software available for download on the World Wide Web, are created when copyright holders agree to license their works in a nonexclusive manner to anyone who agrees to abide by certain terms. The terms usually ensure that the copyrighted works themselves and any derivative works will be made available to future users in the same nonexclusive manner. As patent rights do not arise automatically, but must be actively applied for, open source patent systems have more options available for their formulation. Open source patent systems operate in a diverse manner, and some include inventions that are protected by patent rights whereas others apply to innovations that are not patent-protected. The similarity with all open source copyright is that open source patent initiatives build a free flow of information upon the foundation of innovation [133].

Several functioning examples of open source patent systems exist. The Public Patent Foundation (PPF) is one such initiative that facilitates the creation of a commons wherein patents may be pooled and made freely available to other participants [134]. The specific method applied by the PPF is to grant a nonexclusive and payment-free license to participants. The Biological Innovation of Open Society (BIOS) also involves technologies for which patent rights have been granted.

Its operation is focused on research tools rather than final products, and its goal is to "assemble groups of enabling technologies that together provide the pieces necessary for a particular form of research investigation" [134]. Both PPF and BIOS set licensing terms that achieve their specific goals [134].

The Tropical Disease Initiative (TDI) is an example of an open source patent system in which inventions need not be protected by patent rights [135]. Its aim is to create an accessible Web database to facilitate "searching for new targets, finding chemicals to attack known targets, and posting data from related chemistry and biological experiments" [135], which makes information readily accessible by researchers in developing and developed nations. Eventually, TDI hopes its open source system will aid virtual pharmas—organizations that are not engaged in inhouse development, but that use a grouping of commercial and academic partnerships to create a portfolio of promising drug innovations [135].

12.2.7.4 Compulsory Licensing

The debate about compulsory licenses for patented products occurred in the context of access to HIV/AIDs drugs in Africa. At issue was the effect of patent rights on the accessibility and affordability of pharmaceutical products and vaccines in developing nations. Similar concerns around access and cost are likely to develop with biopharmaceuticals and other innovations resulting from research in health biotechnology.

One policy option for ensuring the accessibility and affordability of biotechnological innovation is for the state to implement compulsory licenses. Compulsory licenses override the exclusive patent right granted to a patent holder. A number of reasons why a state may take such a step exist, including public emergency and public health. Many national patent laws include provisions that permit the application of compulsory licenses. TRIPs also permits WTO members to include compulsory licensing within national patent legislation, in the instances of either "national emergency or extreme urgency," and sets out that the invention is to be applied to a "public noncommercial use" [49].

At its Cancun Ministerial Meeting in 2003, the WTO decided to implement changes to enable the least-developed countries to import cheaper generic drugs manufactured under compulsory licensing in other countries in the event that they were themselves unable to manufacture the pharmaceuticals. Calling it an "historic agreement for the WTO," Director General Supachai Panitchpakdi recognized that it was the first time that the WTO both validated and facilitated the full use of TRIPs' flexibility by developing countries [136].

Canada was the first country to introduce legislation to provide access to affordable medicines under the Cancun agreement. Canada's Patent Act has been amended to permit the award of compulsory licenses to export medications to developing countries in need. The amendments stipulate the conditions under which the government can issue a compulsory licence to a pharmaceutical manufacturer for the manufacture and export of a patented drug to the world's developing and least-developed countries. However, it is too early to tell whether the compulsory licensing regime will actually result in increased access to medicines [137, 138].

12.3.1 INTRODUCTION

The future of pharmaceutical drugs in the United States is likely that of continuing economic growth, as there is increasing use of pharmaceutical drugs in the general population, with an estimated 43% of Americans using at least one pharmaceutical drug between 1999 and 2000 [1]. This fact, in conjunction with an aging population needing and demanding more and cheaper pharmaceutical drugs, with an average of 30 filled prescriptions for non-institutionalized Medicare enrollees aged 65 and

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

older [2], suggests a need for alternative approaches to traditional "vat-based" mammalian cell-based production. Although such production approaches as animal-based "pharming" are promising, among the most promising of approaches is that of Plant-Made Pharmaceuticals (PMPs). These PMPs use genetically engineered plants, a technology used for over 20 years, to express substances that may be used to treat and cure such diseases as cancer, Alzheimer's, diabetes, HIV, heart disease, and others. By using naturally occurring processes in the plant, along with the ability to scale up production quickly, PMPs are a promising technology. However, as with any new technology, the potential pitfalls are plentiful, chief among which are the perceptions of the public, which is largely unaware of this technology, and whose perceptions place it on a threshold of acceptance or rejection, making it a "boundary technology".

PMPs may be considered a boundary technology for a variety of reasons. First, it is a subset of a relatively new technology, that of genetically engineered plants. As a result of its newness, risks from genetic engineering of plants are not well characterized. Although recent events suggest the potential risks, and the current inadequacy of the regulatory system to either prevent or respond to crises (see Section 12.3.3), from genetically engineered plants have not been tangibly experienced by the average American. Instead of actual events, characterized risks tend to exist as either extrapolations from laboratory experiments or as hypothetical events. Although laboratory experiments do provide a good deal of insight into the mechanisms by which events may occur, they do not replicate the reality of the fields in which PMPs may be grown with the field's dynamic, nonlinear, complex systems affected by multiple interacting factors such as weather, soil, cropping systems, chemical usage, and so on. Hypotheticals about PMPs tend to be extreme in nature and politically charged, with Cassandras of doom preaching worst-case scenarios and Candides of optimism trumpeting the best possible future. Neither perspective, however, appreciates the probabilistic nature of risk. Here, risk is defined as hazard multiplied by exposure. And, in the words of Howard and Donnelly, "(I)n order for the risk to be zero, either the exposure or the hazard must be zero" [3], which, of course, is unlikely if not impossible, especially considering increased sensitivity of detection methods and understanding of the effect of different substances on different individuals.

A second reason to consider PMPs as a boundary technology is that they promise to radically change public perceptions by drawing attention to the changed character of the plants themselves. It is here that hypothetical scenarios concerning PMPs make their mark, leading to acceptance or rejection of this technology. Although genetically engineered plants are currently a pervasive part of the agricultural landscape and consumed extensively, with the staple crops of corn and soybean grown in genetically engineered variants in the United States and comprising 45% and 85% of total acreage in 2004 [4], respectively, there is little public awareness of their presence in the food supply [5–7], which is mainly a result of them being genetically engineered to express agronomic qualities, such as herbicide tolerance and pest resistance, which are typically not brought to the attention of the public. Although plants have long been used for medicinal purposes and food can have healing properties, genetically engineered plants, especially dealing with food crops, will likely draw public attention by underlining the transgenic nature of the products that span species and may even incorporate human DNA. Some precedent in public response to genetic engineering may be seen in "second-

generation" food products with enhanced product quality, which, although offering useful characteristics, have yet to be economically successful.

The final reason PMPs may be considered a boundary technology derives from the previous reason. PMPs may be recognized as both a food and a medicinal application of genetic engineering. Although it is highly unlikely that the same plant will be processed for both food and pharmaceutical purposes, it is quite likely the public will perceive them as a unified technology. In terms of public response to date, there have been quite different paths in the reception of genetically engineered pharmaceuticals and medical products and that of genetically engineered plants. There has been little controversy over genetically engineered pharmaceutical products, likely because people are willing to accept risk when it comes to recovering the health they have lost, whereas people are likely to be risk averse when it comes to changing their diet, especially when they perceive nothing wrong with it. By exhibiting both characteristics, PMPs are likely to arouse ambiguity in response, depending on the personal salience of particular pharmaceutical products being developed.

Considering these reasons, this chapter will explore PMPs and their potential with an eye toward public response and policy actions. In this chapter, we first consider potential benefits of new products moving toward the market, such as enhanced access and decreased price. We next look at the risks of this boundary technology, especially adventitious presence in which PMPs might accidentally enter the food supply, which is illustrated by recounting three recent events in which the food chain was either breached or threatened by unapproved food products. We then consider public opinion toward PMPs, both in response to these incidents, as seen in comments to Federal Register changes, and through a regional survey of public opinion. Finally, we consider the federal regulations currently in place and recent political developments before drawing conclusions.

12.3.2 BENEFITS OFFERED BY PLANT-MADE PHARMACEUTICALS (PMPs)

The benefits of PMPs have been well characterized and documented by proponents of this technology. Indeed, much of the research and development of this technology is driven by optimism that PMPs will have tremendous health benefits for an aging and growing population and the potential for economic gain, especially when compared with current production approaches. This outlook is bolstered by awareness of the sheer size of the pharmaceutical drug market. Of this market, an increasing proportion builds on genetic engineering.

According to Elbehri [8], three factors commend PMPs over current approaches to express pharmaceuticals, such as bacteria, yeast, and mammalian cells, and more recent technologies, such as insect cells and transgenic animals. These three factors are cost advantage, production scalability, and safety. The cost advantage of PMPs over the current use of mammalian cell cultures is great, with mammalian cell bioreactors ranging from $106–650 per gram of antibody, whereas PMPs would likely cost four to five times less for the same pharmaceutical.

The second factor is the capacity to more easily scale-up production than is currently the case with mammalian cell-based systems, which is based on the ability to increase production by growing more plants on added acreage in a short period of

time, avoiding the need to build more production facilities with buildings, vats, and other associated capital costs [8]. However, this benefit is offset by production being driven by growing seasons and the ability of plants to reproduce seeds enough to scale-up production [9]. In other words, pharmaceuticals will be produced on the basis of an agricultural cycle, with the inherent difficulties of predicting weather, pest outbreaks, and other factors that influence natural systems. Although storage may not prove problematic, especially if the pharmaceutical is expressed in the seed (which might not be the case), predicting market demand is yet another difficult factor. Another difficulty with scaling up lies with enforcing regulatory controls. Expanding production acreage implies increased potential for inadvertent movement of the PMPs' genes, whether by cross-breeding with other plants or their being blown into neighboring fields, bringing with it legal liabilities for environmental and health damage if they occur. Therefore, expanded acreage implies expanded implementation of safeguards and increased surveillance.

The third and final factor is the belief that PMPs are safer than using proteins from recombinant microorganisms or cells, which is because "PMPs do not carry potentially harmful human or animal viruses into the drug" [8], as plants do not serve as hosts for such human pathogens as HIV, prions, hepatitis, and so on [10]. Furthermore, plants are typically constructed to express a portion of a pathogen or toxin, reducing possible infection or innate toxicity [11]. This, however, does not alleviate concerns over potential allergenicity, which will be present in most pharmaceuticals.

In spite of the benefits offered, PMP development is still in its infancy, with retardation of its progress caused by reasons discussed in the next section. However, analysis of U.S. Department of Agriculture (USDA) data concerning release permits for "pharmaceuticals, industrial, and value-added proteins" over the last two years, during which time stricter regulatory standards were enforced, suggests a still-fertile field of research. Overall, 35 permits were applied for during 2004 and 2005, with permit applications increasing from 15 in 2004 to 20 in 2005, of which nearly 70% were granted and 60% were released into the fields.

Institutions doing research in PMPs tend to be dominated by small research companies (see Figure 12.3-1). Although research universities, mainly Iowa State

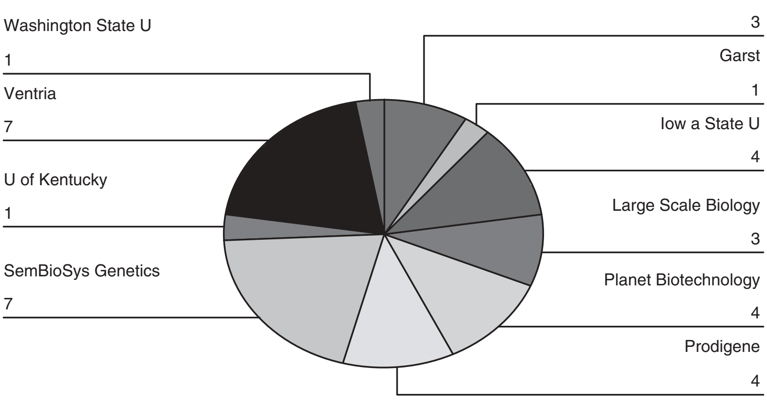

Figure 12.3-1. Institution.

University (four applications) and the University of Kentucky and Washington State University (one application apiece), are involved in research, companies such as SemBioSys Genetics and Ventria (seven applications apiece), Planet Biotechnology and Prodigene (four applications), Large Scale Biology and Chlorogen, Inc. (three applications), and Garst (one application) are the mainstays of research currently being sent to the fields.

The five plants serving as hosts for the experimental activities reflect research realities (see Figure 12.3-2). Tobacco is the preferred host, having nearly one third of the permit applications, reflecting its long-time use as a research plant in genetic engineering. Although corn has long history of experimentation and being used extensively in the field, and, as a result, is the second most popular plant for experimentation, the change in regulations in response to critiques of the regulatory system, and fears of it entering the food supply, has led to its reduced relevance in 2005, where only two university-based field trials were proposed, compared with its more extensive use (seven applications) in 2004. The remaining plants, safflower (seven applications), rice (six applications), and barley (two applications), might prove to be the preferred future host plants for PMPs and industrial products.

Examples of products being developed include Ventria BioScience's work on human recombinant lactoferrin and lysozyme, which may be used as an oral rehydration solution [12]; SemBioSys has been developing PMP-based human insulin (to meet the needs of an increasing population of diabetics) and human APO IP, which reduces and stabilizes arterial plaque associated with "acute coronary syndrome" such as heart attacks and angina, as well as strokes [13]; Planet Biotechnology's treatments of tooth decay by bacterial infection, hair loss through specific forms of chemotherapy, and treatment for the common cold by blocking infection by rhinovirus are likewise promising [14]. Prodigene has brought to market recombinant trypsin, normally produced by the pancreas, which may be used in the production of insulin, human and veterinary vaccines, cell cultures, and wound care [15]. It has also developed a vaccine targeting swine transmissible gastroenteritis [16]. Finally, Chlorogen is developing a "chloroplast transformation technology" that would introduce genes into plants, allowing large-scale production without potential genetic transfer through pollen [17]. These products and others promise

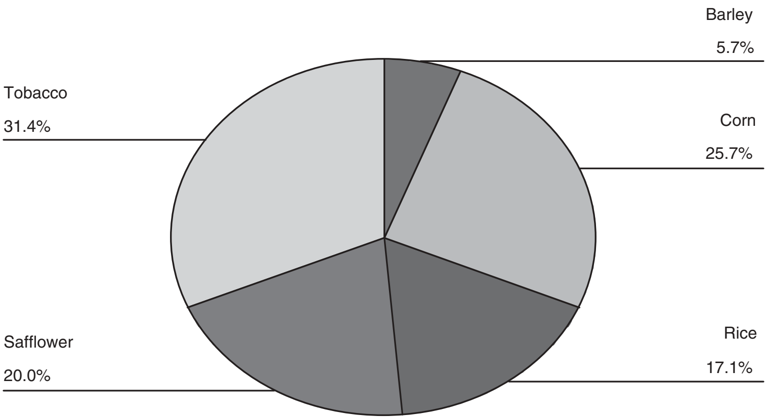

Figure 12.3-2. Host plant.

increased product availability and a range of new products, with health benefits and economic growth implied.

Although the future of PMPs may, like any technology, be difficult to predict, the experimental activity concerning these plants appears to be relatively robust considering recent regulatory changes and increased public skepticism. Although the amount of permit applications are relatively small, especially compared with the sheer numbers of experimentation involving genetically engineered plants, PMPs and associated technologies appear to be growing in importance and in the fields. And given the benefits they offer in the production of new pharmaceutical drugs, this growth can be expected.

12.3.3 THREATS POSED BY PLANT-MADE PHARMACEUTICALS (PMPs)

In spite of the benefits specifically offered by PMPs, and by genetically engineered plants generally, apprehension exists over their release into the environment. According to the National Research Council report "Bioconfinement of Genetically Engineered Organisms" [18], three concerns exist over the unintentional movement of genes placed into target plants. The first is that the inserted genes will lead to the target plant or relatives cross-breeding and becoming weeds by obtaining benefits that enable it to overrun or disrupt ecosystems. The second concern is that wild relatives, especially those with economic, social, or moral values, will be at risk of extinction by either being outcompeted or through hybridization with genetically engineered plants. The third concern, that the genetic material will spread to other domesticated varieties [18], is perhaps one of the highest profile concerns for PMPs, especially when considering that many PMPs are currently being expressed in food plants. Although these concerns are currently being researched and will likely continue to pose a threat as genetically engineered plants dominate the commodity agriculture landscape, no evidence of these concerns coming to fruition have come to light to date.

Another major concern, if not the major concern, is that PMPs will somehow find their way into the food supply. As a result, it is feared the public will respond with decreased institutional trust and will make market decisions that negatively affect food producers. As a result, recent changes to the regulatory structure concerning agricultural biotechnology are occurring because of concerns "that the expansion in agricultural biotechnology increasingly will put pressure on seed production and commodity handling systems" [19] to segregate and control its products. Specifically, concerns exist that the current regulatory scheme is not able to adequately address the amount and variety of new genetically engineered plants, with PMPs chief among them. Doubts over the agricultural biotechnology regulatory system have been raised by three recent events, calling into question the scientific basis for regulation, the effectiveness of regulatory enforcement, and the integrity of the food system.

12.3.3.1 StarLink Bt Corn

The first major event to focus national attention on the potential violability of the U.S. food chain occurred when StarLink corn made its way into the human food

supply in 1999 and 2000. StarLink corn used the Cry9c variant of *Bacillus thuringiensis* (Bt), a protein that kills targeted insects by eating through their guts, leading to sepsis and the inability to digest food. StarLink corn was not deemed fit for either human consumption or export because of presumed possible human allergic reactions. As a result, it was to be used only for animal feed or nonfood industrial purposes.

In September and October of 2000, attention was drawn to the presence of StarLink corn in the food chain when the consumer group Genetically Engineered Foods Alert performed tests on taco shells and other corn-based products being sold in grocery stores and in fast food restaurants [20]. Estimates by the USDA's Economic Research Service suggest 123.8 million bushels were co-mingled in 2000, whereas Aventis', the company responsible for StarLink, estimates that over 430 million bushels were co-mingled in 1999 and 2000 [21] with an estimated 340,908 acres in 28 states planted with StarLink Bt corn [20]. Overall, a total of nearly 300 products were recalled, including 70 types of corn chips, 80 types of taco shells, and almost 100 restaurant food products.

In an attempt to minimize economic loss and public concern, Aventis and USDA bought back existing grain supplies and recalled food containing StarLink corn. However, significant damage was done. In addition to illustrating the failure of the U.S. regulatory system concerning genetically engineered plants, there was disruption of the downstream food manufacturing marketplace with corn exports being affected. Indeed, within a single year, of 110,000 grain tests by federal inspectors, StarLink corn showed up in one-tenth [22]. Although the complexity of market forces allows only estimation, a significant decrease in trade with Japan and South Korea occurred immediately after StarLink corn was found [21]. Since then, the European Union has required labeling and tracing requirements for genetically engineered goods that are seen as greatly hindering U.S. farm product competitiveness, especially with respect to corn and soybean products. Overall, estimates suggest the StarLink event and the recall in its aftermath have cost the food industry $1 billion [23].

12.3.3.2 Prodigene PMP Corn

The second event, that of Prodigene's PMP corn, is one immediately relevant for PMP production. In September and October of 2002, in Iowa and Nebraska respectively, APHIS found "volunteer" corn plants genetically engineered to produce a pharmaceutical to prevent "traveler's diarrhea" growing in soybean fields in violation of permit conditions. Specifically, Prodigene did not abide by the conditions of their field release permit to eradicate all traces of the experimental crop from the fields, as small quantities of this corn ended up in soybean that was to be processed and sold for human consumption.

Although none of this corn made it into the food supply, this near miss drew attention to the regulatory system's lack of readiness in dealing with the next generation of genetically engineered crops, those producing pharmaceutical and industrial products. Prodigene had to pay a civil penalty of $250,000; destroy 500,000 bushels, or $2.7 million dollars worth, of soybean in Nebraska; and incinerate 155 acres of corn in Iowa because of concern that cross-pollination occurred, as well

as posting a $1 million bond and accede to higher compliance standards for future field tests [24]. Perhaps more important in terms of long-term political implications, the Grocery Manufacturers of America (GMA) and other food processing interest groups expressed concern over PMP field test regulations, with John R. Cady, CEO of the National Food Processors Association commenting "(it is) nothing short of alarming to know that at the earliest stages of development of crops for plant-made pharmaceuticals, the most basic preventative measures were not faithfully observed. This apparent violation of rules . . . very nearly placed the integrity of the food supply in jeopardy" [25].

12.3.3.3 Syngenta Bt Corn

The third and most recent event came to light in March 2005 when the seed company Syngenta revealed that it had accidentally sold approximately 146,000 tons of experimental Bt-10 corn that had been approved for experimental use only by USDA but was grown on 37,000 acres over a four-year period (2001–2004). The antibiotic marker gene is often used in the experimental phase of many genetically engineered plant studies to test for the presence or absence of altered genetics.

Although the fact that the Syngenta Bt-10 corn inadvertently entered the food chain raises questions about the effectiveness of the USDA regulatory system, especially after regulatory changes were put in place in response to the StarLink and Prodigene situations, the antibiotic marker gene entering the food supply has raised concern because of perceived problems with increased antibiotic resistance with human infections. Although many other factors contribute to antibiotic resistance, including their extensive use in farm animals, concern over the use of antibiotics in genetically engineered crops date back to the earliest days of genetically engineering when, in 1990, Calgene asked for an opinion concerning their use from FDA, and it was found that there was reasonable certainty no harm would result from its use. However, since that time, concerns are still being raised concerning their near ubiquitous use, whether in genetically engineered plants or in farm animals [26].

Although Syngenta officials argue that the release was relatively small, affecting 0.01% of all corn grown from 2001 to 2004 [23], and has not appeared to affect U.S. consumers, response from abroad suggests that U.S. producers will be affected in the export marketplace. Specifically, on April 15, 2006, the European Union placed a temporary ban on U.S. corn imports unless they are proven to be Syngenta Bt-10-free; on May 25, 2006, they enforced this ban by impounding a U.S. shipment of corn gluten upon its arrival in Ireland when it was found to be tainted with Bt-10. Likewise, in South Korea, imports of U.S. corn are being investigated with certification of future shipments as Bt-10-free required for entry, while most recently (June 1, 2006), a shipment of corn to Japan found to be Bt-10-contaminated was found and held [27].

As a result, Syngenta has been fined $375,000 and ordered to sponsor a compliance training conference by USDA [28–30]. However, the regulatory response appears to be subdued at best, especially in light of previous failures by biotechnology companies to implement federal regulations.

12.3.3.4 Conclusions

According to the 1984 Coordinated Framework for the Regulation of Biotechnology, USDA, EPA, and FDA are responsible for regulating agricultural biotechnology. Although this framework has proved to be serviceable for most of its existence, recent events suggest it is not meeting the challenges posed by the increased volume and variety of genetically engineered crops. The instances discussed above illustrate some of the problems facing U.S. regulators, especially the reduced trust in institutions. However, what is most important for producers is that an inefficient and ineffective regulatory system might push consumers elsewhere.

Although critics argue that the above cases show the system is working by identifying flaws in the regulatory system and changing practices of both government agencies and industry, in the end, consumer trust is what matters most. Although lost consumer trust in domestic markets is a threat, with StarLink-tainted products being recalled from grocer's shelves in 2000, long-lasting effects in the U.S. market have not materialized, especially when the recent Syngenta Bt-10 corn case is considered. International trade disruption, however, has occurred in both StarLink and Syngenta cases and has been costly in terms of trade with the European Union and with Asian trade partners South Korea and Japan. Perhaps most important, trust in the U.S. regulatory system by our trade partners is waning, with a recent editorial title concerning the Syngenta case in the respected science journal *Nature* underscoring diminishing respect: "Don't rely on Uncle Sam" [30].

12.3.4 PUBLIC RESPONSE TO PLANT-MADE PHARMACEUTICALS (PMPs)

Public response to PMPs suggests they are of two minds concerning PMPs. On the one hand, PMPs promise to offer tangible benefits that directly enhance the quality of life by producing less expensive pharmaceutical drugs that may treat a broader range of ailments. This perspective is bolstered in a recent PEW report that showed a strong relationship between perception of PMPs as being a good use of genetic engineering and the likelihood of it having a positive impact on the respondent's family [6].

On the other hand, the risks of PMPs entering the food supply or remaining in the environment as weeds gives pause to critics of the technology. The StarLink and Syngenta Bt-10 cases stand out as examples of the regulatory and food systems' failure to prevent the unwanted presence of genetically engineered crops in the food supply. Although the Prodigene case was a near miss, it also focused attention on the flaws in the regulatory system and may have had a chilling effect on the development of both PMPs and PMIPs. Although these three cases reflect "growing pains" in regulating the technology as more plant products with a greater variety of uses enter the fields, the question remains as to whether this problem will be endemic or a "mere blip" that has been dealt with and will not recur.

12.3.4.1 Interested Public/Pressure Group Comments

The amount of comments in response to the 2003 Federal Register notices dealing with changes to the regulation of PMPs and PMIPs, which in turn are arguably in

response to the Starlink and Prodigene incidents discussed in the previous section, reflect the new-found importance of the field release of genetically engineered plants to the public. The March 10, 2003 Federal Register notice concerning PMP and PMIP field testing requirements attracted at least 847 comments (of which 77 were late). In comparison, changes to the APHIS regulations in 1993 garnered 84 comments, whereas even more wide-ranging regulatory changes in 1997 attracted only 50 comments [31].

Although the numbers of comments received in response to PMP regulatory changes are exponentially higher than those received in response to prior Federal Register notices, multiple factors are responsible. E-government with electronic dockets easing comments on Federal rule-making has expanded public participation, especially with salient issues. For example, proposed organic standards posted in the Federal Register received an unprecedented 275,000 comments. Here, although the usual policy actors interested in genetically engineered plants are still involved, a high percentage of comments were sent by individuals and organizations not normally associated with this debate [32].

As expected, support for the new technology came from biotechnology and biotechnology-related companies, agricultural organizations, state agricultural departments, universities, and agricultural sector pressure groups. Critiques were also received from those who appeared to have ties with the organic movement or environmental groups, as evidenced by the roughly 600 comments e-mailed as cut-and-paste forwards.

Unexpectedly, especially in comparison with previous regulatory changes, concerns were raised by other powerful groups. Namely, the GMA and affiliated groups expressed concern over uncontained field release of PMPs and PMIPs, especially in food and feed plants. Interestingly enough, concern by consumer groups and traditional biotechnology opponents was tempered, likely mitigated by the potential for medical benefits from this new technology.

Comments by the interested public in response to the changes to PMP regulations give insight into concerns the general public may have once their awareness of these new technologies are raised, especially if PMPs and PMIPs enter into widespread production. A few themes stand out when comments of those critiquing the proposed USDA regulations are analyzed. The first theme concerns the science used and its effectiveness in regulating the threats posed by PMPs and PMIPs to the food supply and the environment. The next two themes expand on institutional distrust suggesting that governmental institutions, namely USDA, are either negligent, showing disregard for American farmers and the public by allowing these "dangerous" plants to be grown, or have been captured by corporate interests and are doing their bidding despite the threat posed. The risk perceptions of those commenting on the regulations suggest this technology is unknown, unnatural, uncontrolled, and likely to end in disasters disproportionately affecting future generations [32]. As can be expected by the foregoing responses, PMPs and PMIPs engender a good deal of fear and anger, emotional responses we deal with more systematically in the next section.

12.3.4.2 Public Opinion Concerning PMPs

Although the general public's opinion on PMPs is best analyzed through surveys, little research on their opinion has been carried out in the United States. In

Canada, Einsiedel and Medlock [33] carried out a series of focus groups analyzing attitudes toward PMPs and industrial products after providing information on plant molecular farming generally and five specific examples of this technology. Findings by them suggest greater support for novel medical products benefiting human health or the environment. Risk perceptions were driven by concerns over contamination of the food supply or the environment with higher risk seen as deriving from these products being grown outdoors in food plants that are able to go to seed or that flower, thus dispersing their genetic material to food plants that might be consumed by humans. When risk-benefit analyses were made, Einsiedel and Medlock found "acceptability is predicated on the idea that there are stringent approval processes and long-term measures in place to ensure safety" [33].

One exception to the lack of systematic public opinion research on PMPs is a study carried out by Stewart and McLean [7] using a telephone survey examining consumers living in Arkansas, Louisiana, Texas, Oklahoma, and New Mexico. This study was conducted between May 9 and June 10, 2004 by the Arkansas State University Center for Social Research using computer-assisted telephone interviewing (CATI) technology and had a very good response rate (a total of 680 interviews completed for a response rate of 61% and a margin of error of +/−3.5%). Exact wording of the questions are contained in Appendix A.

Five questions were asked of participants and ascertained personal benefits, likelihood of PMPs entering the U.S. food supply, the likelihood of respondents eating food from PMPs, how worried the respondents would be if they ate food with PMPs in it, and how angry they would be if they ate it without their knowledge. PMPs were characterized as "plants genetically modified to produce pharmaceutical drugs. These are plants that are modified to produce compounds used in manufacturing vaccines for diarrhea, antibodies to fight cancer, and drugs to treat such illnesses as cystic fibrosis."

Findings suggest the respondents have mixed feelings about PMPs. Generally speaking, PMPs are seen as presenting personal benefits to respondents, with two-thirds seeing either "a great deal" or "some benefit" (Figure 12.3-3). Of these, a plurality (36.5%) see a great deal of benefit for themselves, whereas only 12% see themselves as receiving no benefit at all from PMP-based products. Finally, only 12% had no opinion about PMPs.

Although respondents see benefits from PMPs, a majority see adventitious presence as likely to occur, with nearly 60% perceiving PMPs as accidentally entering the U.S. food supply. Only one fourth of respondents see this event as either "somewhat" or "very unlikely" to occur (Figure 12.3-4). Whether this pattern of response is because of the Starlink or Prodigene controversies discussed earlier in this chapter, because of a lack of faith in governmental and food production institutions to prevent this event from occurring, or the result of some other unspecified factor is not known; it may be assumed, however, that a relatively high level of public skepticism exists.

Although respondents see themselves as less likely to eat food with PMP components than see the potential for adventitious presence, those seeing it as either "very" or "somewhat likely" make up a substantial proportion of respondents, with a combined 45% (Figure 12.3-5). At the same time, 38% perceive themselves as able to avoid such foods, responding to the question that they are either "somewhat" or "very unlikely" to eat food coming from PMP plants.

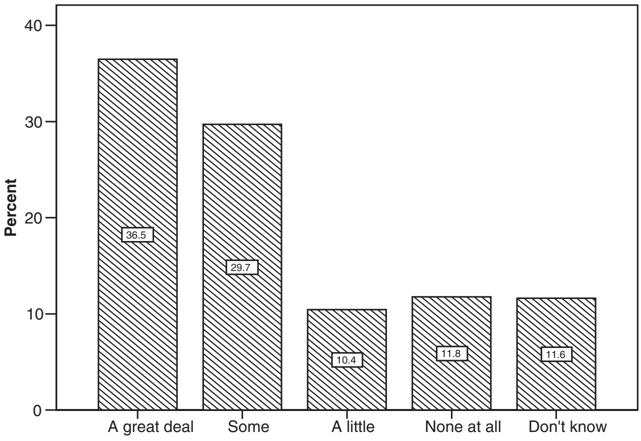

Figure 12.3-3. How much benefit would you get from PMP GM plants?

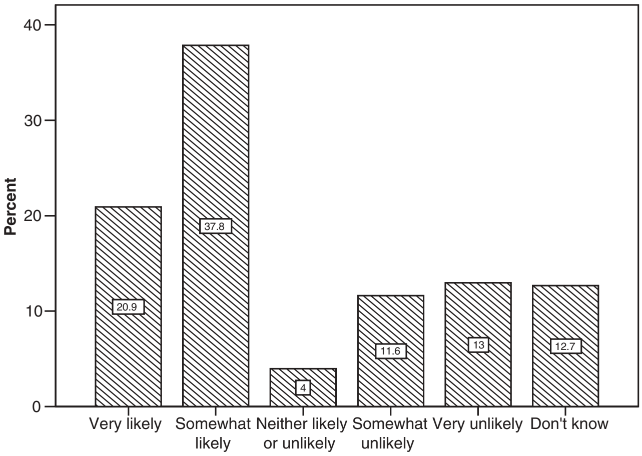

Figure 12.3-4. How likely is it that PMPs might accidentally enter the U.S. food supply?

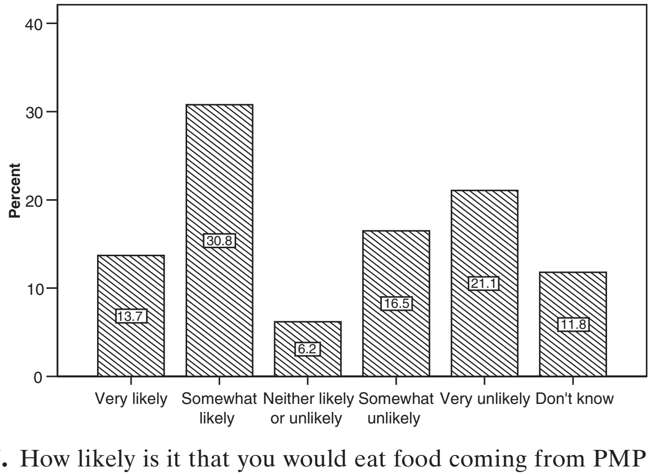

Figure 12.3-5. How likely is it that you would eat food coming from PMP GM plants?

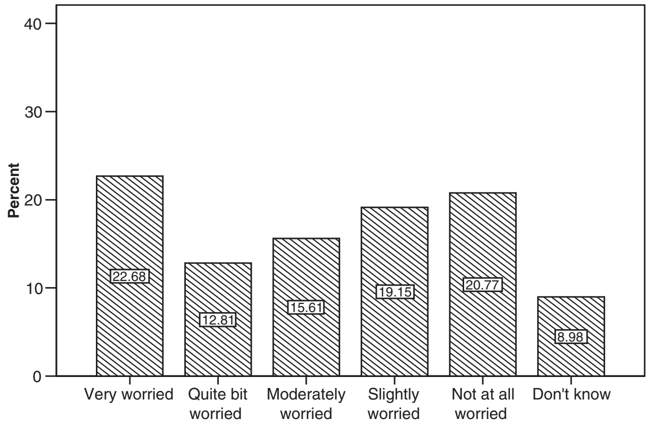

Figure 12.3-6. How worried would you be if you ate food from PMP GM plants?

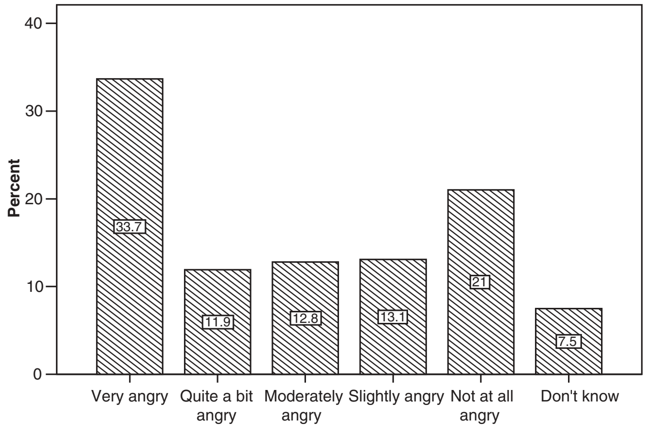

Figure 12.3-7. How angry would you be if you ate food from PMP GM plants?

Emotional response to eating food with PMPs in it suggests survey respondents are at least somewhat worried about the potential for it to occur (Figure 12.3-6). Overall, 23% are "very worried" and 13% are "quite a bit worried" about this event occurring. However, an increasing proportion of respondents show lesser levels of concern, with 16% "moderately worried," 19% "slightly worried," and 21% "not at all worried."

Although levels of concern are not as high as can be expected, great potential exists for upsetting the public. The pattern of response that can be seen in Figure 12.3-7 suggests polarized opinions. Specifically, one-third of respondents state they would be "very angry" if they ate food with PMPs in it without their knowledge, whereas only one-fifth of respondents would be "not at all angry."

12.3.4.3 Conclusions

Research available concerning public attitudes toward PMPs emphasizes it's "boundary technology" nature. Great promise and great risk are inherent in PMPs

because of the personal benefits of increased access to a wider array of pharmaceutical drugs balanced by their potential for accidental release into the food supply or the environment. These ambivalent feelings are likely to persist until either the benefits of PMPs are felt by their products entering the marketplace or an environmental or health catastrophe involving these products occurs. In either case, the absence of awareness of PMPs (and even genetically engineered plants) is a driving issue.

12.3.5 REGULATION OF PLANT-MADE PHARMACEUTICALS (PMPs) IN THE FIELDS

The regulation of PMPs will establish a different, potentially more circuitous, path to the marketplace because of its "boundary technology" nature. Although, as a pharmaceutical, it will be regulated in a traditional manner by FDA, as a plant, it must adhere to standards set forth by USDA. As a genetically engineered plant, it triggers a set of regulations specific to this technology as a whole, and as a PMP specifically, as discussed below.

On the whole, the regulation of agricultural biotechnology has attracted relatively little public involvement until recently, which is most likely because of its highly technical nature and the downstream nature of most of its products, which have predominantly been concerned with replacing or reducing production inputs such as herbicides and pesticides. More recently, the promise of new products and dearth of experienced difficulties in the field experiments have led to relaxed regulations. However, recent events detailed above have publicized and politicized the regulation of agricultural biotechnology with stricter regulations and greater scrutiny by an expanding range of parties with economic and political clout [34].

To address the decreasing trust in the regulatory structure, the Office of Science and Technology Policy (OSTP) published "Proposed Federal Actions To Update Field Test Requirements for Biotechnology Derived Plants and To Establish Early Food Safety Assessments for New Proteins Produced by Such Plants" in August 2002. Specifically, the notice was published to provide guidance to USDA, EPA, and FDA to update field testing requirements for food and feed crop plants and establish early food safety assessments for new plant proteins, most specifically PMPs and PMIPs, in line with the 1986 Coordinated Framework. Three principles in the document are relied on in updating the Coordinated Framework: (1) The level of field test confinement should be consistent with the level of environmental, human, and animal health risk associated with the introduced proteins and trait(s); (2) if a trait or protein presents an unacceptable or undetermined risk, field test confinement requirements would be rigorous enough to restrict outcrossing or comingling of seed and, further, the occurrence of these gene or gene products from these field tests would be prohibited in commercial seed, commodities, and processed food and feed; and (3) even if these traits or proteins do not present a health or environmental risk, field test requirements should still minimize the occurrence of outcrossing and comingling of seed, although low levels of genes and gene products could be found acceptable based on meeting applicable regulatory standards [19].

In light of concerns raised by increased experimentation with PMPs and PMIPs, and addressed by OSTP in their notice [19], USDA's Animal and Plant Health Inspection Service (APHIS) changed rules concerning their field testing of PMPs in March 2003 [35]. Although the resulting regulations are expected to be modified further over the coming years, they currently incorporate significant changes in how PMPs and PMIPs are regulated [36]. Specifically, for all plants genetically engineered to produce pharmaceutical or industrial compounds and field tested under permit, APHIS established seven conditions that can be grouped into three categories. The first considers field test siting, the second the dedication of equipment and facilities to their production, and the third considers procedural matters.

Field test siting regulations proposed by APHIS provide two conditions to be met, with special consideration for pharmaceutical corn. First, the perimeter fallow zone will be increased from 25 feet to 50 feet to prevent inadvertent comingling with plants to be used for food or feed. Second, production of food and feed plants at the field test site and perimeter fallow zone will be restricted for the following season to prevent inadvertent harvesting. Furthermore, specific permit conditions for pharmaceutical corn have been instituted, likely a result of corn being the organism of choice until the Prodigene event drew public concern and regulatory changes were put in place in its wake.

A second theme concerns the dedication of farm equipment and facilities to the production of such crops. First, APHIS requires planters and harvesters to be dedicated to the test site for the duration of the tests, and although tractors and tillage attachments do not have to be dedicated, they have to be cleaned in accordance with APHIS protocols. The equipment and regulated articles must be stored in dedicated facilities for the field test's duration.

The final three requirements from the proposed rules concern procedural aspects of dealing with field tests of PMPs and plants producing industrial compounds. First, APHIS requires submission of cleaning procedures to minimize risk of seed movement. Second, procedures for seed cleaning and drying are required to be submitted and approved to confine plant material and minimize risk of seed loss or spillage. Finally, permittees will be required to implement an APHIS-approved training program to successfully comply with the stated permit conditions [35].

A key factor in any regulatory arrangement is the ability to ensure that those regulated are complying with the requirements set forth. As a result of the potentially contentious nature of PMPs and plant-produced industrial compounds, APHIS plans to increase the number of field site inspections "to correspond with critical times relevant to the confinement measures" [35]. Therefore, in addition to maintaining records of activities related to meeting permitting conditions, and increasing the likelihood of audit-ing them to verify required permit conditions were met, APHIS might inspect permitted field tests up to five times during the growing season: once at pre-planting to evaluate the site location, once at the planting stage to verify site coordinates and adequate cleaning of planting equipment, at midseason to verify reproduction isolation protocols and distances, at harvest to verify cleaning of equipment and their appropriate storage, and again at post-harvest to verify cleanup of the field site. In addition, two post-harvest inspections may occur to verify that the regulated articles do not persist in the environment. Finally, APHIS may inspect more frequently if deemed necessary [35].

As a result of the potential for both PMPs and PMIPs entering into the food supply, and using the PMP regulatory changes as a starting point, APHIS took immediate action to remove the notification track option, requiring complete permit track review in their recent (August 6, 2003) interim rule and request for comments [36].

The rationale given in the interim rule and request for comments was that although 14 field releases (9 notifications, 5 permits) had been carried out to date, the type of genetic engineering being carried out was to enhance such nutritional components as oil content. However, recent genetic modifications have been for "non-food traits with which APHIS has little regulatory experience or scientific familiarity" [36]. As such, the definition of PMIPs has three criteria: (1) the plants produce compounds new to the plant; (2) this compound has not normally been used in food or feed; and (3) the compound is being expressed for non-food/feed purposes [36].

An administrative reorganization of how USDA-APHIS regulates biotechnology created the Biotechnology Regulatory Services (BRS) to address concerns raised by PMPs and PMIPs specifically and genetically engineered organisms generally. According to USDA-APHIS, "Given the growing scope and complexity of biotechnology, now more than ever, APHIS recognizes the need for more safeguards and greater transparency of the regulatory process to ensure that all those involved in the field testing of GE crops understand and adhere to the regulations set forth by BRS."

Changes instituted by BRS include new training for APHIS inspectors in auditing and inspections of field trials, the use of new technologies such as global positioning systems, and analysis of historical trends to inform monitoring and inspection. According to APHIS, there are nine overarching goals that the changes will serve with key components being: (1) enhanced and increased inspections in which risk-based criteria, along with other factors, will be used to assess field test sites with higher-risk sites being inspected at least once a year, with other sites being randomly selected for yearly inspections; (2) auditing and verification of records of businesses and organizations to verify accuracy and implementation; (3) remedial measures to protect "agriculture, the food supply, and the environment in the event of compliance infraction" with the establishment of a "first-responder" group to deal with serious infractions; (4) standardized infraction resolution in which criteria will be established to determine the extent of an infraction and the response, whether further investigation, the issuance of a guidance letter, the issuance of a written warning, or referral to APHIS' Investigative and Enforcement Services (IES) unit for further action; (5) documentation, in which a database will be set up to track field test inspections and resulting compliance infractions, and transparency to keep stakeholders and the public informed on the regulatory decision-making process; (6) continuous process improvements where, as the science of biotechnology advances, so too will regulations and permit conditions to allow safe field testing; (7) an emergency response protocol, being developed with input from EPA and FDA, in which a quick response plan will be put in place "to counteract potential impacts on agriculture, the food supply, and the environment"; (8) training for field test inspectors in their dealings with PMP and PMIP field test sites, as well as the latest in auditing; and (9) certification concerning compliance with the highest level of auditing standards [37].

Although the reorganization can be seen as streamlining and focusing enforcement efforts, the potential for unduly high levels of workload stresses placed on this 26-member unit can be foreseen. First, BRS draws on APHIS inspectors to inspect field tests; however, more than 2600 of these agriculture quarantine inspectors have been transferred to the Department of Homeland Security [36]. The current agreement between USDA-APHIS and DHS allows for continued access by APHIS and BRS, although it can be expected that problems might occur as a result of split responsibilities and duties.

Implementation considerations are still an issue. Although thousands of field tests have been carried out in a variety of sites through the USDA-APHIS field permitting, notification, and petitioning program, these tend to be short-term tests, typically lasting for one growing season and collecting limited data that considers the ecological effect. Little work has been done in the way of long-term effects on the ecology of the regions in which they are sited.

Also, although genetically engineered plants have been in the fields for at least a decade, in the case of herbicide-tolerant and pest-resistant plants, their management has left something to be desired with large numbers of farmers not following federal regulatory standards [38, 39]. Although USDA states that of the 7402 field tests carried out between 1990 and 2001 and regulated by APHIS, only 115 resulted in compliance infractions and, for the most part, these were relatively minor infractions that did not raise public concern [40], concerns still exist. However, regarding PMPs, because of the regulations concerning them and the potential for controversy, it is likely that the regulations will be more stringently followed.

12.3.6 CONCLUSIONS

The "boundary technology" nature of PMPs places it firmly into limbo in terms of social acceptability and, ultimately, economic viability. In terms of benefits, the opportunities afforded by this subset of genetic engineering of plants are in terms of increased diversity of products, reduced production costs, scalability on relatively short notice, and reduced potential for health risks of toxicity and pathogenicity because of less-easily crossed species barriers. The risks of unintentional movement of genes into other plants or the entry of PMP products into the food supply, however unrealized to date, loom large. These threats are especially salient in light of likely scaling up of plantings of PMPs and greater diversity of PMP products. And when current regulatory difficulties are taken into account, it is an especially daunting challenge.

Although the potential benefits of PMPs are large and the risks may be perceived as negligible, even if such products enter the food supply as feared, public opinion looms large in whether this boundary technology is accepted. Given that most Americans are not aware of their current consumption of genetically engineered foods and the extent of their market presence, PMPs entering the food supply would likely be their first "real" exposure to the risks of genetically engineered plants. The resulting response—apathy, hysteria, or somewhere in between—would have an extremely large impact on the future of PMPs and their growth, which is not to discount the effect of other factors that may hasten or retard the development of PMPs. Economic climate, government policies and regulations, international

trade, and a slew of other factors will impact the future of PMPs. What remains is the question of how far and how fast this technology will develop.

APPENDIX I: PLANT-MADE PHARMACEUTICALS QUESTIONS

I would next like to ask you a few questions about plants genetically modified to produce pharmaceutical drugs. These plants are modified to produce compounds used in manufacturing vaccines for diarrhea, antibodies to fight cancer, and drugs to treat such illnesses as cystic fibrosis.

How much benefit do you believe you would personally get from this type of plant? (1, a great deal; 2, some; 3, a little; 4, none at all; 8, DK; 9, refused)

How likely is it that these types of plants might accidentally enter the U.S. food supply? (1, very likely; 2, somewhat likely; 3, neither likely nor unlikely; 4, somewhat unlikely; 5, very unlikely; 8, DK; 9, refused)

How likely would you be to eat food coming from this type of plant? (1, very likely; 2, somewhat likely; 2, neither likely nor unlikely; 4, somewhat unlikely; 5, very unlikely; 8, DK; 9, refused)

How worried would you be if you ate food coming from this type of plant? (1, very worried; 2, quite a bit worried; 3, moderately worried; 4, slightly worried; 5, not at all worried; 8, DK; 9, refused)

How angry would you be if you ate food coming from this type of plant without your knowledge? (1, very angry; 2, quite a bit angry; 3, moderately angry; 4, slightly angry; 5, not at all angry; 8, DK; 9, refused)

Utrecht Institute for Pharmaceutical Sciences, Utrecht University, Utrecht, The Netherlands

When a patent of a drug expires, competitors are allowed to introduce copies of the drug to the market. In the case of classic drugs, which are in general produced by chemical synthesis, a submission for marketing approval needs to contain data showing the generic to be chemically identical to the innovative drug, e.g., with spectroscopic and chromatographic separation techniques, and pharmaceutically acceptable [1]. In addition, in the case of oral products, the bioavailability of the generic product must be shown to be equivalent to that of the reference product as assessed by the results of pharmacokinetic studies demonstrating an equivalent rate and extent of absorption. Bioavailability studies are typically conducted in healthy volunteers in whom the geometric means for pharmacokinetic parameters such as area under the drug plasma concentration-time curve (AUC) and maximum observed plasma concentration (C_{max}) fall within an acceptable range (usually no more than ±20% with a 90% degree of confidence). These bioequivalence requirements make the assumption that two chemically identical products that demonstrate an identical pharmacokinetic profile will also have identical clinical effects. Thus, the randomized clinical trials conducted to demonstrate safety and efficacy that are required for the approval of innovator products are not necessary for the approval of conventional generics as the data generated with the original product can be extrapolated to the generic. Long-term experience with chemical drugs and the availability of sophisticated methods for analysis ensure that the generic products are safe and effective. Because the company marketing a generic product does not need to make the large investments necessary to develop and launch an innovative drug and can take advantage of the extensive experience and possible extensions of the indications gained during the period the drug was patent protected, the price of a generic is relatively low. The introduction of a generic also leads to

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.
Copyright © 2007 John Wiley & Sons, Inc.

a price drop of the original product. Because reducing health costs is a political priority, most countries promote the introduction and use of generics. The competition with generics is also an important incentive for the innovator to improve the original poduct. So generics are an essential part of the innovation cycle of drugs.

For several reasons the classic generic paradigm can only partly be extrapolated to therapeutic proteins [2–5]. The major reasons are listed in Box 12.4-1. Protein pharmaceuticals are mostly large complex molecules showing heterogeneity. This heterogeneity can be due to natural processes in the host cells such as variations in glycosylation or protein clipping. Modifications of the product can also be introduced during production, purification, formulation, and storage. Besides these product-related impurities, host cells and (biological) materials used during production and purification may introduce process-related impurities.

Therapeutic proteins are manufactured by complicated processes, and all steps in production, purification, and formulation may influence the biological and clinicial properties of the final product. The different steps are, therefore, carefully monitored by analytical methods using in-house standards. These analytical methods have, in part, been developed (or at least refined) for each specific product. For many products and especially the first for which the patents will expire shortly, the production process has undergone continuous improvement based on manufacturing and clinical experience.

The features of a particular biopharmaceutical are the result of the basic characteristics of the molecule such as amino acid sequence and three-dimensional structure as well as the specific production, purification, formulation, and storage conditions (Box 12.4-2). To produce a biopharmaceutical of constant required quality, a company also needs the experience and the in-house standards to apply the methods used to analyze the structure of a given product. There are various guidelines of the European Medicine Evaluation Agency, the Food and Drug Administration, the Japanese Ministry of Health and Welfare, and the ICH, which require manufacturers to show that they control the production process and are capable of reproducibly manufacturing batches that not only meet product specifications, but also conform to the definition of the product as established through full characterization. Modifications of the established process are only accepted if the manufacturer can show that the product of the new process is comparable with the initially manufactured product. Comparability studies include revalidation of

BOX 12.4-1. CHARACTERISTICS OF THERAPEUTIC PROTEINS

- Size
  —100–500 times larger than classic drugs
  —Cannot be completely characterized by physico-chemical methods
- Immunogenicity
- Structural heterogeneity
- Relatively high biological activity
- Relatively unstable

BOX 12.4-2. FACTORS INFLUENCING THE ACTIVITY OF THERAPEUTIC PROTEINS

- Gene and promotor
- Host cell
- Culture conditions
- Purification
- Formulation
- Storage and handling
- Unknown factors

BOX 12.4-3. WHAT IS IN A NAME?

- Biogenerics
- Second entry biologicals
- Subsequent entry biologicals
- Off-patent biotech products

the process, reevaluation of process and product-related impurities, recharacterization of the product in side-by-side analyses by all available state-of-the-art methods, and stability studies with the product from the new process in addition to release testing. When considered relevant, these comparability studies also may include clinical studies examining the pharmacokinetic, pharmacodynamic, and immunogenic properties of the new product and some efficacy and safety studies as well.

Little, if any, of the expertise, analytical methods and in-house standards, specifics of the production process, historical process, and validation data or full characterization data required for comparability assessment of therapeutic proteins are available in the public domain. As a rule, they are proprietary knowledge. It is inconceivable, in most cases, that another manufacturer, on the basis of the patent or published data, is able to manufacture a protein pharmaceutical that can be assumed similar enough to the original innovative product that only a limited documentation of physico-chemical characteristics would be sufficient to show equivalence. In most cases only limited data are available in pharmacopoeial monographs and scientific papers. Moreover, even the most sophisticated analytical tools are not sensitive enough to fully predict the biological and clinical characteristics of the product.

Because the generic approach is not applicable to protein drugs, the term *biogenerics* is considered misleading. Other terms have been used over the years, which are listed in Box 12.4-3. Similar biological medicinal products is the official

TABLE 12.4-1. Expiration of Biologics in the United States (US) and European Union (EU)

Pioneer Company	Product	Indication(s)	US Patent/ Market Exclusivity Expires	EU Patent/ Market Exclusivity Expires
Genentech	Nutropin™ (somatropin)	Growth disorders	Expired	Expired
Abbott	Abbokinase™ (eudurase urokinase)	Ischemic events	Expired	Expired

terminology in the European Union (EU), but biosimilars has become the preferred terminology both in scientific and regulatory discussions and publications and will also be used in this chapter.

Table 12.4-1 shows the expiration dates of the patents of several recombinant DNA-derived therapeutic proteins. The patents of products as interferon alpha and epoetin alpha have already expired, and others will follow shortly. Table 12.4-1 also shows the patent and data protection to last longer in the United States than in Europe. This partly explains why the regulations regarding the conditions for marketing authorization in the EU are more developed than in the United States.

In the EU legislation, which became effective in November 2005, biosimilars have been set apart from the generic drugs. Clinical data have legally become mandatory for a marketing authorization submission for biosimilars to the EMEA, which like innovative biotechnology products will need to be evaluated through a centralized procedure and not by national regulatory approval. However, the European regulators do not require a full dossier; the idea of extrapolation of data as with classic generics is maintained, as it is considered unethical to ask for a complete set of clinical data. The CHMP, the scientific committee of the EMEA, has issued several guidelines concerning the data required for marketing authorization. The main issues of these guidelines are listed in Box 12.4-4 [6–8].

Only biosimilars of therapeutic proteins marketed within the EU are allowed. A biosimilar marketing authorization submission should contain the same

BOX 12.4-4. MAIN ELEMENTS CHMP GUIDELINES CONCERNING BIOSIMILARS

- The concept of similar biological product is applicable to any biological medicinal product, but it is more likely applied to highly purified products, which can be thoroughly characterized
- In order to support pharmacovigilance monitoring, the specific product given to the patient should be clearly identified
- The active substance of the biosimilar product must be similar in molecular and biological terms to the active substance of the reference medicinal product e. IFN alpha 2a is not similar to IFN alpha 2b
- The same reference product throughout the comparability program
- The pharmaceutical form, dose, and route of administration of the biosimilar and the reference product should be the same
- If the reference product has more than one indication, the safety and efficacy for all indications have to be justified or demonstrated for each indication separately
- The clinical safety must be monitored on an ungoing basis after marketing approval
- The issue of immunogenicity should always be addressed, and its long-term monitoring is necessary

extensive data on quality and safety as an innovative protein drug. In addition, the submission needs a supplement showing similarity in quality safety and efficacy between the biosimilar and the same reference product.

A biosimilar is defined as any therapeutic protein by its own manufacturing process that may influence the characteristics of the product itself but also introduce specific process-related impurities. The producers of biosimilars therefore need to demonstrate consistency and robustness of their production process. They need to do formulation studies showing stability and compatibility, even if the formulation is identical to the reference product.

The generation of comparative data concerning physico-chemical characteristics and preclinical testing will be complicated because unformulated bulk material of the innovator protein is unavailable to the biosimilar manufacturer. So the competitor can only use formulated marketed material. For some analytical techniques, isolation of the protein from the formulation is necessary. This may induce modifications that can hamper the comparisons. Comparing with the biosimilar isolated from the same formulation is being used to compensate for these possible modifications.

The biosimilar producer needs to do at least one comparative trial, usually a clinical trial with a sufficient number of patients to give the statistical power to find differences in efficacy and safety. The results may be extrapolated to other indications if the mode of action in other disease conditions is identical and the toxicity profile comparable with the population suffering from the other conditions. An example could be interferon alpha 2. If the biosimilar is proven to be similar in efficacy with the innovator protein in chronic hepatitis C virus infection, it will also be active in hepatitis B. However, an extension to cancer indications such as hairy cell leukemia would be blocked by a different mode of action in cancer and a different toxicity profile in tumor patients. For example, the immunogenicity of interferon alpha 2 is significantly different in cancer patients compared with patients with viral infections.

An important issue in the regulatory guidelines is immunogenicity, which is considered a major difference between protein drugs and low-molecular-weight drugs [9–11]. According to the CHMP guidelines on biosimilars, the issue of immunogenicity always needs to be addressed. There are only limited possibilities for the prediction of immunogenicity *in vitro* or in animal studies. This implies that the immunogenicity always needs to be monitored in clinical trials. The assay strategy and the assays employed need to be validated. Moreover, the assays need to meet specifications that allow the detection of immunogenicity differences between the biosimilar and the innovative protein therapeutic.

Sometimes the incidence of the induction of antibody formation in patients is too low to be evaluated in the clinical trials of the biosimilar, but the consequences are so severe that this side effect needs to be excluded for a biosimilar as is the case with epoetin-associated pure red cell aplasia. This can only be accomplished by strict postmarketing surveillance protocols.

The companies marketing biosimilars will need to show their capacity to manage postmarketing protocols, not only to monitor rare side effects but also because the biological and clinical characteristics of therapeutic proteins cannot be completely predicted by physico-chemical analyses, and possible batch-associated side effects need to be identified.

Another specific problem of protein therapeutics is their relative instability, which calls for strict regimens in storage and handling. In principle, protein drugs need a cold chain that is maintained from the manufacturing plant until administration to the patient. The CHMP has indicated that biosimilar producers need to show that they control the distribution of their products.

Nearly all innovative proteins are being administered parentally. They are mainly prescribed by hospital medical specialists for sometimes relatively rare, knowledge intensive conditions needing individualized treatment and specific diagnostic facilities. The marketing of biosimilars needs therefore to be accompanied by specific information to ensure their proper and safe use.

Considering the large investments manufacturers have to do to develop, produce, distribute, and market biosimilars, a large price drop by their introduction will be unlikely. Unlike with classic generics, the market will not be conquered by price alone, but the biosimilar manufacturers and distributors need to show quality and added value of their products.

Another consequence of the relative modest price drop by the introduction of biosimilars on the expensive biotechnology-derived protein drug treatments will be the attractiveness for racketeers to counterfeit protein drugs. Several biosimilars have been produced for many years in countries where patent protection or enforcement is lacking. The quality of these products varies (Figure 12.4-1). Proteins as epoetin, growth hormone, and insulin are also popular as performance enhancers in sports. This is an important part of the illegal demand. Both unbranded products as well as counterfeits, which look like authorized products, have been discovered. Counterfeits of therapeutic proteins have also been detected in the regular medical supply chains of these products. And products as growth hormone are also popular among the illegal drugs offered by the Internet (Figure 12.4-2).

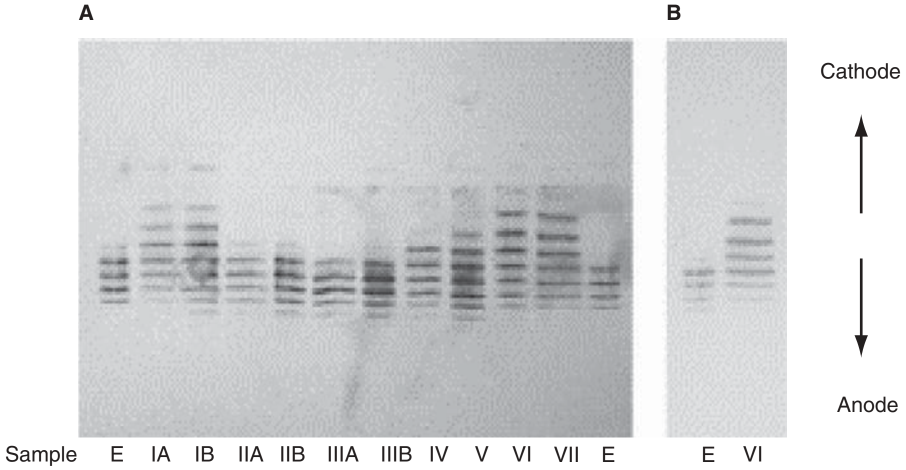

Figure 12.4-1. An example of biosimilar epoetins. This figure shows epoetin alpha's marketed in Asia and South America analyzed by iso-electrical focusing. The different products show large differences in isotype content. Difference can also be seen between different batches of the same manufacturer (IA and IB; IIA and IIB; IIIA and IIIB). E is the epoetin alpha marketed in Europe.

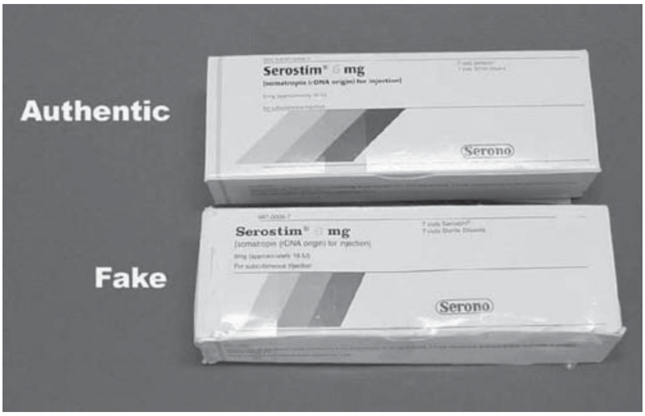

Figure 12.4-2. An example of a counterfeited growth hormone.

In Europe the first patents of protein drugs have expired and the legal conditions for launching biosimilars have been met, the general guidelines describing the regulatory demands have been implemented, and product-specific draft guidelines are under evaluation. The first marketing authorization requests have been submitted, and the marketing of these products will follow in 2006.

The biggest uncertainty concerning biosimilars is the level of similarity the regulatory bodies will find acceptable [12–13]. The only definition of a biosimilar that can be given is a protein that is similar in quality, safety, and efficacy to a reference product. Still, similarity is a matter of taste. Differences between products will always be found, and the question the regulatory agencies need to answer is how relevant these differences are. This is not an easy question because structurally comparable products can show significant differences in biological and clinical properties [14]. There are also examples of products with comparable clinical effects but considerably different structures. With room for interpretation about what a biosimilar is, legal procedures by the innovator or the generic industry challenging the decisions of the EU about marketing authorizations are to be expected. So, in the end the European Court of Justice will define what is a biosimilar.

13.1.1 BACKGROUND

The rapid progress in molecular medicine has sought to understand the molecular basis of human disease with an ultimate goal of developing rationally designed therapies. The *gene discovery phase* has been largely driven by key technological advances including polymerase chain reaction (PCR) and other strategies and

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

methods, high-throughput sequencing, and bioinformatics. Now that the genome is sequenced, there are ongoing efforts to identify genetic polymorphisms (e.g., single nucleotide polymorphisms, SNPs) that may point to disease predisposition or unique responses to therapy such as untoward drug side effects.

Presently, physicians have to optimize a dosage regimen for an individual patient by a trail-and-error method. This kind of blind approach may cause adverse drug reactions (ADRs) in some patients. In fact, ADRs are found to occur in more than 2 million hospitalizations including approximate 100,000 deaths per year in the United States [1]. Similarly, according to a German study, about 6% of ADRs are attributed to new hospital admissions, and these ADRs were found to be preventable [2].

This interindividual variability in drug response could be caused by multiple factors such as disease determinants, genetic and environmental factors, and variability in drug target response (pharmacodynamic response) or idiosyncratic response. These factors affect drug absorption, distribution, metabolism, and excretion [3]. Drug concentrations in plasma can vary more than 600-fold between two individuals of the same weight on the same drug dosage [4]. An understanding of the variability in efficacy and toxicity of the same doses of medications in the human population, therefore, may provide safer and efficient drug therapy.

In general, genetic factors are estimated to account for 15–30% of interindividual differences in drug metabolism and response; but for certain drugs or classes of drugs, genetic factors are of the utmost importance and can account for up to 95% of interindividual variability in drug disposition and effects [4].

The idea that drug response is determined by genetic factors that alter pharmacokinetics and pharmacodynamics of compounds evolved in the late 1950s, when an inherited deficiency of glucose-6-phosphate dehydrogenase was shown to cause the severe hemolysis observed in some patients exposed to the antimalarial primaquine. This discovery explained why hemolysis was observed mainly in African-Americans, in whom the deficiency is common, and rarely in Caucasians of northern, western, and eastern descent [5]. In 1959, Vogel coined the term pharmacogenetics to describe inherited differences in drug responses [6].

Later in 1962, W. Kalow defined **pharmacogenetics** as ". . . the study of heredity and the response to drugs" [7]. It is a well-recognized fact that individuals respond differently to drug therapy; some drugs that are effective or well-tolerated by some people may be ineffective or toxic to others. This variability can often be traced by SNPs in genes encoding drug-metabolizing enzymes, transporters, ion channels, and drug receptors, all of which have been known to be associated with interindividual variation in drug response and have aroused considerable interest in recent years [8].

Taken together, pharmacogenetics is the study of genetic polymorphisms in drug-metabolizing enzymes and the translation of inherited differences to the variability in drug effects. Genes are described as "polymorphic" when allelic variants exist in the population, one or more of which alters the activity of the encoded protein compared with the wild-type sequence. Typically, the polymorphism leads to reduced activity of the encoded protein. Although the focus of pharmacogenetics is the study of drug-metabolizing enzymes like the CYP family, polymorphisms in drug transporters (such as P-glycoprotein) band drug targets (such as receptors) have also received attention.

The original task of pharmacogenetic research is to aid physicians in the prescription of the appropriate medicine in the right dosage in an attempt to attain maximum efficacy and minimum toxicity based on a genetic test, performed before the initiation of the therapy. The new paradigm moves toward the approach of screening for polymorphisms associated with a drug response and tailoring clinical and therapeutic decisions for an individual patient. This strategy of targeting drugs according to the patient's genetic constitution is termed "personalized medicine" [8, 9].

Toward the goal of personalized medicine, after completion of the human genome project, a haplotype map (HapMap) has been developed by the International HapMap Consortium with an intention of profiling DNA sequence variations across the human genome, which should provide a powerful tool to understand the genetic variants and drug responses (biomarkers). This knowledge may ultimately allow the development of personalized medications based on the genotype of each patient [10].

The term "**pharmacogenomics**" was introduced to reflect the transition from genetics to genomics and the use of genome-wide approaches to identify genes that contribute to a specific disease or drug response. A pharmacogenomics approach could allow a specific drug therapy to be targeted to genetically defined subsets of patients and could lead to a new disease and treatment classification on the molecular level.

Although the "blueprints" of human disease and for the drug action may be genetically encoded, the execution of the disease process and the pharmacodynamics of a given drug occurs through altered protein function. Researchers in molecular medicine are currently going from genomics to proteomics. One goal for clinical proteomics will be to characterize the information flow within single cells, tissues, or entire organisms under normal or disease conditions [11]. Therefore, identifying the genetic or epigenetic events leading to wanted or unwanted effects of drugs requires subsequent understanding of the proteomic consequences of these events. Therefore, **pharmacoproteomics** are focused on the influence of drugs on protein–protein interactions, their localization, or whether the encoded proteins are stable expressed, phosphorylated, cleaved, acetylated, glycosylated, or functionally "active." Mounting evidence confirms that the low-molecular-weight (LMW) range of circulatory proteome contains a rich source of information that may be able to detect or better characterize drug–protein interactions and stratify toxicological risk. Current mass spectrometry (MS) platforms can generate a rapid and high-resolution portrait of the LMW proteome. Emerging novel nanotechnology strategies to amplify and harvest these LMW biomarkers *in vivo* or *ex vivo* will greatly enhance our knowledge about pharmacoproteomics [12]. As an example for an pharmacoproteomic approach, it was found that in comparison with tamoxifen-sensitive breast tumor cells, in an tamoxifen-resistant line, 12 proteins were found upregulated, whereas nine were downregulated. Three of the identified proteins (AGL-2 interacting protein and two GDP-dissociation inhibitors) could be directly involved in the resistance phenomenon [13]. Curiously enough, the erythrocyte sedimentation reaction (ESR), which could be defined as a primitive forerunner of functional proteomics, has been used for a long time for clinical diagnostics and for monitoring of pharmacological therapy.

Although genetic variation is clearly important, it seems unlikely that personalized drug therapy will be enabled for a wide range of major diseases using genomic knowledge alone. Therefore, a third modern possibility for enabling personalized pharmacological therapy is the phenotyping by **pharmacometabonomics**. A major factor underlying interindividual variation in drug effects is variation in metabolic phenotype, which is influenced not only by genotype but also by different factors such as *in utero* effects, lifestyle, nutritional status, the gut microbiota, age, disease, environment, and the co- or pre-administration of other drugs. A new approach to personalized drug treatment is the examination of the metabolic profile. The profile, which is a measurement of small molecules such as sugars and amino acids, could be used to predict the pharmacodynamic or toxic response to drugs [14].

Pharmacometabonomics use a combination of pre-dose metabolite profiling and chemometrics to model and predict the responses of individual subjects. ^{1}H nuclear magnetic resonance (NMR) spectroscopy has been applied as a metabolite profiling tool for metabonomic studies, as it enables many endogenous metabolites to be quantified rapidly and reproducibly in biological fluids without derivatization or separation. Pharmacometabonomics has an important theoretical advantage over pharmacogenomics in that it can potentially take account of both genomic and environmental factors affecting drug-induced responses [15].

However, because the time of practical use of pharmacoproteomics and pharmacometabonomics is obviously more distant from today as such for the genetic approaches, we will focus this chapter more on pharmacogenetics and pharmacogenomics. The present knowledge certainly does not allow or recommend individualized therapy on the basis of pharmacoproteomics as well as pharmacometabonomics. They are not ready for profound optimization of clinical drug application or rationale drug development to become a reality in the near future. Intensification of research capacities is assumed, providing optimism for personalized medicine.

In the following sections, depending on the target respective, selected examples for the influence of genetic variability on the drug response are discussed. In most of the cases, we will cite publications from the first half of the year 2006, indicating the enormous progress in this field in the last months. For excellent reviews on individualized therapy solely from 2006, see Refs. 4, 8, 14, 16–25.

13.1.2 DRUG METABOLIZING ENZYMES

A considerable body of evidence suggests that SNP in genes encoding drug-metabolizing enzymes might determine drug efficacy and toxicity. The cytochrome P450 (CYP) enzymes consist of a superfamily of haem-containing monooxygenases, and multiple forms of CYP exist in all mammals. CYPs are responsible for the oxidation of many drugs, environmental chemicals, and endogenous substrates. They exist in the liver and in extrahepatic tissues such as the intestine, lung, and kidney. In humans, xenobiotics are metabolized primarily by three CYP subfamilies: CYP1, CYP2, and CYP3 [26, 27] (Table 13.1-1). Genetic polymorphisms of the genes for CYP2C9, CYP2C19, and CYP2D6 affect the metabolism of 20–30% of clinically used drugs. The frequency of variant alleles of CYP families varies among populations according to the race and ethnic background [28].

TABLE 13.1-1. Selected Drugs Metabolized by Various Cytochrome P450 (CYP) and Other Enzymes

Enzyme	Drug
CYP1A2	Imipramine, Tacrine, Propranolol
CYP1B1	17β-Estradiol, Estrone, Testosterone, Tamoxifen
CYP2B6	Carbamazepine, Efavirenz
CYP2C8	Paclitaxel, Carbamazepine
CYP2C9	Cyclosporine, Ifosfamide, Etoposide Nefazodone, Losartan, Warfarin, Tamoxifen, Phenytoin
CYP2C19	Omeprazole, Lansoprazole, Citalopram, Thalidomide
CYP2D6	Fluoxetine, Paroxetine, Desipramine, Amitryptiline, Imipramine, Nortryptilin, Maprotilin, Metoprolol, Propranolol, Tamoxifen
CYP 3A (responsible for the oxidative metabolism of more than 50% of clinically used drugs)	
CYP3A4	Amitryptiline, Imipramin, Cyclosporine, Docetaxel, Epipodophyllotoxin, Erythromycin, Losartan, Diazepam, Carbamazepine, Nefadozone, Nifedipine, Omeprazole, Terfenadine, Chlorpyrifos (Insecticide), Testosterone, Estradiol, Progesterone, and synthetic sexual steroids
CYP 3A5	Etoposide, Vincristine, Midazolam
CYP7A1	17α-Ethinylestradiol, Statins
CYP7B1	17α-Ethinylestradiol
CYP8B1	17α-Ethinylestradiol
Dihydropyrimidine Dehydrogenase (DPD)	Fluorouracil, Capecitabine, Nifedipine
Glucuronosyl transferase	Labetalol, Morphine, Naloxone
Glutathione—Transferase (GST)	
GSTA1	Cyclophosphamid
GSTM1	Anthracyclines (Doxorubicin, Idarubicin, Mitoxantrone)
GSTM3	Cisplatin
GSTP1	Etoposide, Doxorubicin, Cisplatin, Oxaliplatin, Carboplatin
GSTT1	Prednisolon
N-Acetyltransferase	Amonafide
S-Methyltransferase	Captopril
Sulfotransferase1A1 (SULT1A1)	Tamoxifen
Thiopurine Methyltransferase (TPMT)	6-Mercaptopurine, Azathioprine, Methotrexate
Uridine Diphosphate Glucuronosyltransferase (UGT)	Irinocetan, Etoposide, Epirubicine, Tipifarnib

For instance, there are 78 reported variants of CYP 2D6 that associated with adverse drug reactions. Many of these polymorphic genes encode inactive enzymes. However, these inactive enzymes may produce adverse drug reactions among patients because of their poor metabolic activity (e.g., the adverse effects of the neuroleptic risperidone) [29].

Similarly, several inactivating genetic polymorphisms have been reported in another member of the CYP family, namely CYP2C19 (CYP2C19*2 and CYP2C19*3), which is also associated with adverse drug reactions. This enzyme is responsible for the metabolism of proton pump inhibitors (e.g., omeprazole and lansoprazole) used for the treatment of gastric acid-related disorders such as peptic ulcer and gastroesophageal reflux disease. Approximately 2–4% of Caucasians and 4% of African-Americans have poor metabolism of these drugs [26]. Poor metabolizing patients of proton pump inhibitors carry two nonfunctional alleles, heterozygous extensive metabolizers have one nonfunctional and one wild-type allele, and extensive metabolizers are homozygous for the wild-type allele [4].

Another example is the coumarin warfarin, which is widely used for oral anticoagulation. Major side effects include bleeding complications. It was found that CYP2C9*2 and CYP2C9*3 alleles reduce the clearance of warfarin and increase the risk of bleeding [30]. The data indicate that patients carrying at least one variant CYP2C9 allele require lower maintenance doses and have a significantly higher risk of bleeding. However, SNPs in vitamin K epoxide reductase (VKORC1) may be more important. Recent studies have identified haplotype-dependent predictions for warfarin dosing. VKORC1 haplotype A predicted 21–25% of the required warfarin dose, and the inclusion of CYP2C9 genotypes reduced the required warfarin dose up to 31% in Caucasians. Combining nongenetic factors such as age, sex, body surface area, and drug interactions with the genotype information predicts up to 60% of warfarin dose. The remaining 40% of warfarin dosing variability remains unexplained [31].

CYP2C9*13 allele is associated with reduced metabolism of lornoxicam [32]. Similarly, CYP2C8 plays a role in the disposition of some therapeutic drugs [33].

The intestinal epithelium and liver contain the most abundant member of the CYP family, namely CAP3A, and these enzymes are responsible for the metabolism of more than half of the therapeutic drugs. Its activity also varies among members of a given population. In addition, this enzyme may undergo induction (rifamycins) and inhibition (calcium channel blockers) depending on the drug administration, which may account for its poor or higher metabolic activity. The interindividual variation in the immunosuppressive drugs cyclosporine and tacrolimus could be caused by interindividual differences in the expression of CYP 3A4 and 3A5 and the drug transporter P-glycoprotein. The most frequent allelic variant of CYP3A5 is CYP3A5*3, with a frequency of 87% of all alleles in a French population [34, 35].

An important P450 database in terms of genetic polymorphisms is the CYP alleles database (http://www.imm.ki.se/CYPalleles). However, genetic variants identified in the CYP3A4 and CYP3A5 genes have only a limited impact on the CYP3A-mediated drug metabolism [36], and hence the identification of the genotype for the ABCB1 transporter gene may provide further clues for the individualization of therapy with certain drugs (see below).

Apart from CYPs, some other enzymes involved in the biotransformation of drugs include *N*-acetyltransferase (NAT), glutathione-*S*-transferase, and uridine

diphosphate-glucuronosyl transferase 1A1 (UGT1A1). One of the earlier discoveries of pharmacogenetics is the attribution of the neurological side effects of the antituberculosis drug isoniazid to genetic variability of NAT2. A 98.1% correlation between genotyping of NAT2 and acetylation phenotype has been demonstrated using an allele-specific PCR [37].

Gastric cancer patients treated with 5-FU and cisplatin and possessing the glutathione S-tranferase PI-105 Valine/Valine (GSTPI-105VV) genotype showed a response rate of 67% and medial survival time of 15 months compared with 21% and 6 months, respectively, in patients harboring one GSTPI-105 Isoleucine (GSTPI-1051) allele [38].

Pharmacogenetics of the UGT1A1 gene is known to influence irinotecan-induced diarrhea mediated via the glucuronidation of the active metabolite SN-38 [39]. Irinocetan is an inhibitor of topoisomerase used for the treatment of lung and colon cancer in adults and pediatric solid tumors such as rhabdomyosarcoma and neuroblastoma. The presence of seven repeats, instead of the wild-type number of six (UGT1A1*28) is associated with reduced UGT1A1 expression, leading to reduced SN-38 glucuronidation. It has been shown that the UGT1A1*28 allele leads to significantly increased amounts of SN-38 and a heightened risk of irinocetan-caused diarrhea and leukopenia. Patients homozygous or heterozygous for seven TA repeats have a sevenfold higher likelihood of diarrhea or leukopenia with irinocetan therapy than do patients with the wild-type genotype (six repeats). In a study conducted on Asians, UGT1A1*28 was found to be a common allele in Indians [40]. Thus, it is possible that UGT1A1 genotyping can be used to predict toxicity to irinocetan therapy. The UGT database contains data on genetic polymorphisms of the various UGT alleles (http://som.flinders.edu.au/FUSA/ClinPharm/UGT).

A good example for clinical reality of pharmacogenetic methods is the very frequently performed test for pseudocholinesterase. Inherited deficiency in pseudocholinesterase activity results in prolonged respiratory paralysis when deficient patients receive standard doses of the neuromuscular blockers suxamethonium or mivacurium [41].

13.1.3 DRUG TRANSPORTERS

Genetic variability in drug transporters also plays an important role for individual drug response (see Table 13.1-2). For instance, polymorphism in the ABC-binding cassette (ABC) gene may affect the function and expression of proteins [42] by inducing tumor cell resistance to anticancer therapy, altered disposition of chemotherapeutic agents, and associated chemotherapy toxicity, which may cause certain drug-induced side effects and uncertainty in treatment efficacy. ABCB1, also known as P-glycoprotein (Pgp) alias MDR1 for multidrug resistance, is a member of the ABC family that participates in the energy-dependent efflux of various substrates. A synonymous polymorphism in exon 26 (C345T) was found to influence drug response and exhibit interethnic variability [43]. The importance of haplotype analysis was shown by a meta-analysis of the influence of this SNP on digoxin pharmacokinetics and Pgp gene expression [44].

The ABCB1 genotype of the donor, but not of the recipient, may be a major risk factor for cyclosporine-related chronic nephrotoxicity in recipients of renal transplants. The ABCB1 3435TT genotype, which is associated with lower Pgp

TABLE 13.1-2. Selected Drug Transporters Associated with Individual Variations in Drug Response

Protein	Drug
P-Glycoprotein; Synonyms: Multidrug Resistance 1 (MDR1, ABCB1)	Digoxin, Vinblastine, Vincristine, Irinocetan
Multidrug Resistance-Associated Protein 2 (Canalicular-Multispecific Organic Anion Transporter, MRP2; ABCC2)	Doxorubicin, Vinblastine, Sulfinpyrazone, Irinocetan, SN38, Methotrexate
Breast Cancer Resistance Protein (BCRP, ABCBG2, ABCP)	Mitoxantrone, Methotrexate, Doxorubicin, Camptothecin-based drugs like Topocetan and SN-38
ABCG5/8	17α-Ethinylestradiol
Na^+/taurocholate cotransporting polypeptide (NTCP)	17α-Ethinylestradiol
Organic Anion Transporter Polypeptide-1B1 (OATP1B1; *SLCO1B1*)	Irinocetan
OATP1/2	17α-Ethinylestradiol
OATP1A2 (OATP-A)	Ajmalin, DHEA-Sulfate, 17β-Estradiol, Estrone, Microcystin, N-Methyl-quinidine, Ouabain, Prostaglandin E_2, Rocuronium, Thyroxin (T4), Triiodothyronine (T3)
OATP1B1 (OATP-C/OATP2)	Atorvastatin, Cerivastatin, Fluvastatin, Benzylpenicillin, Rifampicin
OATP1B3 (OATP8)	CCK-8, Digoxin, Fexofenadine, Paclitaxel

expression in renal parenchymal cells, is strongly associated with cyclosporine nephrotoxicity (odds ratio 13.4) [45]. On the other hand, the cyclosporin disposition in heart transplant patients may be influenced by Pgp haplotypes rather than genotypes [46].

Genetic polymorphisms in ABCB1 and ABCg2 may be important also in influencing the pharmacokinetics of irinotecan and its metabolites (see above).

Another notable example is that in certain patients the reduced rate of methotrexate metabolism produced a severe methotrexate overdosing and nephrotoxicity. This defect is attributed to the heterozygous mutation (R412G) in the highly conserved amino acid arginine [47] of the ABCC2 gene, which encodes the human multidrug resistant protein-2 (MRP-2). Interestingly, this mutated region is associated with substrate affinity and hence the mutant protein has a reduced rate of methotrexate elimination. In some other cases, a long-term use of methotrexate induces pancytopenia, which is determined by white blood cells and platelet counts [48]. However, it is also known that polymorphisms always need not have to produce functionally defective proteins. For example, in the multidrug resistant gene (MDR1), certain polymorphisms may not have any effect on the drug response [49]. However, this could be caused by nonsignificant statistical power.

Gwee et al. [50] have devised a rapid and robust assay to simultaneously screen SNPs of the MDR1 gene using a single-tube multiplex minisequencing strategy. Finally, there are several web-based transporter databases (http://www.tp-search.jp; http://www.gene.ucl.ac.uk/nomenclature/genefamily/abc.html and http://lab.digibench.net/transporter).

13.1.4 ION CHANNELS

Organic anion transporting polypeptides (OATPs) mediate the uptake of a broad range of compounds into cells. Substrates for members of the OATP family include bile salts, hormones, and steroid conjugates as well as drugs like the HMG-CoA-reductase inhibitors (statins), cardiac glycosides, anticancer agents like methotrexate, and antibiotics like rifampicin. The identification and functional characterization of naturally occurring variations in genes encoding human OATP family members is in the focus of transporter research [51]. There is a high degree of functional heterogeneity among OAT3 variants, with three variants (p.Arg149Ser, o.Gln239Stop, and p.Ile260 Arg) that results in complete loss of transporter function, and several other variants with significantly reduced function [52].

Common variation in the gene SCN1A affects the maximum dose of phenytoin and carbamazepine, which act on the sodium channel subunit encoded by this gene [53].

The etiology of drug-induced long QT syndrome (LQTS) could also be based on gene variability. A life-threatening form of cardiac arrhythmia has been associated with mutations in the ion channel genes [54]. Therefore, screening of LQTS-associated genes before the initiation of therapy with known QT-prolonging drugs could serve as a precautionary measure against life-threatening adverse effects by avoiding such drugs.

13.1.5 DRUG RECEPTORS

Genetic polymorphisms in drug receptors may alter pharmacological response. For example, variations in β-adrenoceptors, angiotensin-converting enzyme (ACE), and 5-hydroxytryptamine (5-HT) receptors alter drug response to β-adrenoceptor agonists and blockers, ACE inhibitors, and antipsychotic agents, respectively (see the sections cardiovascular dugs and drugs acting on the CNS in this chapter).

Genetic polymorphisms affecting amino acids at positions 16 and 27 within the β_2-adrenoceptor gene have been implicated in the asthma phenotypes and influence on the variability observed in response to use bronchodilator agents. It was found that Arg16 allele was slightly more frequent within the group with the unwanted tachyphylaxis phenomenon, whereas Gly16 allele carriers were overrepresented within the group of good responders (59.7%, $P = 0.0028$). On the other hand, the allele frequency of Gln27 and the proportion of Gln27 carriers was higher within the group with tachyphylaxis and Glu27 allele carriers were overrepresented within the group of good responders ($P = 0.026$) [55]. For asthma, see the section "Cardiovascular Drugs" in this chapter.

Concerning pharmacogenetic aspects of hormone receptors, see the "Endocrinology" section in this chapter.

13.1.6 CANCER DRUGS

Cancer chemotherapy is an area that requires continual monitoring and adjustment of antineoplastic agents to achieve optimal therapeutic outcome, which makes pharmacogenetic approaches attractive in this field.

Drugs such as azathioprines, mercaptopurines, and thioguanine have been used extensively to treat childhood acute lymphoblastic leukemia, rheumatic disease, inflammatory bowel disease, and used for solid organ transplantation. Thiopurine S-methyltransferase (TPMT) is a cytosolic enzyme that is involved in the metabolism of thiopurines (Table 13.1-1). It has been shown that polymorphisms in TPMT result in severe toxicity for patients prescribed with normal doses of the cytotoxic agents mercaptopurine or azathioprine. The variant enzyme was shown to misfold and subsequently form aggresome [56]. It has been reported that the TPMT genotype has a substantial impact on the mercaptopurine treatment response [57]. Previous studies also have shown that patients with homozygous mutant TPMT alleles exhibit very low enzyme activity and develop a severe hematopoietic toxicity after treatment with standard doses of thiopurines [58–60]. TPMT-deficient patients tend to accumulate excessive thioguanine nucleotide concentrations and are, therefore, at higher risk for hematological toxicity. TPMT deficiency can be largely attributed to three mutant alleles (TPMT*2, TPMT*3A, and TPMT*3C). Allele-specific PCR or PCR-restriction fragment length polymorphism strategies have been used to detect the three signature mutations, hence offering a rapid and affordable assay for identifying >90% of all mutant alleles [61]. Today, one of the most frequently performed pharmacogenetic tests are for TPMT. Patients who inherit two nonfunctional variant alleles should be given 6–10% of the standard dose of thiopurines. TPMT deficiency has also been associated with a high risk of irradiation-induced brain tumors in patients given thiopurines concomitantly with radiation therapy [62].

Similarly, the response rate of 5-fluorouracil (5-FU) -based treatment of advanced colorectal cancer is significantly linked to 677 C $\rightarrow$ T polymorphism in the methylenetetrahydrofolate reductase gene [63]. Additionally, polymorphisms in the thymidylate synthase gene promoter (TYMS enhancer region, TSER) has been linked to tumor downstaging in patients with rectal cancer who were treated preoperatively with 5-FU-based chemoradiation. In a study of 65 patients with stage T2–T4 rectal cancer, patients with at least one TSER*2 allele had a 38% increased frequency of tumor downstaging at the time of surgical resection compared with TSER*3/TSER*3 patients [64].

The first genotype-guided clinical trial in North America is based on TYMS TSER genotype. Rectal cancer patients (stage T3 and T4) with the "good risk" TSER*2 allele are treated in a phase II study consisting of standard therapy (radiation and 5FU). The sample size was calculated to detect a downstaging rate of 60%, compared with the historical downstaging rate of 45%. Patients homozygous for TSER*3 ("bad risk" genotype) are also enrolled in a phase II study, in which they receive the standard radiation and 5-FU along with additional irinocetan. The sample size was calculated to detect an improvement from the previously reported TSER*3/TSER*3 downstaging rate of 22–45%. Preliminary data implied an improved response rate in both treatment groups, suggesting an enrichment for positive response [22].

Genetic polymorphisms in the epidermal growth factor receptors (EGFR) impact on pharmacological response to gefitinib and erlotinib, tyrosine kinase inhibitors used as monotherapy in the treatment of metastatic non-small cell lung cancer. The drugs are effective in only 10–15% of patients. Responders were found to harbor activating mutations in the gene coding for EGFR [65]. The EGFR assay for tumor mutation analysis provides a platform in personalized therapy with the EGFR inhibitors gefitinib or erlotinib (http://www.dxsgenotyping.com).

The use of the other tyrosine kinase inhibitor imatinib, which blocks the enzymatic action of the BCR-ABL fusion protein, has represented a critical advance in chronic myeloid leukaemia (CML) treatment. However, a subset of patients initially fails to respond to this treatment. Use of complementary DNA (cDNA) microarray expression profiling, a set of 46 genes was differentially expressed in imatinib responders and non-responders. A six-gene prediction model was constructed, which was capable of distinguishing cytogenetic response with an accuracy of 80% [66].

Another case of already practical use of pharmacogenetic methods is the test for mutations in tumors that overexpress the human EGFR, HER2. Trastuzumab, a humanized monoclonal antibody, is effective in only 10–15% of breast cancer patients whose tumors overexpress HER2 [67]. Therefore, the pretreatment detection of HER2 is essential for the trastuzumab therapy.

13.1.7 CARDIOVASCULAR DRUGS

Variation in two genes encoding angiotensin-converting enzyme and endothelial nitric oxide synthase influence the effects of standard therapies [68]. In addition, polymorphism in the sodium channel gamma-subunit promoter region is significantly associated with blood pressure response to hydrochlorothiazide [69]. Similarly, SNPs in angiotensinogen (T1198C), apolipoprotein B (G10108A), and adrenoreceptor alpha 2A (A1817G) significantly predict the change in left ventricular mass during antihypertensive treatment [70]. Although common variants may influence the blood pressure response to a given class of antihypertensive medication, studies of polymorphisms have generally provided conflicting results [71]. For instance, polymorphisms in the alpha 2B adrenergic receptor does not show any association with azepexole hypertensive response [72]. However, patients with Gly 389 variant and Ser 49 homozygous of the beta-adrenergic receptor require increases in heart failure medication [73, 74].

One study has reported that the effect of statins in lowering low-density lipoprotein (LDL)-cholesterol levels was slightly greater in -204AA homozygotes of CYP7A1 [75].

Most of the studies to date have failed to demonstrate any link between polymorphism in tumor necrosis factor alpha and both cardiomyopathy and coronary artery disease [76].

In the case of asthma that causes substantial economic burden, morbidity, and mortality, patients exhibit an extensive interindividual variation in the response to beta-agonists acting at beta 2 adrenergic receptors, which could be caused by one nonsynonymous polymorphism [1772M9 of adenylyl cyclase type 9 (AC 9)] gene. This variation results in decreased catalytic activity (M772) and, therefore, alters

albuterol (bronchodilator) responsiveness in the presence of a corticosteroid [77]. Additionally, in an Indian population, response to salbutamol treatment of asthmatic patients depends on polymorphism of the beta 2 adrenergic receptor [78].

13.1.8 DRUGS ACTING ON THE CNS

A meta-analysis of the quantitative contribution of CYP2D6 polymorphism to the interindividual variation in dosage of antidepressants has shown that the metabolism and dosage of imipramine, doxepin, maprotiline, trimipramine, desipramine, nortryptiline, clomipramine, and, partially, paroxetine depend on the CYP2D6 genotype and phenotype. Pharmacokinetic data suggest dose adjustments for these drugs that range from 28% to 60% of the normal dose for poor metabolizers and from 180% to 14% of the normal dose for ultrarapid metabolizers. In general, based on the impact of CYP2D6 on dosage adaption of antidepressants and antipsychotics, 40–50% of drugs may be subject to important pharmacokinetic alterations owing to CYP2D6 polymorphism [79].

A considerable variability also exists in efficiency and toxicity of other antipsychotic drugs. For instance, in the case of mood disorder, approximately 30–40% of patients do not completely respond to pharmacological treatment [80, 81]. However, serotonin transporter gene promoter (5HTTLPR) length polymorphisms has been implicated in the pathogenesis of mood disorders as well as in the therapeutic response to serotonergic drugs [82]. Reduction in the Liebowitz social anxiety scale and in the brief social phobia score during treatment with serotonin reuptake inhibitors (SSSRIs) was significantly associated with 5HTTLPR genotype [83]. When patients were treated with serotonin-blocking antidepressants, a significantly higher occurrence of side effects was found in patients with the HTTVNTR2.10/2.10 genotype (52.6%) than in patients with the 2.10/2.12 (12.5%) and 2.12/2.12 (0%) genotypes [84].

In patients with schizophrenia, Taq I polymorphism in the dopamine D2 receptor is associated with greater improvement of symptoms after treatment. Similarly, Gly 9 allele (Ser 9 Gly) of the dopamine D3 receptor and His 452 Tyr polymorphism in the 5-hydroxytryptamine 2A receptor (5-HT2A) are associated with response to clozapine. The side effects (weight gain) induced by antipsychotics seems to be associated with the -759C allele of the 5-HT2C receptor. Additionally, Gly 9-variant of dopamine D3, the 102C-variant of the 5-HT2A, and the Ser 23-variant of the 5-HT2C receptors (in females) seem to increase the susceptibility to tardive dyskinesia [85, 86].

Epilepsy is a difficult disease to treat because different patients require different ranges of doses, and some patients may even experience side effects such as increase in seizures, depression, and double vision. To control epilepsy, drugs such as phenytoin and carbamazepine have been extensively prescribed throughout the world. At present, evaluation of the allelic variation between individuals relies on the prior identification of candidate genes and their therapeutic effects of antiepileptic drugs [87]. Variants in the CYP2C9 and SCN1A (encodes a brain protein) genes are often found in patients treated with the highest doses of both phenytoin and carbamazepine [53]. Additionally, in Han Chinese, the carbamazepine side effects like Stevens–Johnson syndrome and toxic epidermal necrolysis are strongly associated

with the HLA-B*1502 gene, which also means that genetic susceptibility to carbamazepine-induced cutaneous adverse drug reactions is phenotype-specific [88]. Pharmacoresistant epilepsy is still a major clinical problem in epilepsy, and it could be caused by multiple factors, but also multidrug transporters may play a key role in resistance phenotypes. However, studies on one variant in the ABCB1 gene provided inconclusive evidence so far [89].

Long-term treatment of Parkinson patients with L-Dopa exhibits L-Dopa-induced dyskinesis in some patients, which could be caused by genetic polymorphisms among patients. Therefore, pharmacogenetic studies may provide an explanation of neuronal plasticity among Parkinson patients [90].

Furthermore, drug addictions are major social and medical problems and therefore impose a significant burden on society. Epidemiological, linkage, and association studies have shown a significant contribution of genetic factors to the addictive diseases. Studies of polymorphisms in the mu-opioid receptors and transporter genes have contributed significantly to the knowledge of genetic influence on opioid and cocaine addiction and the efficacy of opioid therapy in pain management [91–94].

13.1.9 ENDOCRINOLOGY

At present, a lot of scientific efforts are being employed to use pharmacogenetics/pharmacogenomics for protein/peptidergic hormone therapy as well as for treatment with steroids. The main topics are polymorphisms in the membranous and nuclear receptors, including their subtypes and isoforms, and the genetics of steroid transforming enzymes (aromatases, 5α-reductases, sulfotransferases). It seems that, in comparison with other fields of pharmacological approaches, the pharmacogenetics in endocrinology are relatively advanced and, in certain parts, ready for clinical use.

Growth hormone receptor (GHR) transcripts exist in several isoforms in humans, among which is the retention (GHRfl) or exclusion (GHRd3) of exon 3, which encodes a 22-residue sequence in the extracellular domain of the membrane-located receptor. In Western Europe an populations, it has been estimated that 68–75% of alleles are GHRfl, whereas 25–32% are GHRd3. In short children, the homozygous or heterozygous presence of GHRd3 resulted in a significantly greater growth response in both year 1 and year 2 of GH therapy [95, 96]. Logically, patients who are homozygous for GHRd3 were less responsive to short-term and long-term hGH therapy [97].

Exogenous sexual hormones are used worldwide by women as oral contraceptives and hormonal replacement therapy. Some epidemiological studies have shown an increased risk of venous thromboembolism (VTE). It was found, that the risk/benefit ratio could be, in part, mediated by the genetic predisposition of women. Genetic thrombophilia might be implicated in the risk of VTE patients who use exogenous hormones.The most common causes of genetic hypercoagulability known today are factor V Leiden, G20210A prothrombin polymorphisms, and the genetic variant C677T of the methylenetetrahydrofolate reductase (MTHFR) gene. Therefore, an increasing number of kits for these two thrombophilic mutations are becoming commercially available, and screening for inherited thrombotic risk

before giving the "pill" is among the most requested genetic tests in molecular diagnostic laboratories [98].

It seems that use of oral contraceptives or postmenopausal hormone replacement in women with the germ line mutations in the two genes BRCA1 and BRCA2 are more at risk for breast cancer than women also carrying these mutations but without hormonal interventions [99].

CYP1A2, CYP2C19, and CYP3A5 are responsible for estrone oxidation. These enzymes are all known to be genetically variant in the human population, and studies to asses the role of these CYP P450 enzymes in breast cancer risk are indicated [100].

The estrogen receptor-subtype ERα mediates the hepatotoxicity of 17α-ethinylestradiol (EE2). Upon EE2 treatment, ERα represses the expression of bile acid and cholesterol transporters (bile salt export pump, BSEP), Na^+/taurocholate cotransporting polypeptide (NTCP), OATP1, OATP2, ABCG5, and ABCG8 in the liver [101]. The genetic variability of some of these transporters is well known and could explain, at least in part, the interindividual differences for the tolerability of oral contraceptives.

Estrogen receptor α variations increase or decrease the action of estrogens; but, at present, no clinical studies are available that show that pharmacogenomic checking of ERα before estrogen-treatment (OCs or hormone replacement) can reduce the risk of adverse drug reactions.

The progesterone receptor 660L allele (PGR-12(rs1042638)V660L) may be associated with a moderately increased risk of breast cancer [102].

The polymorphism of UDP-glucuronosyl transferase (UGT2B17) is strongly associated with the bimodal distribution of the testosterone excretion [103].

Interestingly enough, besides the encouraging findings of genetics in the field of clinical endocrinology, proteomic approaches on the effects of estrogens, progestins, and androgens on the mammary gland are advancing step-by-step [13, 104, 105].

And what happens with diabetes mellitus? In 525 Caucasian type 2 diabetic patients, the common E23K variant of KCNJ11 encoding the pancreatic β-cell adenosine 5′-triphosphate-sensitive potassium channel subunit Kir6.2 was associated with increased risk for secondary failure to treatment with sulfonylurea-like glibenclamide [106].

13.1.10 ENVIRONMENTAL FACTORS

Needless to say, the genetic background and the gene variability is only one aspect of pharmacodynamics. Apart from potential gene–gene interactions, drug actions are also deeply affected by gene-environment interactions such that a particular genetic marker may present a variable pharmacological response in individuals with different nutritional states, lifestyle habits, and general well-being. Thus, the genetic information is not a reliable predictor of drug response, and therapeutic drug monitoring, with several notable exceptions, remains generally empirical. The sum and substance is as follows: Prescription genotyping serves more a predictive rather than a diagnostic role [8].

Here, we give only two examples for the role of the environment. Interindividual variability has been seen in liver UDP-glucuronosyltransferase 1A6 (UGT1A6)

enzyme activity that glucuronates various drugs and toxins (Table 13.1-1). Its expression is associated with polymorphisms in the 5′-regulatory and exon 1 regions. The three most common non-synonymous polymorphisms are S7A, T181A, and R184S. However, it did not explain the interindividual variability in glucuronidation and alcohol consumption, which suggests that environmental factors may have a significant role in alcohol consumption [107, 108]. Similarly, alcohol dependence is not associated with single-nucleotide polymorphisms in the corticotrophin releasing hormone receptor 1 (CHRH 1) gene [109].

13.1.11 ETHNICITY

To use genomic knowledge to develop drugs and to improve health, we need to consider ethnical differences in different populations [110, 111]. There exists inter-ethnical differences in polymorphisms of genes encoding drug metabolizing enzymes, transporters, and disease-associated proteins [112, 113]. Meanwhile, a population genetics-based method to calculate the probability value for a variation in the gene is proposed [114]. Genetic differences are greater within socially defined racial groups than between other groups [115]. Additionally, it has been found that genetic diversity decreases in noncoding regions, whereas diversity of coding non-synomous SNPs is lower in regions containing a known protein sequence motif in individuals of European origin [116].

Drug treatment may be tailored for greater effect if important genetic variation exists between racial and ethnic groups. By knowing these variants, patients can be classified into low-, intermediate-, and high-dose groups [31, 117]. For instance, coumarins are characterized by a narrow therapeutic index and a wide interindividual variability in dose response; daily maintenance doses of warfarin range from less than 1 mg to over 20 mg [30] and, additionally, warfarin therapy shows a wide variation among patients of different ancestries. This variation could be caused by polymorphisms in the gene encoding vitamin K epoxide reductase complex 1. Accordingly, Chinese patients require lower dosages of heparin and warfarin than those usually recommended for white patients [118, 119]. Additionally, the combination of isosorbide dinitrate and hydralazine for treatment of heart failure in African-American heart patients reduced mortality by 43%, claiming that African-Americans and Caucasians differentially respond to the treatment, which is claimed to be because of genetic differences in the pathophysiology of heart failure between the two groups [120]. In other words, biological differences exist between the two racial groups. However, in this study, there is no comparison population and hence results should be interpreted cautiously. The distribution of haplotype profile of MDR1 (Pgp, ABCB1) has also been shown to exhibit inter-ethnic variabililty [121].

The ethical and moral concerns that develop in the midst of genetic testing are factors that hamper the development of personalized medicine. The deciphering of the genetic code may pose a threat to the protection of one’s privacy. Moreover, some variants that predict drug response are also markers for disease predisposition. For example, the apolipoprotein E4 allele known to influence response to cholesterol-lowering (statin) is also associated with an increased risk of Alzheimer’s disease, which may subsequently lead to medico-legal implications, such as the issue of data confidentiality and the possibility of stigmatization: whether

employers and insurance companies should be given rights to asses the genetic data and the chance of the information falling into the hands of unauthorized parties. In addition, a positive result for a genetic determinant underlying therapeutic failure for a critical illness may inflict additional emotional trauma and dampen the willpower of the patient to combat the disease [8].

Nevertheless, the debate on the biological basis of race and ethnicity and pharmacogenetics may provide a useful understanding of ethnic and racial differences. Even in this case, however, we should not ignore several important parameters such as diet, economic, environmental, and psychosocial factors. However, pharmacogenetic studies on race and ethnicity are worthwhile because they are useful indicators of genetic variation. However, this kind of race and ethnicity classification for medical treatment could lead to discrimination [122].

13.1.12 TECHNOLOGICAL ASPECTS

Mutation screening technologies can generally be categorized into mass screening for novel variants and specific genotyping approaches. Although the former approach is more often adopted in academic research to uncover novel mutations and unravel functional consequences, the latter is more suited for practical diagnostic purposes. Rapid, precise, and cost-effective high-throughput technological platforms are essential for performing large-scale mutational analysis of genetic markers. However, genotyping techniques have generally been laborious in nature, rendering large-scale analysis time-consuming and inefficient from a cost perspective. However, SNP detection technologies have recently evolved to some of the most highly automated, robust, and affordable methods in biomedical research. Genotyping is often performed in conjunction with phenotyping (e.g., pharmacometabonomics) [8].

It is not the task of this chapter to discuss the advantages or disadvantages of the different technological platforms and bioinformatics tools in detail. Only a short presentation is possible (for review, see Ref. 8). Commercially provided services, such as Signature Genetics (http://www.signaturegenetics.com) are based on the analysis of integrated results from a detailed genetic test and comprehensive questionnaire. The report addresses the efficacy and toxicity of medications, potential drug interactions, and customized information on nutrition and recommended lifestyle modifications. Another example of a personalized medicine company (DxS, Manchester, U.K.) is focused on SNP testing, haplotyping, and clinical genotyping. DxS has applied the Amplification Refractory Mutation System and Scorpions (a homogenous fluorescent PCR detection system) technologies to the development of a highly sensitive oncology test panel [123].

The Roche AmpliChip CYP Genotyping test is FDA-approved and combines Roche's PCR amplification technology and Affymetrix high-density microarray technology to allow rapid, simultaneous analysis of multiple SNPs within the CYP family. This genotyping strategy relies on the hybridization of complementary fluorescent-tagged DNA sequences to an array of sequence-specific oligonucleotide probes (http://www.roche-diagnostics.com/press_releases/archive/2003_06_25.html). Drug MEt is another microarray-based pharmacogenetic test used for simultaneous detection of 29 SNPs of CYP and phase II enzymes involved in drug

metabolism (http://arrayit.com/Products/Microarray/DrugMEt/drugmet.html). Invader UGT1A1 Molecular Assay is an *in vitro* diagnostic test for genotyping UGT1A1 alleles and is FDA-approved. This assay appears to be an accurate method for the rapid detection of UGT1A1 polymorphisms (http://www.ons.org/fda/documents/FDA93995insert.pdf).

The TRUGENE Human Immunodeficiency Virus (HIV-1) Genotyping Kit and OpenGene DNA Sequencing System is yet another example illustrating the use of genetic testing in personalized medicine. TRUGENE is a sequence-based assay designed for detecting HIV genomic mutations (in the protease and part of the reverse transcriptase regions of HIV) that confer resistance to certain antiretroviral drugs. The assay has been shown to be robust, reproducible, and accurate and is considered a significant advance in the treatment of HIV infection [124].

New technologies like matrix-assisted laser desorption ionization-time-of-flight (MALDI-TOF) mass spectrometry (MS) and GOOD assay (requires no purification steps) have to bring in wider use. The next challenge is the demand for more accurate, economical, and large-scale technologies for SNP association studies. There are several review papers describing the technological platforms in pharmacogenetic research [8, 125–127].

The technological challenges for pharmacoproteomics are exceptional (see Table 13.1-3). Protein microarrays are an emerging class of nanotechnology for tracking many different proteins simultaneously. However, translation into the medical practice is very slow. On the other hand, proteomic changes in cultured cell lines might not fully reflect pharmacodynamic interactions because of the lack of the tissue microenvironment [11].

Although the molecular genotyping and phenotyping techniques are well established in major research institutes, the facilities for genetic testing and measurement of parent and metabolic concentrations are not always accessible in the diagnostic laboratory. Furthermore, mutational screening using the current state-of-the-art technology is still laborious and time-consuming. The hassle of having to courier samples to an external laboratory and the turnaround time for sample processing diminish the feasibility of adopting the approach in the fast-paced healthcare setting.

TABLE 13.1-3. The Hurdles for Protein Compared with Nucleic Acid Analysis in Human Tissue [11]

• More than 1 million proteins estimated (compared to 22.000 human genes)
• More than 300 posttranslational modifications known (phosphorylation, glycosylation)
• Wide dynamic range for protein abundances: 10^{10} (for mRNA:10^4)
• No protein amplification method available (comparable to PCR in genomics)
• Specific detection methods (only a few very good antibodies available)
• Senstivity (fM to aM needed, like ELISA)

PCR, polymerase chain reaction
ELISA, enzyme linked immunosorbent assay
fM, femtomolar (10^{-15} molar)
aM, attomolar (10^{-18} molar)

13.1.13 LIMITATIONS

A big problem limiting the progress of the pharmacogenetic approach is the fidelity of genotyping results and the confidence in associating SNPs with altered drug response. The ambiguity that sometimes develops in classifying an individual's genotype based on the laboratory results is another important contributory factor. In addition, the phenotyping method may give rise to false-positive results because the metabolic ratio can be influenced by other factors, such as epigenomic signaling, concomitantly administered drugs, nutritional state, and general health, hence affecting the validity of genotype-phenotype correlations [8].

The exact association between many SNPs of the drug target genes with therapeutic outcome is still unclear. However, few mutations have been characterized to ascertain their potential functional severity and limited definitive functional correlates established. As such, the functionality of these SNPs and their causative role remain largely speculative. In cases of functionally characterized SNPs, care should be exercised when translating research findings into an investigative tool, particularly in the extrapolation of observations from *in vitro* studies to a physiological effect. Even if the pharmacokinetic parameters are altered by genetic variants, the impact on pharmacodynamic or therapeutic effects may not be apparent. No standard guidelines exist on how the dosages of a drug should be adjusted, as a specific drug target may affect its panel of substrates to different extents, which increases the complexity of drug prescription because the dose adjustments differ among the various substrates in individuals carrying the same gene mutation [8].

Clinical use of pharmacogenetic testing has been severely limited by a lack of prospective clinical trials. Such trials are required to establish that pharmacogenetic testing benefits the selection of the appropriate drug and dose for the individual patient, thereby improving therapeutic responses or reducing ADRs. One key point that will affect the integration of pharmacogenetics into clinical practice will be the cost-effectiveness of these approaches, which may be influenced by several factors. Drugs with a narrow therapeutic index with more severer and expensive side effects are ideal candidates for pharmacogenetic testing. Drugs for which there are no established methods for monitoring adverse events (e.g., methotrexate) are also best-suited for pharmacogenomic analyses. However, for such approaches to be cost-effective, a well-established association should exist between genotype and clinical phenotype, and the frequency of the variant gene should be high. For example, if the frequency of a vriant allele is only 0.5%, then ~200 patients will have to be tested to identify one patient with the variant allele. Similarly, the strength of association between genotype and clinical phenotype will be important [128].

13.1.14 EDUCATIONAL ASPECTS

The resistance in the medical community to switching from the "trial-and-error" treatment approach to the gene-based approach is still prominently evident. Physicians in clinical practice, trainee physicians, and medical undergraduates have not been adequately educated in the field; the concept of pharmacogenetics has not been incorporated in the curriculum of medical courses worldwide. They are, thus,

neither well-versed in the selection of target genes for ordering a genetic test nor equipped with the knowledge to interpret and analyze the report. Thus, the bridging of the gap between basic science and medicine requires the collaborative efforts of researchers and clinicians.

Professionals in medicine and the life sciences must be prepared to adapt to this new approach. However, systems-based pharmacogenomics is unlikely to be ready for clinical application in the near future. To benefit patients today, the already available options of pharmacogenetics should be carefully implemented in clinical practice as soon as possible. Teaching the current, continuously updated knowledge of pharmacogenomics should not be postponed until the new paradigm arrives [19].

13.1.15 CONCLUDING REMARKS

The well-known interindividual differences in drug response could be caused by genetic and environmental factors and by the dose-response curve of a given drug. Knowledge of the individual genetic variability in drug response is, therefore, clinically and economically very important. Pharmacogenetics (focus is on single genes) and pharmacogenomics (focus is on many genes) are the two recent developments to investigate interindividual variations of drug response. This type of genetic profiling of the population doubtless provides benefits for future medical care by predicting the individual drug response.

The field of pharmacogenetics/pharmacogenomics has seen exciting advances in the recent past. The Human Genome Project and International HapMap projects have uncovered a wealth of information for researchers. The discovery of clinically predictive genotypes (e.g., UGT1A1*28 for irinocetan therapy; TPMT alleles for avoiding severe ADRs if patients receive standard doses of mercaptopurine and azathiopurine; TYMS TSER for treatment of rectal cancer; HER2 for optimizing the trastuzumab treatment in mammary Ca patients; BCA1, BRCA2, and factor V Leiden for improvement of oral contraception as well as hormone replacement), haplotypes (e.g., VKORC1 haplotype A for individualization of warfarin therapy), and somatic mutations (e.g., epidermal growth factor receptor for tailoring of tyrosine kinase inhibitors), along with the introduction of FDA-approved pharmacogenetic tests (UGT1A1*28) and the initiation of a genotype-guided clinical trial for cancer therapy (TYMS TSER in rectal cancer) have provided the first steps toward the integration of pharmacogenomics into clinical practice [22].

The translation from population-based (one dose fits all) to personalized medicine in the clinical setting is progressing at an incredibly slow pace. But why?

Several issues and problems need to be considered and solved before pharmacogenetics can be fully integrated into clinical practice (and also into drug development in the pharmaceutical industry). The ideal pharmacogenetic assay would quickly, accurately, and inexpensively provide composite genotypes for an individual patient to allow selection of the most suitable drug for the patient. Today, some approaches including suitable assays are very successful and have reached the level of clinical routine methods. Most other approaches (some are presently under investigation) are not mature. However, ongoing research is sure to bring one of the promises of the human genome project to fruition soon, that being

individualized drug therapy. We should always keep in mind that, although in some cases polymorphism in a gene is associated with poor efficacy and adverse drug reactions, in many cases the clinical relevance remains to be understood or is irrelevant. Therefore, pharmacogenetics/pharmacogenomics may not be applicable to all diseases and all treatments [129]. However, the many pharmacogenomic complexities, and particularly time-dependent changes of gene expression, will never allow personalized medicine to become an error-free entity.

The suggestion that individuals will be genotyped at birth and their “HapMap genotype” carried lifelong as an implantable identity may be too Orwellian for some. However, it may be close to the reality of clinical pharmacology practice in decades to come. By the way, we will have the data needed to extract the genetic risk from a genome and effectively model dosages and the risks of adverse reactions based on an individual’s genotype, which is further than most imagined electronic prescription would go, but it is an attractive prospect. Pharmacogenomics has a long way to go to achieve this goal, but its potential is clear enough [130].

However, at present, pharmacogenomics’ practical impact on medicine is more or less minimal, and the greatest challenge is to understand the genotype-environmental factor interactions, extensive geographic variations in genes (ethnicity) and to optimize study design for the accuracy, high level of quality, and consistency of technologies [131].

In comparison with pharmacogenomics, the successful transition of proteomic technologies (including novel nanotechnology strategies) from research tools to integrated diagnostic platforms will require much more effort and much more time.

After the great enthusiasm about mastering of the Human Genome Project, at present, we are in the post-genetics skepticism, which should not block our efforts for bringing pharmacogenomics and pharmacoproteomics into the clinical practice, which, however, is a long and interesting road. Like other methods in medicine, pharmacogenomics as well as pharmacoproteomics will optimize only certain parts of pharmacological therapy, not the whole field of clinical pharmacology. Taken together, prescription genotyping is only intended to aid the doctor in making individualized therapeutic decisions and is not a substitute for a physician’s judgment and clinical experience.

13.2.1 INTRODUCTION

Proteomics is often cited as the global (genome-wide) study of protein expression in a given living cell, tissue, or organism. Over the past decade, tandem mass spectrometry (MS/MS) has emerged as an essential analytical tool for large-scale

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

proteomic analysis [1, 2]. The critical challenge is to accurately and reproducibly identify and quantify large numbers of proteins in a given sample with good overall sensitivity and dynamic range. Currently, two shotgun (peptide level) tandem mass spectrometry-based proteomic approaches are widely employed to survey protein levels in complex biological samples. The first, known as MudPIT (for Multidimensional Protein Identification Technology), was developed by Yates and colleagues as an effective brute-force method for the comprehensive shotgun sequencing of large collections of peptide products of proteolytic digests of entire proteomes [3–5], whereas the second approach, prefractionation, requires sample separations to alleviate protein complexity before MS/MS analysis. In the latter approach, two avenues have generally been explored: gel electrophoresis (GE) and high-performance liquid chromatography (HPLC) pre-fractionations [6–8].

GE is a well-documented method [9] and is systematically used around the globe even though it is tedious, time-consuming, and often difficult to achieve reproducible results. On the other hand, HPLC prefractionation techniques [10, 11] such as size exclusion chromatography, reverse phase chromatography, affinity chromatography, and anion exchange chromatography represent more robust, simple-to-execute, rapid, and ultimately more reproducible sample prefractionation platforms that are also amenable to automation. These different HPLC methods can be characterized in terms of resolution as well as whether the method is denaturing. Choice of HPLC method will depend on the separation goals, with the primary goal usually being of obtaining the maximum nonoverlapping polypeptide fractions. Reverse phase HPLC, a popular and particularly effective separation method that fractionates proteins according to hydrophobicity, is typically used if sample denaturation (and the subsequent loss in protein activity) is not a consideration [12]. Alternatively, size exclusion chromatography, which separates proteins according to molecular size, is an excellent method to recover the proteins in their native conformation, albeit with relatively low resolution. Affinity chromatography is a powerful way to isolate proteins for which a biospecific interaction to a suitable selective adsorbent is available, but it is not suitable for the study of a whole proteome. The most flexible, convenient, and "widely used" method, however, for protein fractionation in biochemical studies is ion-exchange chromatography, or IEX–HPLC. Similar to size exclusion and affinity chromatography, this method also allows for the collection of proteins in their native conformations, without significant sample loss, but maintains the maximum possible resolution suitable for effective separations of complex biological samples. Surprisingly, despite its exciting potential, only limited use of IEX–HPLC in combination with proteomic analysis has been reported to date.

In IEX–HPLC, the resolution of a mixture of proteins is performed according to the differential retention due to inherent variations in the surface charge properties of the globular proteins in solution [13]. It involves the selective binding of target proteins to a suitably charged solid phase material or adsorbent, followed by sequential elution by increasing the mobile phase salt concentration (or, alternatively, under denaturing conditions, by altering the pH) to disrupt ionic interactions. Many such resins or prepacked columns are commercially available and can be used to efficiently resolve protein mixtures in a reasonable time frame. Anion exchange columns, which consist of positively charged functional groups, can be used to separate negatively charged proteins (which represent most typical cellular soluble proteins under near physiological pH), whereas cation exchange columns

resolve positively (e.g., histidine, lysine, and arginine rich) proteins. In principle, the development of a method that combines the two types of columns should provide a more effective analytical separation tool for protein fractionations before proteomic analysis using MS/MS that could be applied to different types of biological samples.

In this chapter, we described an easily implemented, effective, and highly reproducible dual-column HPLC prefractionation method that we have developed for improving routine proteomic analyses. The approach results in multifold increases in the numbers of proteins that can be confidently identified by LC–MS of whole cell lysates without fractionation. We outline the key steps in the overall procedure, from sample preparation through to MS/MS and attendant data analysis, using yeast soluble protein extract as a test mixture.

13.2.2 MATERIALS

The chemicals, biologicals, equipment, and instruments listed are those routinely used in our laboratory for proteomics analyses. Substitutions could be made with equivalent items as available.

13.2.2.1 Chemicals

1. Tris-(hydroxymethyl)-aminomethane (TRIS base), Sodium chloride (NaCl), Trichloroacetic acid (TCA), Sodium azide (NaN_3), Ammonium bicarbonate (NH_4HCO_3), HPLC-grade water, Calcium chloride ($CaCl_2$), HPLC grade acetonitrile (ACN), and HPLC-grade glacial acetic acid (AA) were all purchased from Fisher Scientific (Whitby, ON, Canada).
2. Hydrochloric acid (6N HCl) was from VWR International (Mississauga, ON, Canada).
3. HPLC grade acetone was obtained from Sigma-Aldrich (Oakville, ON, Canada).
4. Bio-Rad dye reagent (Bio-Rad, Mississauga, ON, Canada).
5. Heptafluorobutyric acid (HFBA) was purchased from Pierce (Rockford, IL).

13.2.2.2 Yeast Protein Extraction

1. Standard laboratory *Saccharomyces cerevisiae* yeast strain W303 (Mata ade2-1, ura3-1, his3-11,15, trp1-1, leu2-3,112, can1-100) (Open Biosystems, Huntsville, AL).
2. Lysis Solution: 10-mM Tris-HCl, 30-mM NaCl, and 3-mM NaN_3 (pH 7.8) to minimize microbial growth in the buffer.
3. Protease cocktail inhibitor (Roche Diagnostic, Laval, QC, Canada).
4. Bovine serum albumin (BSA) (Sigma-Aldrich, Oakville, ON, Canada).
5. Silica beads (Fisher scientific, Whitby, ON, Canada).
6. Ice bucket.

7. Microtube vortex adaptor (placed in cold room).
8. Eppendorf centrifuge (cooled at 4°C) or placed in cold room.
9. 1.5-mL Eppendorf microcentrifuge tubes cooled at 4°C.
10. 1.0-mL plastic cuvettes (Bio-Rad, Mississauga, ON, Canada).
11. Ultrospec1100 pro UV/VIS Spectrophotometer (Biochrom, Cambridge, U.K.) or an equivalent instrument.

13.2.2.3 IEX-HPLC Analysis

1. 80–100-µg total soluble protein from yeast (W303) crude soluble cell lysate as measured by Bradford (approximate concentration: [$10\,\mu g \cdot \mu L^{-1}$]).
2. Buffer A (binding buffer): 10-mM Tris-HCl, pH 7.5 with 3-mM NaN_3.
3. Buffer B (eluting buffer): Buffer A with 600-mM NaCl.
4. 0.22-µm membrane vacuum-driven disposable bottle top filter (Millipore, Cambridge, ON, Canada).
5. Anion exchange column (PolyWAX LP, 50 × 2.1 mm i.d., 5 µm, 1000 Å), cation exchange column (PolyCAT A, 50 × 2.1 mm i.d., 5 µm, 1000 Å), anion exchange guard cartridge (PolyWaX LP, 10 × 2.1 mm i.d., 5 µm, 1000 Å), and pre-guard column sieves with high flow, 2 µm (IT9085-20-10) were from Canadian Life Science (Peterborough, ON, Canada).
6. Agilent 1100 quaternary HPLC pump system (Agilent Technologies, Mississauga, ON, Canada).
7. Microcentrifuge tubes (precooled at 4°C).

13.2.2.4 Precipitations and Proteolysis of Proteins in IEX–HPLC Fractions

1. 100% TCA in HPLC-grade water: dissolve 20 g of solid TCA in 9.0 mL of water (prepare fresh solution).
2. Applied Biosystems immobilized trypsin beads (Applied Biosystems, Foster City, CA).
3. Pierce immobilized TPCK-trypsin beads (Pierce, Rockford, IL).
4. Digestion buffer: 50-mM NH_4HCO_3, 1-mM $CaCl_2$, pH 8.0.
5. 1-M $CaCl_2$ in HPLC-grade water.
6. Ice cold HPLC-grade acetone (keep at –20°C until use).
7. Eppendorf centrifuge 5417C (14,000 rpm capacity) or its equivalent.

13.2.2.5 1D-LC-MS Shotgun Tandem Mass Spectrometry Proteomic Analysis

1. An LTQ linear ion trap tandem mass spectrometer (Thermo Finnigan Corp, San Jose, CA) is routinely used in our laboratory. XCalibur Software is used to automate the acquisition of tandem mass spectra over a 400–1600-m/z range and to control precursor ion selection by the instrument in a data-dependent, data-acquisition mode, with dynamic exclusion activated.
2. 100-µm capillary microcolumn silica tubing (Polymicro Technologies, Phoenix, AZ).
3. 5-µm pore size C18 reverse-phase packing material (Zorbax eclipse XDB-C_{18} resin) (Agilent Technologies, Mississauga, ON, Canada).
4. Solvent A: 5% ACN, 0.5% AA, and 0.02% HFBA.

5. Solvent B: 100% ACN.
6. HPLC quaternary gradient pump, with flow splitter.

13.2.3 METHOD

The following method is designed to allow the routine prefractionation, leading to enhanced identification of proteins from complex sample matrices, such as a representative crude soluble cell extract prepared from a standard laboratory *S. cerevisiae* yeast strain, by IEX–HPLC and LC–MS techniques. This method can be readily customized to investigate other biological samples. Specific details regarding sample preparation, chromatography prefractionation, precipitation, and tryptic proteolysis of the protein samples followed by proteomic LC–MS analysis are included. The major steps of the entire procedure, from protein sample mixture prefractionation to subsequent analysis by LC–MS, are summarized schematically in Figure 13.2-1.

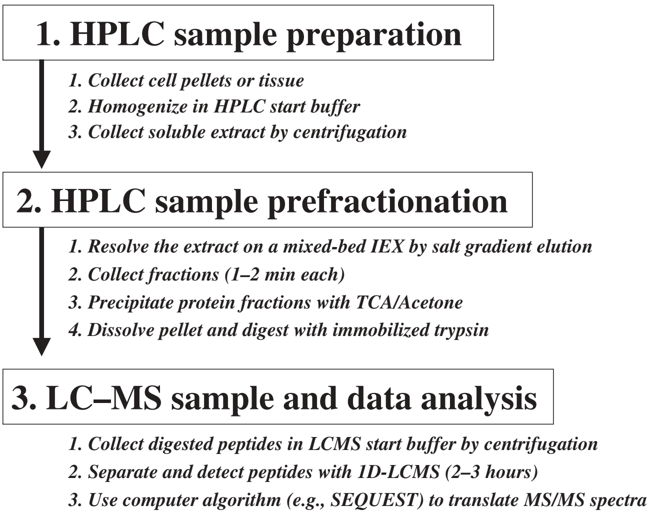

Figure 13.2-1. Representative workflow for IEX–HPLC prefractionation of a proteome sample (e.g., the yeast *S. cerevisiae*) before proteomic analysis by LC–MS. (1) Sample preparation is performed in IEX–HPLC starting buffer (pH 7.8) containing protease inhibitors. The soluble extract is recovered and clarified by centrifugation. (2) The sample is prefractionated using IEX–HPLC salt gradient, and a total of 27 fractions (1.3 minutes each) is collected using a dual-column system (tandem anion and cation-exchange columns placed in series) and a standard HPLC binary pump system. The collected protein fractions and a crude soluble sample lysate, as a reference control, are subjected to precipitation and tryptic digestion. (3) The peptide mixtures are separated and detected by single-dimension liquid chromatography coupled to automated tandem mass spectrometry. The resulting tandem mass spectra are computationally translated to a short amino acid sequence, and their corresponding cognate protein identity is determined using a suitable database algorithm searching against a relevant protein sequence database. High confidence protein identifications (≥90% probability) are parsed into an in-house database, and diverse data clustering and mining strategies used to find interesting patterns of protein expression for biological validation and detailed analysis. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

13.2.3.1 HPLC Sample Preparation

To facilitate the process and to maintain reproducible results, minimal sample handling is highly recommended for success of an IEX–HPLC experiment. To meet this requirement, a one-step sample pretreatment approach is employed. This approach allows recovering the sample in a low salt buffer compatible with HPLC while preserving the native conformation of the proteins. Here, a simple Tris-HCl-based buffer system at or near the physiological pH is used to solubilize the yeast cell pellet and to collect a soluble fraction by high-speed centrifugation. The yield of this crude extract is approximately 10-mg protein/mL. The protocol below allows for collection of a protein sample mixture ready for the direct injection onto a standard analytical grade HPLC column without further treatment.

1. To approximately 500 µL of *S. cerevisiae* cell pellets on ice, add an equal volume of the fresh Lysis Buffer Solution (described in Section 13.2.2.2, prefiltered through a 0.22-µm membrane) containing protease inhibitors (follow the vendor's instructions for preparation) and vortex extensively to fully resuspend the pellet.
2. Allow the mixture to stand for 1 minute on ice and add a half volume of glass beads (stored at 4°C) for cell disruption.
3. Insert tube into a vortex adaptor placed in the cold room and vortex vigorously at maximum speed for a period of 1 minute; repeat 10 times, equilibrating the tubes on ice for 2 minutes between bursts.
4. Allow to stand for 10 minutes and sediment the cell debris and the beads by microcentrifugation at 14,000 rpm for 10 minutes.
5. Collect the supernatant in a new prechilled microtube with a micropipette[1] and clarify the sample by centrifugation 10 minutes at 14,000 rpm in an eppendorf centrifuge.[2]
6. Measure protein concentration before injection onto the column.[3] Take 1- to 10-µL aliquots to measure the protein concentration, following the standard procedure Bio-Rad Assay for microtiter plate instructions, using BSA as a standard reference protein.
7. Dispense sample by dividing into 20-µL aliquots in the 1.5-mL microtubes for injection and immediately freeze the remainder at −80°C (if possible, freeze the sample in nitrogen liquid first).

[1] The tube contains two layers; take only the top layer that contains soluble protein, and estimate the concentration of protein for the subsequent step.

[2] The sample to be loaded onto the HPLC system must be free of the particulates susceptible to clog its valves, lines, and columns. The particulates may be removed either by filtration with 0.22–0.45-µm membrane or by centrifugation. Yeast crude cell lysate solution can be difficult to filter due to the presence of glass beads so centrifugation is the method of choice.

[3] Failure to measure the amount of the protein in the sample may lead to the injection of an excessively concentrated sample, which may cause the protein to precipitate out in the HPLC tubing or within the column itself, causing a pressure rise. The shelf lifetime of the column is also shortened by loading the protein in excess of the maximum capacity of the column.

13.2.3.2 HPLC Sample Prefractionation

To achieve the high degree of resolution while maintaining results reproducibility and getting fractionation of the protein in a reasonable time frame, a binary or quaternary eluent strategy is required. Our basic binary strategy involves the separation of protein mixtures using a binary eluent IEX–HPLC method. This approach uses a combination of two mobile phase buffers differing only in salt concentration, either 10-mM Tris-HCl, pH 7.5, no salt (*buffer A*), or 10-mM Tris-HCl + 600-mM NaCl, pH 7.5. The fractionation is accomplished by applying the gradient of salt during a 30–90-minute chromatographic run to resolve and separate the proteins.

The protocol described in this section is an example of the one currently performed in our laboratory for routine proteomic analyses. All of our fractionation experiments are carried out on the Agilent 1100 HPLC system equipped with a vacuum degasser, a binary pump, a refrigerated autosampler with a 100-µL injector loop, 2-D column compartments with a thermostat, a multiwavelength detector (MWD), a cooled autocollection fraction module, and an Agilent ChemStation for chromatograms acquisition and instrument control. As a test case, soluble yeast proteins were fractionated using two combined column chromatography, an anion-exchange column (PolyWAX LP 50 × 2.1 mm i.d., 5 µm, 1000 Å) connected upstream of the cation-exchange column (PolyCAT A, 50 × 2.1 mm i.d., 5 µm, 1000 Å) and protected with a precolumn guard cartridge.[4]

Using the above-described HPLC system and columns together with the salt gradient and the appropriate instrument preparation, 27 HPLC fractions may be collected in less than 35 minutes. Figure 13.2-2 depicts the typical chromatograms obtained when the following protocol was applied to the yeast soluble cell lysate:

1. Flush and equilibrate the entire HPLC system with 40 mL of the binding buffer (Buffer A) at 2 mL.min^{-1} using an empty union in place of the column.
2. Stop the flow, remove the union, and install the guard cartridge and the columns (make sure your columns are compatible with the buffer systems); use a 10-cm-long Peek tubing (0.13 mm i.d.) to connect the anion exchanger to a cation-exchange column.
3. Set the column temperature at 17°C to enhance protein integrity during the run, and turn on the HPLC system, flush columns with 80% of Buffer B at a flow rate of 250 µL.min^{-1} for 20 minutes. Follow the manufacturer's instructions when using new columns, and carefully monitor the column pressure for any backpressure indicating possible clogging.
4. Condition columns with pure Buffer A (10-mM Tris-HCl, 3-mM NaN_3, pH 7.5) at the above flow rate and time or until you get a flat Ultraviolet baseline at 280 nm.

[4] As discussed, crude cell lysate can contaminate the anion-exchange column resulting in increased backpressure and decreased efficiency. Poly WAX LP (10 × 2.1 mm, 5 µm, 1000 Å) precolumn is used before the PolyWAX LP column to act as a prefilter because the material is the same as the anion exchanger but is inexpensive. The use of a preguard column extends the lifetime of the anion-exchange column and so can save both time and money.

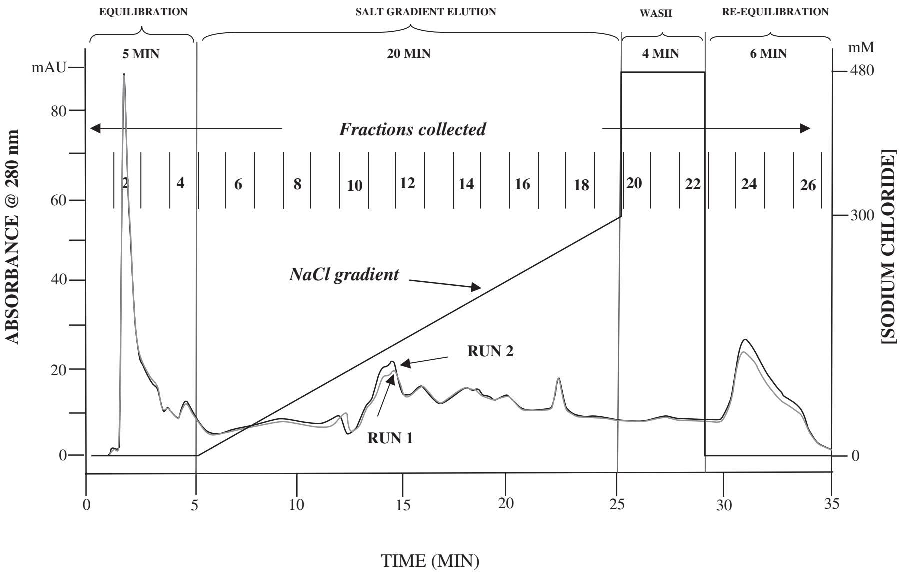

Figure 13.2-2. Repeat ultraviolet-traces (280 nm) recorded for a representative yeast whole cell lysate separated by IEX–HPLC showing the reproducibility of the procedure. Chromatography was performed at 17°C using a mixed bed of ion-exchange columns, PolyWAX LP (50 × 2.1 mm i.d., 5 µm, 1000 Å) and PolyCAT A (50 × 2.1 mm i.d., 5 µm, 1000 Å). The injection of 80-µg total protein onto the column was followed by 5 minutes of column equilibration with 100% of buffer A, and then 20 minutes of protein fractionation with a linear NaCl gradient from 0% to 50% of buffer B. After protein separation, the column was flushed with 80% buffer B for 4 minutes and then re-equilibrated for 6 minutes with the starting buffer A. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

5. Apply 5–10 µL of the centrifuged crude soluble cell extracts (80–100-µg total protein) onto the column using automated (autosampler) injector that has been kept at 4°C.
6. Refer to Figure 13.2-2 for protein fractionation with the given salt gradient condition.
7. Monitor protein separation with a MWD set at 280 nm.
8. Collect HPLC fractions based on time (e.g., 1–2 minutes per fraction) by use of an automated sample collector, kept at 4°C, with 1.5-mL Agilent Well Plate fraction collector (325-µL fractions are typically collected per 1.5-mL microtubes).

PROTEOLYSIS AND LC–MS SAMPLE PREPARATION. The following procedure allows for digestion of the proteins in collected HPLC fractions or the control unfractionated crude cell lysate to enable their analysis by LC–MS. After fractionation with HPLC, fractions are precipitated and digested as follows:

1. To each HPLC fraction, add one-tenth cold TCA (100%, fresh solution); vortex the tubes and incubate 30 minutes on ice or overnight at 4°C (cold room).

2. Spin the tubes for 30 minutes at maximum speed (14,000 rpm) in a cooled or refrigerated microcentrifuge; aspirate half of the supernatant (be careful not to disturb the pellet).
3. To each tube, add 600-μL ice-cold HPLC-grade acetone and incubate at –20°C for 10–20 min.
4. Spin tubes as in step 2 and aspirate the total supernatant out of the tube without breaking the pellet.
5. Leave the cap open for air drying (in the fume-hood) for 20 minutes with a protective tissue (e.g., Kimwipes) cover held loosely over it (check the sample frequently to prevent overdrying).
6. Dissolve the pellet in 30 μL of the immobilized trypsin solution (600 μL of the digestion buffer, 60 μL of Pierce immobilized trypsin beads, 30 μL of the Applied Biosciences immobilized trypsin beads, and 2 μL of 1-M $CaCl_2$); check the pH (should be ~8.0) with the pH strip; and neutralize with 5 μL of 1-M TRIS (pH 8.0) if necessary.
7. Incubate the sample for two days at 30°C with rotation or agitation.
8. Stop digestion by adding 30 μL of the LC–MS solvent A, and spin the peptides mixtures for 5 minutes at maximum speed (room temperature) in a microcentrifuge to sediment the trypsin beads.
9. Carefully, recover 20 μL of the peptide mixtures into small disposable (e.g., PCR) tubes, and either immediately analyze by LC–MS or store at –20°C.

13.2.3.3 LC-MS Sample and Data Analysis

A single capillary scale reverse phase high-performance liquid chromatography system coupled online to automated electrospray ion trap tandem mass spectrometry (1D–LCMS) is usually performed to characterize the protein fractions. The following protocol is an example of the implementation of the method to identify the peptide components of tryptic digests of the yeast HPLC fractions analysis using the ion trap tandem mass spectrometer instrument described in Section 13.2.2.5, and typical results are shown in Figure 13.2-3.

1. Pack a silica capillary-scale microcolumn (150 μm i.d.) 7.5 cm of C18 reverse phase packing material (Zorbax eclipse XDB-C_{18} resin).
2. Place the packed column in line with the LC-MS buffer pump and ion source power supply.
3. Load the peptide mixture onto the column using an autosampler.
4. The digested proteome is chromatographically resolved and the peptides subject to automated precursor ion selection. The following gradient may be increased or decreased according to sample complexity: 100% of solvent A for 1 minute, 0% to 5% of solvent B in 1 minute, 5% to 30% of solvent B in 58 minutes, 30% to 80% of solvent B in 10 minutes, 80% of solvent B for 5 minutes, 80% to 30% of solvent B during 5 minutes, and then step the gradient back at 100% of solvent A. The flow rate at the tip of the needle is set to 150 μL. min^{-1} for 2 minutes, rise to 175 μL. min^{-1} in 58 minutes, and maintain the flow constant for 25 minutes and then reduce to 5 μL. min^{-1} in 5 minutes.

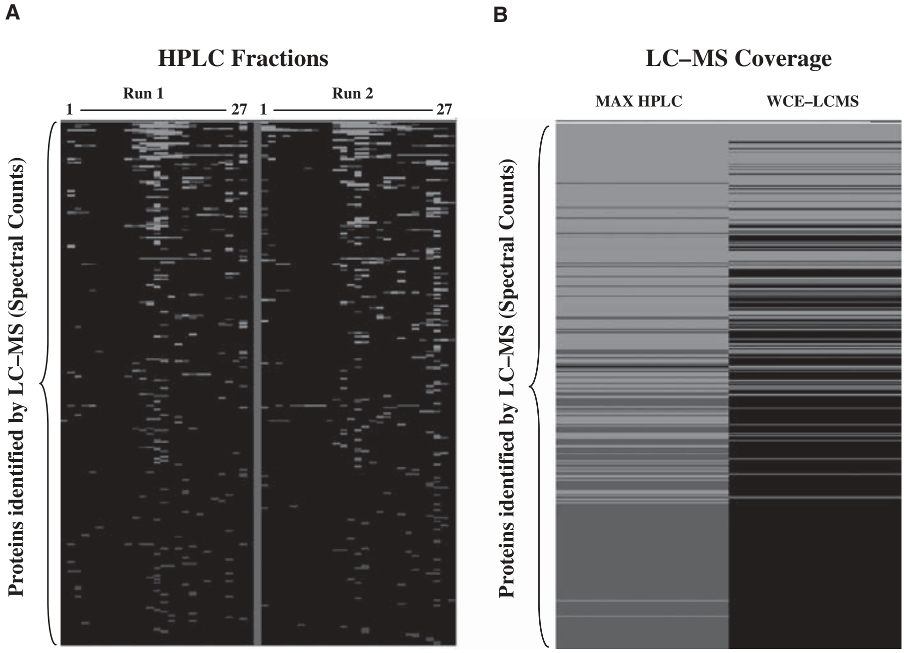

Figure 13.2-3. Yeast cell extract HPLC fractionation and LC–MS analysis. (*A*) Comparison of representative proteomic patterns recorded for two consecutive HPLC prefractionations. (*B*) Graphical comparison of HPLC prefractionation and straight analysis of the whole cell extract (WCE) by LC–MS (a maximum protein spectral count was recorded for two successive HPLC runs and compared with the corresponding value for the WCE). Black-to-red color shading indicates increasing spectral counts. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

5. The mass spectrometer cycles through a full mass precursor ion scan, followed by 2–10 successive tandem mass scans using data-dependent ion isolation and fragmentation of the 10 most intense ions as the gradient progresses. Dynamic exclusion is implemented to prevent repeated fragmentations of the same peptide.
6. Candidate peptide sequences from the mixture are later identified using a computerized database search algorithm (e.g., SEQUEST) [14] and validated using the STATQUEST probabilistic scoring program [15].
7. Comparison of relative protein expression levels between chromatographic runs can be performed using the clustering algorithm Cluster 3.0 and the patterns visualized in a "heat map" format using Java Treeview freeware software.

13.3.1 INTRODUCTION

Metabonomics is the comprehensive and simultaneous systematic profiling of metabolite levels and their temporal changes in whole organisms through the study of biofluids, tissues, and tissue extracts [1, 2]. A parallel approach mainly from plant science and from the study of *in vitro* systems has led to the term *metabolomics* also

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

being coined [3], and the methods and approaches used in the two disciplines are highly convergent. For the pharmaceutical and medical communities, this multivariate approach holds out the promise of a means by which real disease and drug effect endpoints can be obtained. In this monograph, the main technologies used in metabonomics are summarized, brief details of the types of samples used are given, and the current applications of metabonomics are described. Some prospects for the future are then discussed.

One main problem with integrating information at the three main levels of biomolecular organization and control, transcriptomic, proteomic, and metabonomic, is because these are highly interdependent and can have very different time scales of change. As a result, difficulties can occur in correlation of effects seen by the different omics approaches because some time courses can be very rapid (gene switching), some require much longer time scales (protein synthesis), or some encompass enormous ranges of time scales (metabolite levels). Additionally, biochemical changes do not always occur in the order that would intuitively be expected, i.e., transcriptomic, proteomic, and metabolic, because, for example, pharmacological or toxicological effects at the metabolic level can induce subsequent adaptation effects at the proteomic or transcriptomic levels. One important potential role for metabonomics, therefore, could be to direct the timing of proteomic and genomic analyses in order to maximize the probability of observing “omic” biological changes that are relevant to functional outcomes.

In addition, overlaid with this complexity, is the fact that environmental and lifestyle effects have a large effect on gene and protein expression and on metabolite levels and these have to be considered as part of intersample and interindividual variation. Interpretation of genomic data, in terms of real biological endpoints, is therefore a major challenge because of the modification of gene expression levels by environmental factors. The modeling of such diverse information sets poses significant challenges in terms of bioinformatics. Highly complex animals such as man can be considered as “superorganisms” with an internal ecosystem of diverse symbiotic gut microbiota and parasites that have interactive metabolic processes and for which, in many cases, the genome is not known. The many levels of complexity of the mammalian system and the diverse features that need to be measured to allow “omic” data to be fully used have been reviewed recently [4]. In addition, novel approaches will continue to be required to measure and model metabolic processes in various compartments in different interacting cell types, with genomes that are connected by cometabolic processes in such a global mammalian system [5].

Typically, mammalian metabonomics studies of relevance to the pharmaceutical industry are carried out on biofluids because these are often easy to obtain and can provide an integrated view of the whole system’s biology. The biochemical profiles of the main diagnostic fluids, blood plasma, cerebrospinal fluid (CSF), and urine, can reflect both normal variation and the impact of disease and drug toxicity or efficacy on single or multiple organ systems. Urine and plasma are obtained essentially noninvasively, and hence, are most appropriate for clinical trials monitoring and disease diagnosis. However, there is a wide range of fluids that can be, and have been, studied, including seminal fluids, amniotic fluid, synovial fluid, digestive fluids, blister and cyst fluids, lung aspirates, and dialysis fluids. In addition, several metabonomics studies have used analysis of tissue biopsy samples and their

lipid and aqueous extracts. This is particularly true for studies in fields other than mammalian systems, such as for plants, or for model organisms such as yeast and cell culture studies. Additionally, the approach can be used to characterize *in vitro* cell systems such as Caco-2 cells commonly used for cell uptake studies [6] or tissue spheroids, which can be used, for example, as model systems for liver or tumor investigations [7].

As described in more detail in Section 13.3.2, the main analytical techniques that are employed for metabonomic studies are based on nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS). The latter technique requires a preseparation of the metabolic components using either gas chromatography (GC) after chemical derivatization or liquid chromatography (LC), with the newer method of ultra-high-pressure LC (UPLC) being used increasingly. The use of capillary electrophoresis (CE) coupled to MS has also shown promise. Other more specialized techniques such as Fourier transform infrared spectroscopy and arrayed electrochemical detection have been used in some cases.

All metabonomics studies result in complex multivariate datasets that require a variety of chemometric, bioinformatic, and visualization tools for effective interpretation. The aim of these procedures is to produce biochemically based fingerprints that are of diagnostic or other classification value. A second stage, crucial in such studies, is to identify the substances causing the diagnosis or classification, and these become the combination of biomarkers that reflects actual biological events. Thus, metabonomics studies allow real-world or biomedical endpoint observations to be obtained.

There have been several reviews of metabonomics and metabolomics recently that describe the various techniques used and that summarize the main areas of application. These provide more detail than can be given here and serve to act as pointers to the original literature studies [8–11].

13.3.2 METABONOMICS ANALYTICAL TECHNOLOGIES

13.3.2.1 NMR Spectroscopy

NMR spectroscopy is a nondestructive technique, widely used in chemistry, that provides detailed information on molecular structure, both for pure compounds and in complex mixtures [12]. NMR spectroscopic methods can also be used to probe metabolite molecular dynamics and mobility as well as substance concentrations through the interpretation of NMR spin relaxation times and by the determination of molecular diffusion coefficients [13].

Standard pulse-Fourier transform NMR spectra typically take only a few minutes to acquire, often using robotic flow-injection methods, with automatic sample preparation involving buffering and addition of D_2O as a magnetic field lock signal for the spectrometer. For large-scale studies, bar-coded vials containing the biofluid are used and the contents of these can be transferred and prepared for analysis using robotic liquid handling technology into 96-well plates with the whole process under LIMS system control. Using NMR flow probes, the capacity for NMR analysis has increased enormously recently, and around 200 samples per day can be measured on one spectrometer. Alternatively, for more precious samples or for

those of limited volume, conventional 5-mm NMR tubes are usually used, either individually or using a commercial sample tube changer and automatic data acquisition. Typical NMR spectra of human biofluids are shown in Figure 13.3-1.

A ^{1}H NMR spectrum of urine acquired as seen in Figure 13.3-1, typically contains thousands of sharp lines from predominantly low-molecular-weight metabolites. This spectrum is the result of 64 co-added scans each requiring about 5 s, thus yielding a total data acquisition time of around 5 minutes. The large interfering NMR signal arising from water in all biofluids is easily eliminated by use of appropriate standard NMR solvent suppression methods, either by secondary radiofrequency (RF) irradiation at the water peak chemical shift or by use of a specialized NMR pulse sequence that does not excite the water resonance. The position of each spectral band (known as its chemical shift and measured in frequency terms, in ppm, from that of an added standard reference substance) gives information on molecular group identity and its molecular environment, e.g., methyl group on an aromatic ring, olefinic hydrogen, pyridyl ring proton, or aldehyde. The reference compound used in aqueous media is usually the sodium salt of 3-trimethylsilylpropionic acid (TSP) with the methylene groups deuterated to avoid giving rise to peaks in the ^{1}H NMR spectrum. The multiplicity of the splitting pattern on each band, and the magnitudes of the splittings (caused by a nuclear spin–spin interaction mediated through the electrons of the chemical bonds, and known as

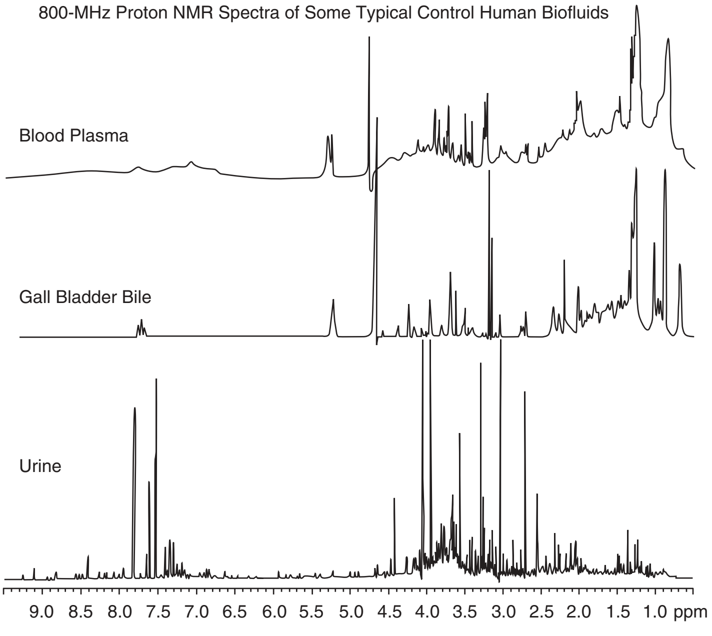

Figure 13.3-1. Shown are 800-MHz ^{1}H NMR spectra of control human biofluids. The peaks arise from different chemical types of hydrogen in the biochemicals present. The peak areas are related to molar concentrations, and the peak positions and splittings allow information to be obtained, after expert interpretation, of the molecules responsible for the peaks. The signal from water has been suppressed by an NMR procedure to avoid problems of dynamic range in the detection process.

J-coupling), provide knowledge about nearby protons, their through-bond connectivities, the relative orientation of nearby C–H bonds, and hence molecular conformations. The band areas relate directly to the number of protons, giving rise to the peak and hence to the relative concentrations of the substances in the sample. Absolute concentrations can be obtained if the sample contains an added internal standard of known concentration, if a standard addition of the analyte of interest is added to the sample, or if the concentration of a substance is known by independent means (e.g., glucose in plasma can be quantified by a conventional biochemical assay).

Blood plasma and serum contain both low- and high-molecular-weight components, and these give a wide range of signal line widths. Broad bands from protein and lipoprotein signals contribute strongly to the ^{1}H NMR spectra, with sharp peaks from small molecules superimposed on them. Standard NMR pulse sequences, where the observed peak intensities are edited on the basis of molecular diffusion coefficients or on NMR relaxation times (known as T_1, $T_{1\rho}$, and T_2), can be used to select only the contributions from proteins, and other macromolecules and micelles, or alternatively to select only the signals from the small-molecule metabolites, respectively [12]. A typical ^{1}H NMR spectrum from human blood serum is shown in Figure 13.3-1, and a series of edited NMR spectra, from rat blood serum, based on the approaches described above are given in Figure 13.3-2.

The spin-echo spectrum has the broader peaks from nuclei with shorter spin relaxation times attenuated (these are macromolecules and substances involved in

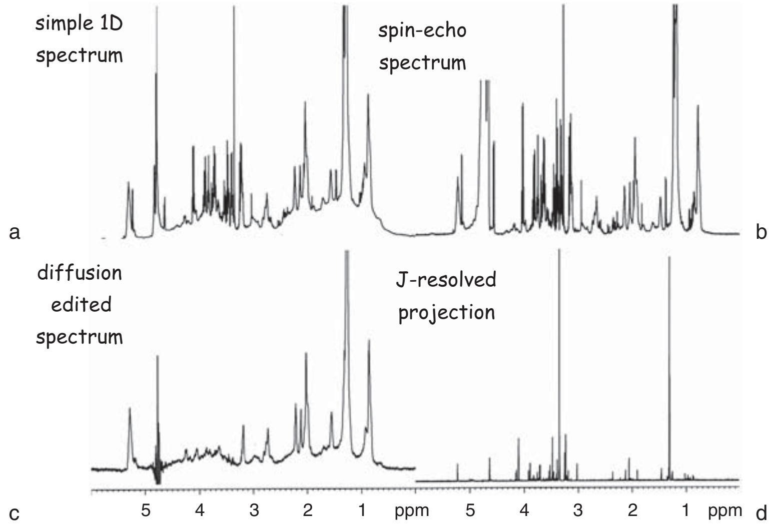

Figure 13.3-2. ^{1}H NMR spectra of rat serum illustrating the various NMR responses that are possible through the use of different pulse sequences, which edit the spectral intensities: (a) standard water suppressed spectrum, showing all metabolites; (b) CPMG spin-echo spectrum, with attenuation of peaks from fast relaxing components such as macromolecules and lipoproteins; (c) diffusion-edited spectrum, with attenuation of peaks from fast diffusing components such as small molecules; and (d) a projection of a 2D J-resolved spectrum on to the chemical shift axis, showing removal of all spin–spin coupling and peaks from fast relaxing species.

chemical exchange). The diffusion-edited spectrum, on the other hand, has peaks only from macromolecules and other slow-moving species present, with the peaks from highly mobile small molecules attenuated. Thus, it is also possible to use these approaches to investigate molecular mobility and flexibility, and to study intermolecular interactions such as the reversible binding between small molecules and proteins [14].

Two recent improvements in NMR detector technology have resulted in major improvements in sample quantity requirements for NMR spectroscopy. The first is the commercialization of miniaturized detectors. Now it is possible to study metabolic profiles by NMR using as little as 2–20 μL of sample, and examples have been published using CSF and blood plasma [15]. Secondly, the availability of cryogenic NMR probe technology where the detector coil and preamplifier are cooled to around 20K has provided an improvement in spectral signal-to-noise ratios of up to a factor of 5 by reducing the thermal noise in the electronics of the spectrometer. This allows use of smaller samples, and when this approach is combined with the use of miniaturized probes as described above, optimum sensitivity and sample requirements are achieved. Conversely, because the NMR signal-to-noise ratio is proportional to the square root of the number of co-added scans, shorter data acquisition times by up to a factor of 20–25 become possible for the same amount of sample. NMR spectroscopy of biofluids detecting the much less sensitive ^{13}C nuclei, which also only have a natural abundance (1.1%), also becomes possible because of the increase in signal-to-noise ratio [16].

Within the last few years, the development of a technique called high-resolution ^{1}H magic angle spinning (MAS) NMR spectroscopy has made feasible the acquisition of high-resolution NMR data on small pieces of intact tissues with no pretreatment [17–21]. Rapid spinning of the sample (typically at ~4–6 kHz) at an angle of 54.7° relative to the applied magnetic field serves to reduce the loss of information caused by line broadening effects observed in nonliquid samples such as tissues. These broadenings are caused by sample heterogeneity and residual anisotropic NMR parameters that are normally averaged out in free solution where molecules can tumble isotropically and rapidly. NMR spectroscopy on a tissue matrix in an MAS experiment is the same as solution-state NMR, and all common pulse techniques can be employed to study metabolic changes and to perform molecular structure elucidation. Typical ^{1}H NMR spectra from a range of tissue types are shown in Figure 13.3-3. In most cases, a standard set of one-dimensional (1D) sequences is used to describe the biochemical changes in the pool of low-molecular-weight metabolites and lipids. The different spin properties of macromolecules and small molecules can also be exploited using spectral editing techniques to filter out certain subgroups of peaks, as in solution-state NMR spectroscopy.

MAS NMR spectroscopy has straightforward sample preparation, although this still has to be carried out manually. Snap-frozen tissue samples (as little as 10 mg), which have been stored at −80°C, are defrosted and cut to select the region of interest. The original samples should be frozen rapidly using small specimens in liquid nitrogen to avoid microcrystallization of the water in the cells and consequent cell damage. Then, the tissue is rinsed with 0.9% D_2O/saline to wash off remaining blood and the specimen is transferred into a 4-mm-diameter zirconia rotor and a Teflon spacer is used to restrict the sample volume, to eliminate trapped air bubbles, and to increase sample homogeneity. As soon as the sample has been

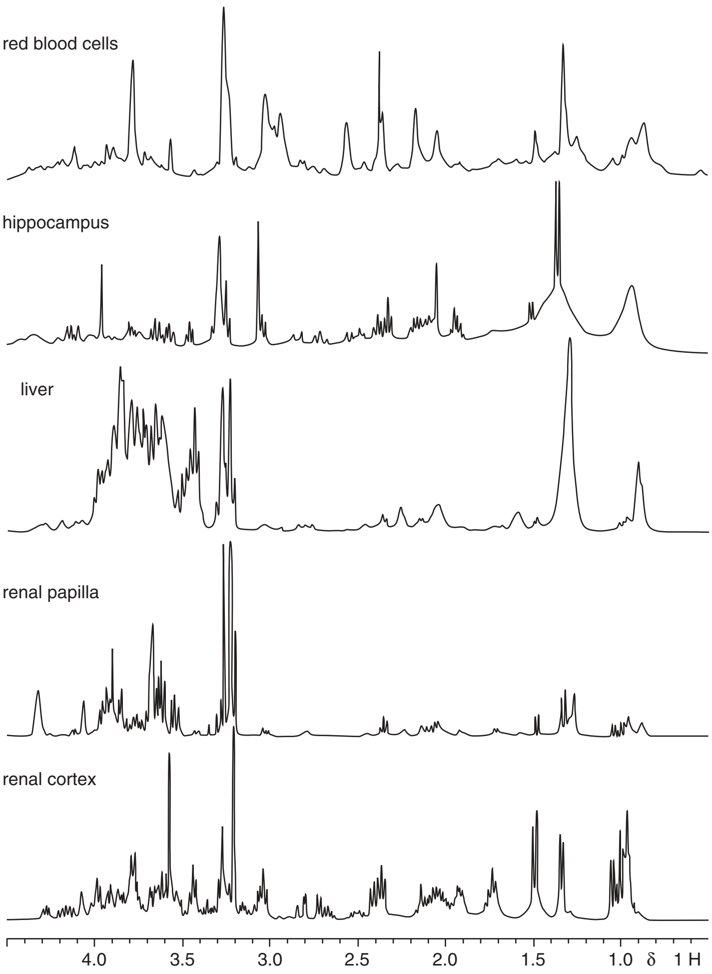

Figure 13.3-3. High-resolution 400-MHz ^{1}H MAS NMR spectra of various tissues, with sample spinning at 4.2 kHz.

transferred into the rotor, a trace volume of 0.9% D_2O/saline is added to provide a field-frequency lock for the ^{1}H MAS NMR data acquisitions. In cases where the chemical shifts of signals have not been identified previously, it is necessary to add a reference standard such as TSP in the saline solution, although sometimes it is possible to use a well-characterized peak of an easily assigned compound, such as the anomeric proton resonance of α-glucose, as a secondary chemical shift standard. Fast rotation of the sample can cause frictional heating, and this is prevented by a controlled cooling of the input gas to compensate.

Identification of biomarkers can involve the application of a range of techniques, including two-dimensional (2D) NMR experiments [12]. Although, all of the armory of the usual analytical physical chemistry can and should be used, including mass spectrometry, ^{1}H NMR spectra of urine and other biofluids, even though they are very complex, allow many resonances to be assigned directly based on their chemical shifts, signal multiplicities, and by adding authentic material, and further

information can be obtained by using spectral editing techniques, as described above.

Two-dimensional NMR spectroscopy can be useful for increasing signal dispersion and for elucidating the connectivities between signals, thereby enhancing the information content and helping to identify biochemical substances. These include the ^{1}H-^{1}H 2-D J-resolved experiment, which attenuates the peaks from macromolecules and yields information on the multiplicity and coupling patterns of resonances, which is a good aid to molecule identification. The projection of such a spectrum on to the chemical shift axis yields a fingerprint of peaks from only the most highly mobile small molecules, with the added benefit that all spin-coupling peak multiplicities have been removed (see Figure 13.3-2). Other 2D experiments known as COSY and TOCSY provide ^{1}H–^{1}H spin–spin coupling connectivities, thus giving information on which hydrogens in a molecule are close in chemical bond terms. Use of other types of nuclei, such as naturally abundant ^{13}C or ^{15}N or where present ^{31}P, can be important to help assign NMR peaks, and here heteronuclear correlation NMR experiments can be obtained by use of appropriate NMR pulse sequences. These benefit by the use of so-called inverse detection, where the lower sensitivity or less abundant nucleus NMR spectrum (such as ^{13}C) is detected indirectly using the more sensitive/abundant nucleus (^{1}H) by making use of spin–spin interactions such as the one-bond ^{13}C–^{1}H spin–spin coupling between the nuclei to effect the connection. These yield both ^{1}H and ^{13}C NMR chemical shifts of CH, CH_2, and CH_3 groups, which are useful again for identification purposes. There is also a sequence that allows correlation of protons to quaternary carbons based on long-range ^{13}C–^{1}H spin–spin coupling between the nuclei.

13.3.2.2 Mass Spectrometry

Mass spectrometry has also been widely used in metabolic fingerprinting and metabolite identification, with most studies to date on plant extracts and model cell system extracts, although its application to mammalian studies is increasing. In general, with the exception of some studies using Fourier transform, or ion-cyclotron-MS, a prior separation of the complex mixture sample using chromatography is required. MS is inherently considerably more sensitive than NMR spectroscopy, but in complex mixtures of very variable composition such as biofluids, it is necessary generally to employ different separation techniques (e.g., different LC column packings) for different classes of substances. MS is also a mainstay technique for molecular identification purposes, especially through the use of MS^n methods for fragment ion studies. Analyte quantitation by MS in complex mixtures of highly variable composition can also be impaired by variable ionization and ion suppression effects. Chemical derivatization might be necessary to ensure volatility and analytical reproducibility, in complex mixtures such as biofluids.

For both profiling and metabolite identification, most published metabonomics studies on mammalian biological systems have used NMR spectroscopy, but HPLC–MS techniques are increasing in usage, particularly using electrospray ionization. Thus, for metabonomics applications on biofluids such as urine, an HPLC chromatogram is generated with MS detection, and usually both positive and negative ion chromatograms are measured. At each sampling point in the chromatgram, there is a full mass spectrum and so the data are three-dimensional in nature, i.e.,

retention time, mass-to-charge ratio, and intensity. Given this very high resolution, it is easy to cut out any mass peaks from interfering substances such as drug metabolites, without compromising the dataset.

For plant metabonomics studies, the principal approach has been to make extracts of the samples followed by chemical derivatization, and then to employ separation using GC with molecular identification using MS by comparing spectra against publically available and single-laboratory databases [10, 11].

UPLC is a new combination of a 1.7-μm reversed phase packing material and a chromatographic system, operating at around 12,000 psi. This has enabled a marked improvement in chromatographic performance to be obtained for complex mixture separation, with better peak resolution and increased speed and sensitivity. UPLC gives more than doubling of peak capacity compared with HPLC, an almost 10-fold increase in speed, and a 3- to 5-fold increase in sensitivity compared with that generated with a conventional stationary phase. Because of the much improved chromatographic resolution of UPLC, the problem of ion suppression from co-eluting peaks is greatly reduced. UPLC–MS has been used for metabolic profiling of urines from males and females of two groups of phenotypically normal mouse strains and a nude mouse strain [22].

Recently, CE coupled to mass spectrometry has also been explored as a suitable technology for metabonomics studies [23]. Charged metabolites are first separated by CE based on charge and size and then selectively detected using MS by monitoring over a large range of m/z values. This method was used to measure 352 metabolic standards and then employed for the analysis of 1692 metabolites from *Bacillus subtilis* extracts, revealing significant changes in metabolites during the bacterial sporulation.

For biomarker identification, it is also possible to separate out substances of interest from a complex biofluid sample using techniques such as solid phase extraction or HPLC. For metabolite identification, directly coupled chromatography–NMR spectroscopy methods can be used. The most powerful of these “hyphenated” approaches is HPLC–NMR–MS [24] in which the eluting HPLC peak is split with parallel analysis by directly coupled NMR and MS techniques. This can be operated in on-flow, stopped-flow, and loop-storage modes and thus can provide the full array of NMR and MS-based molecular identification tools. These include MS–MS for identification of fragment ions and FT–MS or TOF–MS for accurate mass measurement and hence derivation of molecular empirical formulae.

In summary NMR and MS approaches are highly complementary, and use of both is often necessary for full molecular characterization. MS can be more sensitive with lower detection limits provided the substance of interest can be ionized, but NMR spectroscopy is particularly useful for distinguishing isomers, for obtaining molecular conformation information, and for studies of molecular dynamics and compartmentation.

13.3.2.3 Other Technologies

Although most metabonomics applications have used either NMR spectroscopy or chromatography coupled to mass spectrometry, other techniques have been explored. Fourier transform infrared spectroscopy has been applied to a few metabolomics investigations including the evaluation of different *E. coli* mutants by

analysis of their secreted metabolites [25]. Although in principal, different responses can be achieved from different sample classes, and analyzed using pattern recognition methods, the main limitation of this technique is the low level of detailed molecular identification that can be achieved, and indeed in the case quoted above, MS was also employed for metabolite identification.

An alternative approach has been pioneered by Lewitt et al. [26]. This uses an array of coulometric detectors following HPLC separation to detect redox-active compounds in a complex mixture such as in CSF or tissue extracts. Although this approach does not identify compounds directly, the combination of retention time and redox properties can serve as a basis for database searching of libraries of standard compounds. The separation output can also be directed to a mass spectrometer for additional identification experiments.

13.3.3 DATA ANALYSIS USING CHEMOMETRICS

13.3.3.1 Chemometrics Methods

The complex data that arise from, for example, an NMR spectrum of a sample can be thought of as an object with a multidimensional set of metabolic coordinates, the values of which are the spectral intensities at each data point. Thus, each spectrum becomes a point in a multidimensional metabolic hyperspace. In chemistry, the term *chemometrics* is generally applied to describe the use of both parametric and nonparametric multivariate statistical approaches to chemical numerical data. The general aim is to classify an object based on identification of inherent patterns in a set of experimental measurements or descriptors and to identify those descriptors responsible for the classification. The approach can also be used for reducing the dimensionality of complex datasets, for example, by 2D or 3D mapping procedures, to enable easy visualization of any clustering or similarity of the various samples. Alternatively, in what are known as "supervised" methods, multiparametric datasets can be modeled so that the class of separate samples (a "validation set") can be predicted based on a series of mathematical models derived from the original data or "training set" [27].

Principal components analysis (PCA) is one of the simplest techniques that has been used extensively in metabonomics, and this expresses most of the variance within a dataset using a smaller number of factors or principal components. Each PC is a linear combination of the original data parameters whereby each successive PC explains the maximum amount of variance possible, not accounted for by the previous PCs. Each PC is orthogonal and therefore independent of the other PCs. Thus, the variation in the spectral set is usually described by many fewer PCs than the original data point values because the less important PCs describe the noise variation in the spectra. Conversion of the data matrix to PCs results in two matrices known as scores and loadings. Scores, the linear combinations of the original variables, are the coordinates for the samples in the established model and may be regarded as the new variables. In a scores plot, each point represents a single sample spectrum. The PC loadings define the orientation of the computed PC with respect to the original variables and thus indicate which variables carry the greatest weight in transforming the position of the original samples from the data matrix into their new position in the scores matrix. In the loadings plot, each point represents a dif-

ferent spectral intensity. Thus, the cause of any spectral clustering observed in a PC scores plot is interpreted by examination of the loadings that cause any cluster separation. In addition, there are many other visualization methods such as non-linear mapping and hierarchical cluster analysis.

The upper part of Figure 13.3-4 shows a PC scores plot where each point is based on the ^{1}H NMR spectrum of a rat urine sample. In this case, the open and filled symbols represent samples of rat urine received from two different sites, from animals dosed with a model liver toxin, hydrazine, and sampled at various time points in hours after dosing as shown [28].

One of many widely used supervised methods (i.e., using a training set of data with known outcomes) is partial least squares (PLS). This method relates a data matrix containing independent variables from samples, such as spectral intensity values (an X matrix), to a matrix containing dependent variables (or measurements of response) for those samples (a Y matrix). PLS can also be used to examine the

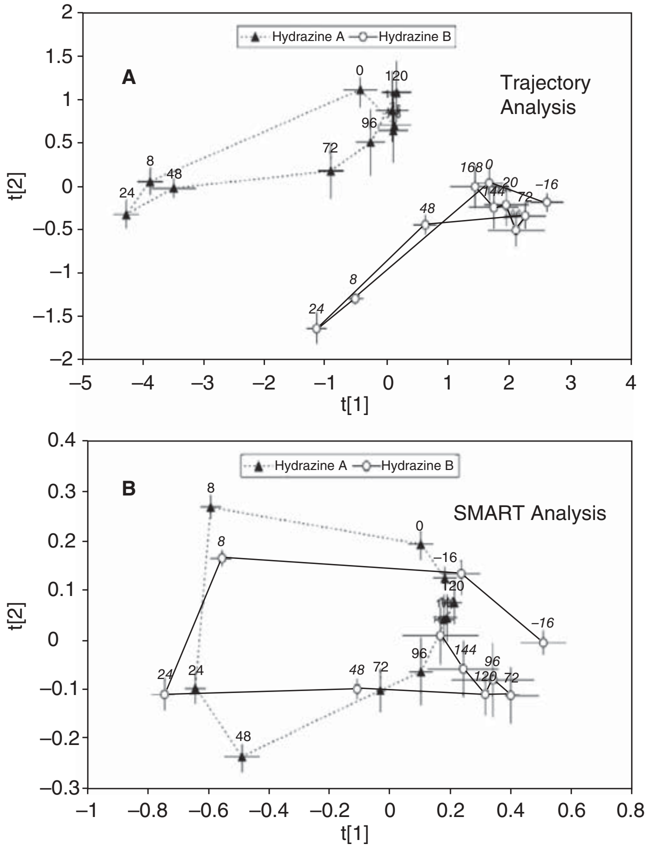

Figure 13.3-4. Principal components scores plots (PC1 vs. PC2) based on 600-MHz ^{1}H NMR spectra of rat urine. (a) Standard trajectory analysis of urinary NMR data obtained after treatment with hydrazine from identical studies repeated at different sites, open and closed symbols. (b) The same data after application of the trajectory matching technique, SMART. Error bars represent the standard error for each time point average [28].

influence of time on a dataset, which is particularly useful for biofluid NMR data collected from samples taken over a time course of the progression of a pathological effect. PLS can also be combined with discriminant analysis (DA) to establish the optimal position to place a discriminant surface that best separates classes. It is possible to use such supervised models to provide classification probabilities or even quantitative response factors for a wide range of sample types, but given the strong possibility of chance correlations when the number of descriptors is large, it is important to build and test such chemometric models using independent training data and validation datasets. Extensions of this approach allow the evaluation of those descriptors that are completely independent (orthogonal) to the Y matrix of endpoint data. This orthogonal signal correction (OSC) can be used to remove irrelevant and confusing parameters.

Apart from the methods described above that use linear combinations of parameters for dimension reduction, classification, or regression, other methods exist that are not limited in this way. For example, neural networks comprise a widely used nonlinear approach for modeling data. A training set of data is used to develop algorithms, which "learn" the structure of the data and can cope with complex functions. The basic software network consists of three or more layers, including an input level of neurons (spectral descriptors or other variables), one or more hidden layers of neurons that adjust the weighting functions for each variable, and an output layer that designates the class of the object or sample. Recently, probabilistic neural networks, which represent an extension to the approach, have shown promise for metabonomics applications in toxicity [29]. Other approaches that are currently being tested include genetic algorithms, machine learning, and Bayesian modeling [30].

13.3.3.2 Biomarker Identification using Chemometrics

Recently, a new method for identifying multiple NMR peaks from the same molecule in a complex mixture, hence providing a new approach to molecular identification, has been introduced. This is based on the concept of statistical total correlation spectroscopy and has been termed *STOCSY* [31]. This takes advantage of the multicollinearity of the intensity variables in a set of spectra (e.g., ^{1}H NMR spectra) to generate a pseudo-two-dimensional NMR spectrum that displays the correlation among the intensities of the various peaks across the whole sample. This method is not limited to the usual connectivities that are deducible from more standard two-dimensional NMR spectroscopic methods, such as TOCSY. Added information is available by examining lower correlation coefficients or even negative correlations, because this leads to a connection between two or more molecules involved in the same biochemical pathway. In an extension of the method, the combination of STOCSY with supervised chemometrics methods offers a new framework for analysis of metabonomic data. In a first step, a supervised multivariate discriminant analysis can be used to extract the parts of NMR spectra related to discrimination between two sample classes. This information is then cross-combined with the STOCSY results to help identify the molecules responsible for the metabolic variation. To illustrate the applicability of the method, it has been applied to 114 ^{1}H NMR spectra of urine from a metabonomic study of a model of insulin resistance based on the administration of a carbohydrate diet to three different mice strains in

which a series of metabolites of biological importance could be conclusively assigned and identified by use of the STOCSY approach [31].

13.3.4 SELECTED APPLICATIONS OF METABONOMICS

13.3.4.1 Phenotypic and Physiological Effects

To determine therapeutic or toxic effects or to understand the biochemical alterations caused by disease, it is necessary first to understand any underlying physiological sources of variation. To this end, metabonomics has been used to separate classes of experimental animals such as mice and rats according to several inherent and external factors based on the endogenous metabolite patterns in their biofluids [32]. Such differences may help explain differential toxicity of drugs between strains and interanimal variation within a study. Many other effects can be distinguished using metabonomics, including male/female differences, age-related changes, estrus cycle effects in females, diet, diurnal effects, and interspecies differences and similarities [32].

Metabonomics has also been used for the phenotyping of mutant or transgenic animals and the investigation of the consequences of transgenesis such as the transfection process itself [33]. Genetic modifications used in the development of genetically engineered animal models of disease are often made using such transfection procedures, and it is important to differentiate often-seen unintended consequences of this process from the intended result. Metabonomic approaches can give insight into the metabolic similarities or differences between mutant or transgenic animals and the human disease processes that they are intended to simulate and hence their appropriateness for monitoring the efficacy of novel therapeutic agents. This suggests the method may be appropriate for following treatment regimes such as gene therapy.

The importance of gut microfloral populations on urine composition has been highlighted by a study in which axenic (germ free) rats were allowed to acclimatize in normal laboratory conditions and their urine biochemical makeup was monitored for 21 days [34]. The combined influence of gut microflora and parasitic infections on urinary metabolite profiles has also been elucidated [35].

13.3.4.2 PreClinical Drug Candidate Safety Assessment

Despite the regulatory requirements and the huge investment by pharmaceutical companies in safety testing in animals, unexpected results are sometimes observed in the clinic and drugs occasionally still have to be withdrawn from the marketplace. The selection of robust candidate drugs for development based on mimimization of the occurrence of drug adverse effects is therefore one of the most important aims of pharmaceutical R&D, and the pharmaceutical industry is now embracing metabonomics for evaluating the adverse effects of candidate drugs. The National Center for Toxicological Research, a part of the U.S. Food and Drug Administration, is also investigating the usefulness of the approach.

In this application, NMR-based metabonomics can be used for (1) definition of the metabolic hyperspace occupied by normal samples; (2) the consequential rapid classification of a biofluid sample as normal or abnormal; (3) if abnormal,

classification of the target organ or region of toxicity; (4) biochemical mechanism of that toxin; (5) identification of combination biomarkers of toxic effect; and (6) evaluation of the time course of the effect, e.g., the onset, evolution, and regression of toxicity. An example of a metabolic trajectory is shown in Figure 13.3-4(a), where each point represents an NMR spectrum of a rat urine sample at various time points after dosing with the model liver toxin, hydrazine [28]. There have been many studies using ^{1}H NMR spectroscopy of biofluids to characterize drug toxicity going back to the 1980s [36], and the role of metabonomics in general, and magnetic resonance in particular, in toxicological evaluation of drugs has been comprehensively reviewed recently [37].

Metabonomics has already been applied in fields outside human and other mammalian systems. For example, studies in the environmental pollution field have highlighted the potential benefits of this approach by studies of caterpillar hemolymph [38] and earthworm biochemical changes as a result of soil pollution by model toxic substances [39]. In addition, a study of heavy metal toxicity (As^{3+} and Cd^{2+}) in wild rodents living on polluted sites has been concluded successfully [40]. In terms of monitoring water quality, one study has evaluated adverse effects in abalone using NMR-based metabonomics [41].

The usefulness of metabonomics for the evaluation of xenobiotic toxicity effects has recently been comprehensively and successfully explored by the Consortium for Metabonomic Toxicology (COMET). This was formed by five pharmaceutical companies and Imperial College, London, United Kingdom [42], with the aim of developing methodologies for the acquisition and evaluation of metabonomic data generated using ^{1}H NMR spectroscopy of urine and blood serum from rats and mice for preclinical toxicological screening of candidate drugs. The successful outcome is evidenced by the generated databases of spectral and conventional results for a wide range of model toxins (147 in total) that served as the basis for computer-based expert systems for toxicity prediction. The project goals of the generation of comprehensive metabonomic databases (now around 35,000 NMR spectra) and multivariate statistical models (expert systems) for prediction of toxicity, initially for liver and kidney toxicity in the rat and mouse, have now been achieved, and the predictive systems and databases have been transferred to the sponsoring companies.

A feasibility study was carried out at the start of the project, using the same detailed protocol and using the same model toxin, over seven sites in the companies and their appointed contract research organizations. This was used to evaluate the levels of analytical and biological variation that could both arise through the use of metabonomics on a multisite basis. The intersite NMR analytical reproducibility revealed the high degree of robustness expected for this technique when the same samples were analyzed both at Imperial College and at various company sites. This gave a multivariate coefficient of regression between paired samples of only about 1.6% [43].

Additionally, the biological variability was evaluated by a detailed comparison of the ability of the companies to provide consistent urine and serum samples for an in-life study of the same toxin, with all samples measured at Imperial College. There was a high degree of consistency between samples from the various companies, and dose-related effects could be distinguished from intersite variation [43].

As a precursor to developing the final predictive expert systems, metabonomic models were constructed for urine from control rats and mice, enabling identifica-

tion of outlier samples and the metabolic reasons for the deviation. To achieve the project goals, new methodologies for analyzing and classifying the complex datasets were developed. For example, as the expert system takes into account the metabolic trajectory over time, a new way of comparing and scaling these multivariate trajectories was developed (called SMART), and this is illustrated in Figure 13.3-4 [28]. Additionally, a novel classification method for identifying the class of toxicity based on all NMR data for a given study has been generated. This has been termed "Classification Of Unknowns by Density Superposition (CLOUDS)" and is a novel non-neural implementation of a classification technique developed from probabilistic neural networks [44]. Modeling the urinary NMR data according to organ of effect (control, liver, kidney, or other organ), using a model training set of 50% of the samples and predicting the other 50%, over 90% of the test samples were classified as belonging to the correct group with only a 2% misclassification rate between these classes. This work showed that it is possible to construct predictive and informative models of metabonomic data, delineating the whole time course of toxicity, the ultimate goal of the COMET project.

13.3.4.3 Disease Diagnosis and Therapeutic Efficacy

Many examples exist in the literature on the use of NMR-based metabolic profiling to aid human disease diagnosis, including the use of plasma to study diabetes, CSF for investigating Alzheimer's disease, synovial fluid for osteoarthritis, seminal fluid for male infertility, and urine in the investigation of drug overdose, renal transplantation, and various renal diseases. Most of the earlier studies using NMR spectroscopy have been reviewed [45]. For example, a promising use of NMR spectroscopy of urine and plasma, as evidenced by the number of publications on the subject, is in the diagnosis of inborn errors of metabolism in children [46].

Some studies have been undertaken in the area of cancer diagnosis using perchloric acid extracts of various types of human brain tumor tissue [47], and the spectra could be classified using neural network software giving ~85% correct classification. Tissues can be studied by metabonomics through the MAS NMR technique, and published examples include prostate cancer [16, 48], renal cell carcinoma [18], breast cancer [19, 49], and various brain tumors [50]. Other recent studies include an NMR-based urinary metabonomic study of multiple sclerosis in humans and non-human primates [51].

Recently metabonomics has been applied to provide a method for diagnosis of coronary artery disease noninvasively through analysis of a blood serum sample using NMR spectroscopy [52]. Patients were classified, based on angiography, into two groups, those with normal coronary arteries and those with triple coronary vessel disease. Around 80% of the NMR spectra were used as a training set to provide a two-class model after appropriate data filtering techniques had been applied, and the samples from the two classes were easily distinguished. The remaining 20% of the samples were used as a test set, and their class was then predicted based on the derived model with a sensitivity of 92% and a specificity of 93% based on a 99% confidence limit for class membership.

It was also possible to diagnose the severity of the disease that was present by employing serum samples from patients with stenosis of one, two, or three of the coronary arteries. Although this is a simplistic indicator of disease severity, separation of the three sample classes was evident even though none of the wide range

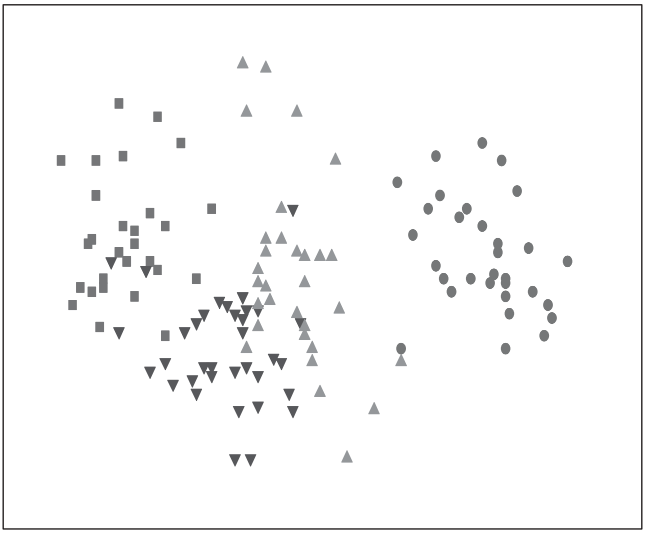

Figure 13.3-5. Partial least-squares discriminant analysis model for the classification of blood plasma samples in terms of coronary artery disease, based on their ^{1}H NMR spectra with visualization of the degree of coronary artery occlusion. Each point is based on data from a ^{1}H NMR spectrum of human blood plasma from subjects with different degrees of coronary artery occlusion. Circles—no stenosis, triangles—stenosis of one artery, inverted triangles—stenosis of two arteries, and squares—stenosis of three arteries. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

of conventional clinical risk factors that had been measured was significantly different between the classes. The visualization of the separation of patients with zero, one, two, or three coronary arteries occluded is shown in Figure 13.3-5.

13.3.5 INTEGRATION OF -OMICS RESULTS

The value of obtaining multiple datasets from various biofluid samples and tissues of the same animals collected at different time points has been demonstrated. This procedure has been termed "integrated metabonomics" [2] and can be used to describe the changes in metabolic chemistry in different body compartments affected by exposure to toxic drugs. An illustration of the types of information that can be obtained is shown in Figure 13.3-6, from an NMR spectroscopic study of the acute toxicity of α-naphthylisothiocyanate, a model liver toxin [53]. Such timed profiles in multiple compartments are characteristic of particular types and mechanisms of pathology and can be used to give a more complete description of the biochemical consequences than can be obtained from one fluid or tissue alone [54].

Integration of metabonomics data with that from other multivariate techniques in molecular biology such as from gene array experiments or proteomics is also feasible. Thus, it has also been possible to integrate data from transcriptomics and metabonomics to find, after acetaminophen administration to mice, common metabolic pathways implicated by both gene expression changes and changes in metabolism [55]. In a similar fashion, changes in gene expression detected in microarray

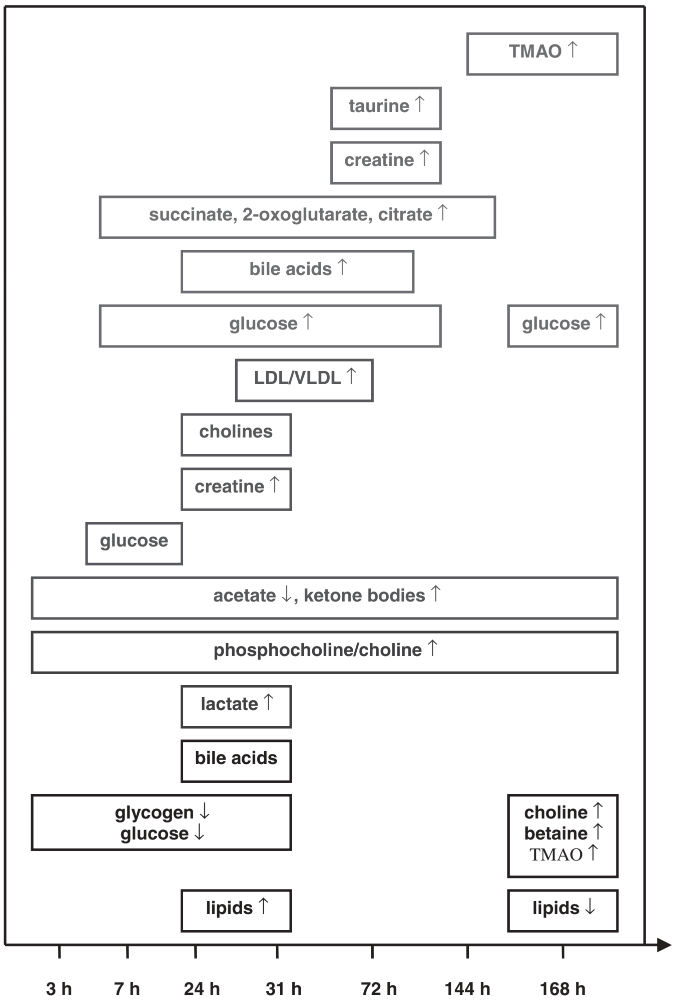

Figure 13.3-6. Representation of the information that can be obtained from an integrated metabonomics study. This shows the metabolites that are changed in a range of biofluids and tissues as a function of time after a single acute administration of the liver toxin α-naphthylisothiocyanate [53]. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

experiments can lead to the identification of changed enzyme activity, and this can also be achieved by analysis of metabolic perturbations [56].

13.3.6 FUTURE PROSPECTS

It has become accepted that the main pharmaceutical areas where metabonomics is impacting include validation of animal models of disease, including genetically modified animals; preclinical evaluation of drug safety studies; allowing ranking of candidate compounds; assessment of safety in humans in clinical trials; after product launch, quantitation, or ranking of the beneficial effects of pharmaceuticals,

both in development and clinically; improved understanding of the causes of highly sporadic idiosyncratic toxicity of marketed drugs; and patient stratification for clinical trials and drug treatment (pharmaco-metabonomics).

In addition, in terms of disease studies, metabonomics is playing a role in improved, differential diagnosis and prognosis of human diseases, particularly for chronic and degenerative diseases, and for diseases caused by genetic effects. A better understanding of large-scale human population differences through epidemiological studies is also being achieved.

Other applications include nutritional studies, sports medicine, and lifestyle studies, including the effects of diet, exercise, and stress, and evaluation of the effects of interactions between drugs, and between drugs and diet. Additionally, the metabolic profiles of plants, including genetically modified species, and quality control studies (essential equivalence) are now being achieved together with applications in microbiological characterization; forensic science, including the biochemical effects of drug overdose; and environmental effects of pollutants monitored using marker species, both terrestrial and aquatic.

One long-term goal of using pharmacogenomic approaches is to understand the genetic makeup of different individuals (their genetic polymorphism) and their varying abilities to handle pharmaceuticals both for their beneficial effects and for identifying adverse effects. If personalized health care is to become a reality, an individual's drug treatments must be balanced so as to achieve maximal efficacy and avoid adverse drug reactions. Very recently, for the first time, an alternative approach has been proposed for understanding intersubject variability in response to drug treatment using a combination of multivariate metabolic profiling and chemometrics to predict the metabolism and toxicity of a dosed substance, based solely on the analysis and modeling of a predose metabolic profile [57]. Unlike pharmacogenomics, this approach, which has been termed *pharmaco-metabonomics*, is sensitive to both the genetic and the modifying environmental influences that determine the basal metabolic fingerprint of an individual, because these will also influence the outcome of a chemical intervention. This new approach has been illustrated with studies of the toxicity and metabolism of acetaminophen (paracetamol) administered to rats.

A major initiative has been under way to investigate the reporting needs and to consider recommendations for standardizing reporting arrangements for metabonomics studies, and to this end, a Standard Metabolic Reporting Structures (SMRS) group was formed (see www.smrsgroup.org). This group has produced a draft policy document that covers all of those aspects of a metabolic study that are recommended for recording, from the origin of a biological sample, the analysis of material from that sample, and chemometric and statistical approaches to retrieve information from the sample data, and a summary publication has ensued [58]. The various levels and consequent detail for reporting needs, including journal submissions, public databases, and regulatory submissions, have also been addressed. This has been followed up with a workshop and discussion meeting sponsored by the U.S. National Institutes of Health, from which firm plans are being developed to define standards in a number of areas relevant to metabonomics, including characterization of sample-related meta-data, technical standards, and related data; meta-data and QC matters for the analytical instrumentation; data transfer methodologies and schema for implementation of such activities; and development of standard vocabularies to enable transparent exchange of data.

NMR- and MS-based metabonomics are now recognized as independent and widely used techniques for evaluating the toxicity of drug candidate compounds, and they have been adopted by several pharmaceutical companies into their drug development protocols. For drug safety studies, it is possible to identify the target organ of toxicity, derive the biochemical mechanism of the toxicity, and determine the combination of biochemical biomarkers for the onset, progression, and regression of the lesion. Additionally, the technique has been shown to be able to provide a metabolic fingerprint of an organism ("metabotyping") as an adjunct to functional genomics and hence has applications in design of drug clinical trials and for evaluation of genetically modified animals as disease models.

Using metabonomics, it has proved possible to derive new biochemically based assays for disease diagnosis and to identify combination biomarkers for disease, which can then be used to monitor the efficacy of drugs in clinical trials. Thus, based on differences observed in metabonomic databases from control animals and from animal models of disease, diagnostic methods and biomarker combinations might be derivable in a preclinical setting. Similarly, the use of databases to derive predictive expert systems for human disease diagnosis and the effects of therapy require compilations from both normal human populations and patients before, during, and after therapy.

It is expected that further integration of the techniques into pharmaceutical R&D activities will continue. One potential advantage of this approach is the transferability in principle of metabolic biomarkers between species and ultimately into humans.

The ultimate goal of systems biology must be the integration of data acquired from living organisms at the genomic, protein, and metabolite levels. In this respect, transcriptomics, proteomics, and metabonomics will all play an important role. Through the combination of these, and related approaches, will come an improved understanding of an organism's total biology, and with this, better understanding of the causes and progression of human diseases and, given the twenty-first century goal of personalized health care, the improved design and development of new and better targeted pharmaceuticals.

13.4.1 PREFACE

The very fundamental characteristics of bioterrorism are presented, alongside with the distinct multidisciplinary configuration of the term and phenomenon. Some unique attributes are outlined that make bioterrorism an entity nourished by different essentials and bearing various, in part far-reaching, implications.

Infectious diseases—the most effective extraneous regulator controlling the size of many animal populations in nature—are largely restrained in relation to mankind, thanks to the advancement of preventive and therapeutic medicine. The balance thus created is at any rate fragile, especially as human population density is steadily increasing, overall, whereas pathogens persist in acquiring drug-resistance. Pharmaceutical biotechnology is one major contributing arena to medicine, in that context; bioterrorism constitutes a counter-arena that unfortunately may amplify or substitute for the natural control mechanisms signified for by infectious diseases. Paradoxically, yet, pharmaceutical biotechnology in itself represents a potential key resource for bioterrorism. This is the case because pharmaceutical biotechnology is becoming an unparalleled front area, bearing a melting pot of remarkably sophisticated and multidisciplinary know-how, substances, and appliances. Large portions of which are dual use and may readily be exploited decently or viciously.

This built-in, intriguing duality is an essential feature, in that bioterrorism may imbibe extra potency from the very capacity destined to prevent and cope with bioterrorism. Although a very old way of sabotage, bioterrorism is presently, or soon to be, immeasurably more powerful, potentially, than ever, due to marked breakthroughs achieved in biopharmacology and biomedicine. Scientifically, this evolving, dichotomic course is inevitable, albeit significantly augmenting bioterrorism resources. The comprehension and practice allowing for combating pathogens and toxins may serve then, as well, to upgrade bioterrorism. It is becoming but a matter of their degree of availability of those bioagents. The same principle applies for pathogens of farm animals and plants, which form an additional dimension of bioterrorism—agricultural bioterrorism (agroterrorism). Also, the increasing availability of recreational drugs—mostly a sort of phytotoxins, in their essence—propels another terrorism variant—narcoterrorism.

In a sense, then, bioterrorism may embody the golem that rose against its creator. It can trigger a confined outbreak, an extensive epidemic, or a colossal pandemic, intentionally engined by man himself. The perpetrators may not even figure the anticipated impact—medically, psychologically, and logistically—which may immensely exceed what they want to achieve. Inversely, the in-effect impact may be but marginal, much less than that quested for. This uncertainty stems from various unknowns still marking the behavioral profile of infectious diseases. The interface between pathogens and man retains its enigmatic identity, although largely deciphered. At any rate, as James Woolsey, former CIA director has put it: “Germ terrorism is the single most dangerous threat to our national security in the foreseeable future.” The magnitude of bioterrorism, yet, extends far beyond the boundaries of the United States.

Man only can eradicate, either locally or globally, long-lasting formidable pathogens—as was the case with smallpox—by means of extraneous, far-reaching intervention, namely vaccination; antibiotics are not less important for wiping out certain bacterial pathogens. Yet man is, at the same time, the prime messenger of their possible reemergence, particularly through bioterrorism. Conceivably, his intelligence and impulse both shape, thus, a delicate balance, one that might branch unthinkable ramifications. It is, then, his own and absolute responsibility to pursue a steady state that would eliminate or minimize the risk of epidemic self-destruction. In general, calculated self-destruction is unsupprisingly, antagonistic to the very nature of most species.

The menace of terrorism at large, in its broad sense, is an unparalleled phenomenon that may be considered, basically, to be a sort of a limited self-destruction mechanism for mankind. In a way, it is even worse then wars, because of its inherent unpredictability, irrationalism, and wide scope, as well as the built-in, unapparent, vitality, and durability marking it. When the dimension of biological warfare is added to this featuring, it turns out to pose uncontrollable potentiality.

Addressing the complicated domain of bioterrorism has to necessarily be conducted through a multidisciplinary approach. Therefore, the following chapter covers varitype aspects altogether, namely, microbiological, epidemiological, medical, technological, demographical, political, and strategic; the integration of which is essential, so as to comprehend the substance, complexity, and implications of bioterrorism. The entire issue of bioterrorism may thus gain a typical multidimensional structure and meaning.

13.4.2 DEFINITION AND ESSENCE OF BIOTERRORISM

Integrating two spheres that are innately unconnected to each other—terrorism and pathogens—the entity of bioterrorism reflects a complex, although in a sense fairly old, phenomenon of mankind. Given this starting point, the definition and essence of bioterrorism, together with its meaningfulness, are complicated. At the same time, the protean nature of bioterrorism endows it with uncommon attractiveness and advantageousness that may meet various courses.

The two elements comprising bioterrorism, namely terrorizing by means of biological agents, represent two distinct spheres, each bearing multiple contents. Those two spheres form, thereby, a singular, mighty conjunction between strategic studies and life sciences.

Terrorism at large, can be variedly featured, according to the following parameters:

- Conducted by a country, organization, group, or individual.
- Against a country, organization, group, or individual.
- By threatening and/or attacking.
- Covertly or overtly.
- Terror may be the goal or a by-product of an in-effect damage.
- The direct impact may be the ultimate objective or propel the occurrence of the ultimate objective.
- The impact is intended to form in the short, medium, or long run.
- With or without taking responsibility by the perpetrator.

Biological agents include, basically, pathogens and toxins, which may be classified in the following ways:

- Live—hence reproducing—agents (pathogens) or nonviable agents (toxins). Prions, as reproducing molecules, constitute a notable, exceptional intermediate.

- Lethal or sublethal (not a clear-cut division).
- Transmissible—hence epidemic—pathogens or nontransmissible pathogens.
- Natural or modified/engineered pathogens and toxins.
- Abruptly or gradually affecting the target.
- Affecting humans, husbandry, crops, or materials.
- The vehicle may be natural (infected arthropod, animal, or human being) or artificial (man-made disseminator, i.e., sprayers and envelopes).
- The route of penetrating the body is the respiratory system, alimentary tract, or skin.

Remarkably, almost any combination of the various mentioned parameters featuring terrorism and biological agents is feasible. That is one main attribute underlying the attractiveness and potential might of bioterrorism. Another one is the outstanding ratio between the amount of biological agent to be used and the resulting impact, especially with reference being made to epidemic pathogens. At the extreme, which is certainly feasible, an individual saboteur can disperse a scarcely existent, unapparent amount of a fully epidemic, virulent pathogen, be it pestilence, smallpox, or influenza, and give rise to a transgressing, questionably controllable, lethal plague.

Biocrimes, biosabotage, and biowarfare are terms appreciably dovetailing with bioterrorism, in different manners. Although biological crimes accentuate the illegal dimension of bioterrorism, they pertain, as well, to a variety of acts, such as the very holding or transferring of a certain microorganism, which are in violation of national or international rules and conventions. Biological sabotage is the in-effect employment of biological agents for whatever operational sabotage purpose, whether or not terrorism-oriented, usually by means of guerilla warfare. Biological warfare basically reflects a military confrontation in which biological weaponry is used; yet broadly, it may be waged against civilian target populations, thus explicitly having the quality of bioterrorism.

Bioterrorism may be perceived, overall, as the calculated, deliberate use of pathogens or toxins (or threat of using them) against civilian populations or economic/logistical infrastructures, in order to attain goals that are political, social, religious, financial, ideological, or personal in nature; this is done through intimidation or coercion or instilling fear. It may still be subclassified, then, as follows:

- The unlawful release of biological agents or toxins with the intent to intimidate or coerce a government or civilian population to further political or social objectives. Humans, farm animals, and cultivars are often targets.
- Use of microorganisms or toxins to kill, sicken, or cause other malfunction in people, animals, plants, or useful materials.

In its broad scope, thus, bioterrorism includes, beyond its classic targeting against humans:

- Agroterrorism, which may involve anti-plant pests, in addition to anti-plant and anti-animal pathogens.

- Narcoterrorism, namely the constant on-purpose input of recreational drugs onto a target population.
- Any other type of sabotage achievable by means of microbes, such as fuel-eating bacteria, asphalt eating-bacteria, and alike.

In a way, the core of bioterrorism, both objectively and subjectively, is horrifying, whereas the involved weapon in itself consists in, absurdly, some of the most powerful natural foes of humanity, and can in practice bring about a very significant direct impact, far beyond horror. Hence, it may regretfully be regarded, in a sense, as the potential promoter of various infectious diseases that are currently being suppressed, pharmacologically and medically, just waiting for their opportunity to come.

One chief character of bioterrorism is, nonetheless, the conceivably immeasurable disproportion between effort and outcome, particularly when the latter is at its maximum. It thus poses a strong temptation. Any other weapons, terror means—and apparently any other context—are not competent in sustaining such disproportion. Technically, then, this attribute mostly represents the essence of bioterrorism, such that nears a legendary identity. The distance from reality is at any rate secondary, especially as it can readily be bridged over, in affect, quite soon. In that concern, recent breakthroughs made in the field of genetic engineering amplify at the same time, paradoxically, both imagination and practicality.

All in all, within the sphere of terrorism at large, three distinctions typify the essence of bioterrorism:

1. The distinction between bioterrorism and conventional terrorism.
2. Between bioterrorism and other unconventional terrorism (chemical, radiological, nuclear).
3. Between bioterrorism and biological warfare.

The projection of those three distinctions altogether reflects the whole substance of bioterrorism, as aimed, among other things, to be shown in this chapter.

13.4.3 CONCEPT AND INCENTIVES

Several common denominators are outlined, which mark both terrorism-oriented states and terror organizations, on their way to resorting to bioterrorism. Other elements of their concept and incentives regarding bioterrorism comparatively differ, naturally, owing to their dissimilar essences. Various motives and objectives may then underlie their encouraged attitude toward bioterrorism. The roots are at any rate historical, appreciably shaping during time.

Intuitively, not having any concrete knowledge in terms of toxinology and bacteriology until the nineteenth century, man adopted poisonous and infective substances for attacking rivals. It was mainly practical common sense that guided him. Much later, paving its way toward scientific horizons, man gradually mastered the related technical fundamentals. The recognition of infective microorganisms and naturally produced toxic molecules accumulated and ripened. It reached the level of having the full capacity to operate them as warfare agents.

But, anthropologically, the concept underlying bioterrorism extends far beyond technical and operational features, whether state or non-state sponsored. The very notion of afflicting passive civilian populations with infectious diseases seems to be, objectively, profoundly evil, even if accompanied by different considerations and calculations. In its simplest form, then, bioterrorism reflects but an extreme way of malevolence. Variably, the dimensions of governance and insidiousness may certainly play a roll, in conjunction. *A priori*, the power to generate epidemics was possessed only by God and nature. Thus, biblically, God waged, initially, the epidemics included within the Ten Plagues of Egypt. Later on, comprehending the principal mechanism and impact of epidemics, man tried to emulate and immobilize that route against adversaries. As a matter of fact, it was around 1500 BC, when the Hittites sent plague victims into the lands of their enemies [1].

The fundamental incentive and concept of bioterrorism did not substantially change, up to these days. What did alter, obviously, are the know-how, the technical tools, and the strategic approach. Strategically, there are three basic alternatives shaping the concept of bioterrorism acts:

- The perpetrator (either state or non-state sponsored) would seek to remain unidentified.
- The perpetrator would be indifferent as to its identity.
- The perpetrator would seek to be identified.

The first and third alternatives have each two variants, respectively:

- Anonymity would rely on objective inability to epidemiologically determine whether the event was an act of bioterrorism.
- Anonymity would rely on objective inability to trace the perpetrator by means of investigation or intelligence (even if epidemiologically affirmed to be an act of bioterrorism).
- Identification would rely on direct announcement, either before or subsequent to the act of bioterrorism.
- Identification would rely on investigative and intelligence findings—either evidential or, deliberately, merely circumstantial (hence less valid)—without taking responsibility.

Several technological, political, and psychological explanations underly the quest of terrorists and terrorism-oriented states to opt for acquiring weapons of mass destruction (WMD), particularly biological agents, among them are the cheap cost of such weapons and the sense of prestige and security they grant to the owner. Parallel to offensive considerations, the inverse dimension of deterring capacity also plays a roll. All in all, terrorists or terrorism-oriented states may choose bioterrorism among many options, both conventional and unconventional. Preference may be given to bioterrorism due to various reasons. In terms of a pragmatic, clinical feasibility study, bioterrorism is, at least potentially, the most efficient form of sabotage, particularly when conducted indistinguishably from a natural event. Moreover, it may have a fully strategic impact; hence, it is often reckoned to be the ultimate mode of terrorism. Notably, most biological agents are not contagious; yet

they might generate extensive outbreaks, if not epidemics, due to their transmissibility in other ways.

A terrorist group or terrorism-oriented state, intending to employ biological agents, will likely be attracted to their mass killing potential [2]. In addition, their delayed impact may also enable the saboteur to escape detection. Also, an attacker might reckon the resemblance between a natural and an unnatural epidemic to be close enough to divert suspicion, or at least make it extremely difficult to trace [3]. That would make it difficult to retaliate with a massive punitive strike, the expectation of which ordinarily serves as deterrent to an unconventional assault. Thus, the subsequent intimidation and chaos resulting from the inherently unknowable may make biological agents the terrorist weapon of choice [4]. On the whole, the related line of terms accentuating the significance and potential impact of bioterrorism at large include, then: high consequence terrorism; catastrophic terrorism; total terrorism; asymmetric terrorism; superterrorism; ultraterrorism, and so on.

Beyond, terrorists and terrorism-oriented states are certain to decide for themselves whether the conduction of bioterrorism serves their cause. Moreover, it is believed that biological weapons are preferable for terrorist groups, and that the allure for terrorists of biological weapons is currently intensifying due to the increase in availability of biotechnologists and sophistication of manufacturing methods [5].

Overall, one fundamental motive of bioterrorism (within the context of WMD at large), then, is the will to generate what is currently called high consequence terrorism, total terrorism, or catastrophic terrorism. Under certain circumstances it may be regarded as pure asymmetric terrorism, the purpose of which is not to take lives or destroy property. It is rather the mechanism by which the attacker seeks to achieve weakening of the sense of cohesion that binds communities together, to reduce its social capital, and to sow distrust, fear, and insecurity. Within this narrow course, it is but a method of waging a sort of social and psychological warfare.

The availability of pathogenic agents, alongside with technical feasibility and operational modality of bioterrorism at large, are basically rather in favor of the saboteur or terrorism-oriented state. Still, the bioterrorism events that already took place overall, seemingly exhibit but a portion of its potentiality, whereas the essence of the related threshold of proliferation is vague. Resultantly, built-in limitations interfere with thoroughly comprehending and foreseeing the course of bioterrorism.

13.4.4 BIOTERRORISM-PATTERNED NATURAL EPIDEMICS

The apparent resemblance between natural epidemics and induced ones mostly leads to recognizing the relevance of bioterrorism-patterned natural epidemics as prime demonstrative occurrences. Let alone, that various infectious diseases, chiefly viral, are emerging or reemerging in an unpredictable, often overwhelming, manner. It would therefore be advisable to diligently observe some prominent natural epidemics that took place during the recent decade.

The most distinct bioterrorism-patterned natural epidemics are typically those concerned with water- and food-borne infectious gastroenteritis, stemming from

the contamination of a current collective source. Such epidemics would include, principally, two phases:

- The first wave of infections is generated directly by the consumption of the collective source.
- An additional wave is brought about, dependent on the degree of ongoing communicability or contagiousness of the causative agent toward potential secondary victims that are prone to be exposed, irrespective of the initial collective source.

This type of epidemic locally occurs very often, worldwide, in the form of relatively restricted innocent outbreaks. They bear the potency to expand, however. And they are quite easy to be produced deliberately, in practice. But, at any rate, they represent the simplest bioterrorism-patterned natural epidemics.

Bioterrorism-patterned natural epidemics might be by far more complex and hazardous, nonetheless. It so happened that the past 10 years were marked by some outstanding epidemic events perfectly illustrating the tremendous potentiality of biological agents at large, as well as the candidature of certain pathogens for acts of bioterrorism, in particular. Those events are presented here in detail, then, so as to demonstrate the general effectuality of various bioterrorism-patterned scenarios. They include six virus- and germ-propelled catastrophic epidemics.

13.4.4.1 Ebola Hemorrhagic Fever

The 14th of April, 1995, Zaire (now the Democratic Republic of Congo). A 36-year-old laboratory technician checked into the medical clinic in Kikwit, complaining of a severe headache, stomach pains, fever, dizziness, weakness, and exhaustion [6].

Surgeons did an exploratory operation to try to find the cause of his illness. To their horror, they found his entire gastrointestinal tract was necrotic and putrefying. He bled uncontrollably and within hours was dead. By the next day, the five medical workers who cared for him, including an Italian nun who assisted in the operation began to show similar symptoms, including high fevers, fatigue, bloody diarrhea, rashes, red and itchy eyes, vomiting, and bleeding from every body orifice. Less than 48 hours later, they, too, were dead, and the disease turned to form a deadly, uncontrollable epidemic.

As panicked residents fled into the bush, government officials responded to calls for help by closing off all travel, including humanitarian aid into or out of Kikwit, about 400 km from Kinshasa, the national capital. Fearful neighboring villages felled trees across the roads to seal off the pestilent city. No one dared enter houses where dead corpses rotted in the intense tropical heat. Boats plying the adjacent Kwilu River refused to stop to take on or discharge passengers or cargo. Food and clean water became scarce. Hos-pitals could hardly function as medications and medical personnel became scarce.

Deadly tropical fevers are an unfortunate fact of life in Central Africa but rarely are they this contagious or lethal. The plague that afflicted Kikwit was Ebola hemorrhagic fever, a viral disease for which there is no known treatment. Within a few weeks, about 400 people in Kikwit had contracted the virus and 350 were dead.

Where a 10% mortality rate is considered high for most infectious diseases, Ebola kills up to 90% of its victims, usually within only a few days after exposure. Still, contagiousness seems to be low.

The Kikwit Ebola outbreak was neither the first nor the last appearance of this dread disease. The first recognized Ebola epidemic occurred in 1976 in Yambuku, Zaire (near the Ebola River, after which the virus was named), where at least 280 people died. Three years later, 22 patients died in Sudan from a slightly different and less virulent form of Ebola. In 1996, about 100 people were killed by Ebola in two separate episodes in Gabon, and in 1999, an outbreak in the gold mining town of Durba in the Democratic Republic of Congo killed at least 63 people.

Ebola is one of two members of a family of RNA viruses called the Filoviridae (the other one being Marburg fever). No host or vector is known for Ebola, but it has been observed that monkeys and other primates can contract related diseases. Why viruses remain peacefully in their hosts for many years without causing much more trouble than a common cold, but then erupt sporadically and unpredictably into terrible human epidemics, is a new and growing question in environmental health and risk assessment. Although certainly a formidable pathogen, this virus exhibits changing rates of virulence (which is at times extremely high, more than any other pathogen), communicability, and, hence, epidimicity, the latter being rather restrained, in effect (400 infected and diseased people, out of 600,000 residents in Kikwit). Therefore, a shift in the transmissibility level of Ebola virus may be crucial and is immensely feared.

13.4.4.2 AIDS

AIDS, or acquired immunodeficiency syndrome, is a fatal disease caused by a rapidly mutating retrovirus that attacks the immune system and leaves the victim vulnerable to infections, malignancies, and neurological disorders. It was first recognized as a disease in 1981. The virus was isolated for the first time not long ago, in 1983. It is steadily spreading. During 2004, as a representation, around five million adults and children became infected with HIV (human immunodeficiency virus), the virus that causes AIDS. By the end of the year, an estimated 39.4 million people worldwide were living with HIV/AIDS. The year also saw more than three million deaths from AIDS, despite the availability of HIV antiretroviral therapy, which reduced the number of deaths in high-income countries. African and South-American tropical regions are heavily afflicted in particular for long periods of time.

But in certain regions the disease has risen remarkably swiftly during recent years. One of those arenas is Leningrad, were a notably exponential AIDS epidemic started in 1997. Beginning in that year and proceeding up to 2001, all patients in the Narcology Hospital of Leningrad Regional Center of Addictions (LRCA), were tested for HIV antibody [7]. These clinical records (i.e., serostatus, gender, age, and addiction) and data from the HIV/AIDS Center in the Leningrad Region were reviewed.

It has thus been shown that HIV prevalence at the LRCA increased from 0% to 12.7% overall, 33.4% among drug-dependent patients, and 1.2% among alcohol-dependent patients. During the same 5-year period (1997–2001), 2826 persons were registered at the HIV/AIDS Center: 6, 6, 51, 780, and 1983 persons in 1997, 1998, 1999, 2000, and 2001, respectively.

So, HIV infection is exploding in the Leningrad Region, currently in injection drug users, but potentially more broadly. The known high-per-capita alcohol intake in Russia heightens concern regarding the sexual transmission of HIV. Overall, the number of HIV-infected people in the Leningrad Region has risen to 2929 by the beginning of 2001, which is 2.3 times more than in 2000. Young people aged from 14 to 30, mostly drug addicts, account for 85% of the overall number of HIV-infected people. The number of teenagers sick with AIDS has risen by 2.5 times since last year. Particular concern was caused by a 10-fold increase in the number of AIDS victims among pregnant women. A total of 350 births given by HIV-infected mothers has been registered in the past year, and in 10 cases, parents gave up their babies [8].

However, the AIDS pandemic, in its broad essence, is actually a global long-term eroding factor toward mankind at large. Caused by a type of attritional bioterrorism agent, analogicolly, its ultimate real impact is expected sometime in the future, unforeseeably. For now, and in relation to the magnitude of humanity, it is just crawling, slowly yet steadily. It may be regarded as an inherent, low-rate—although undefeatable, for the time being—cryptic, ostensibly overt pandemic, accumulating its critical mass.

13.4.4.3 SARS

The SARS (sever acute respiratory syndrome) virus emerged—and possibly rather formed, somehow, little earlier, in reality—on the 16 of November 2002. In Foshan, southern China, on the Pearl River Delta, the first case of SARS involved a man, a "super-infector" who subsequently infected four others [9].

It soon exploded. By November 31, 2002, a deadly outbreak of SARS carried on in China and has killed at least 34 people in the south and three in Beijing. Hundreds have been infected. Clearly an infectious disease, the illness was named and registered only clinically, owing to the unidentified nature of its casual agent. It was certainly recognized to be a virulent virus, at any rate. At that stage, the new virus seemed to be fairly confined. But during December, the disease "hitch-hiked" 200 km to Heyuan city, the provincial capital of Guangzhou. Virus spread to five hospital workers. Panic ensued in Heyuan, and the local authorities tried to calm the people with news that there was not epidemic. Within days, the alarm subsided. Somewhere during this time, provincial party leaders curbed the media from publishing details of the disease, hindering further efforts to contain the virus. By the end of December 2002, Guangdong had reported at least 300 cases.

Although showing to be a new virus, a comprehensive genomic analysis has established that the relationship between SARS Coronavirus and group 2 CoVs is monophyletic [10]. Apparently, then, the SARS virus evolved as a strange zoonotic offshoot of group 2 CoVs, bearing greatly enhanced infectivity toward man.

Actually, SARS is the first major novel infectious disease to hit the international community in the twenty-first century. It originated in southern China in November 2002 and spread rapidly thereafter to 29 countries/regions on five continents. At the end of the epidemic, the global cumulative total was 8098 with 774 deaths. Seven Asian countries/regions were among the top 10 on the list. It has alarmed the world with its infectivity and significant morbidity and mortality, its lack of a rapid, reliable diagnostic test, and lack of effective specific treatment and

vaccination. The adverse impact on travel and business around the world, particularly in Asia, has been enormous [11].

The consequences of the SARS epidemic were remarkable. In Taiwan, as an example, the impact of the SARS epidemic on the utilization of medical services was studied [12]. Using interrupted time-series analysis and National Health Insurance data between January 2000 and August 2003, this study assessed the impact of SARS epidemic on medical service utilization in Taiwan. At the peak of the SARS epidemic, significant reductions in ambulatory care (23.9%), inpatient care (35.2%), and dental care (16.7%) were observed. People's fears of SARS appear to have had a strong impact on access to care. Adverse health outcomes resulting from accessibility barriers posed by the fear of SARS are significant.

13.4.4.4 West-Nile Encephalitis

In late August of 1999, an unusual cluster of severe cases of encephalitis was noted in an area around Queens in New York City [13]. An epidemiologic investigation by the New York City Department of Health identified eight such cases and revealed that all of the patients had been previously healthy, had resided within the same 16 square mile area, and had recently engaged in outdoor activities. All but one had developed severe acute flaccid paralysis in the setting of encephalitis. At that point, the ethological agent had not yet been deciphered, though it seemed to be a basic virulent virus.

Both before and during the human encephalitis investigation, an epizootic among birds associated with a high fatality rate had been noted in and around New York City [14]. Pathologic assessment of the dead birds displayed involvement of multiple organs, including evidence of encephalitis; however, common avian pathogens were not detected [15]. The diseased birds were initially felt to be unrelated to the human epidemic. But genomic analyses using polymerase chain reaction and genome sequencing with specimens from New York City birds, infected mosquitoes collected in Connecticut, and human brain tissue from a fatal case of encephalitis, as well as expanded serological testing of specimens from suspected human cases identified WNE virus, a mosquito-borne pathogen, as the etiologic agent of this outbreak—4 weeks after the outbreak in humans was first reported to New York City public health officials [16–19]! By the end of the summer of 1999, 62 patients with serologic evidence of acute WNE virus infection, including 59 hospitalized patients, had been identified. Seven died. Similar to more recent outbreaks of the virus, the epidemic seemed to be associated with a high rate of CNS involvement and a preponderance of cases in patients older than 60 years [20].

The introduction of WNE virus in North America was followed by progressive spread throughout the United States. During the summer of 2000, 21 cases of human WNE virus illnes, were identified, 2 died occurred among 10 counties in northeastern states [21]. The following year, 66 cases were detected among a much more widespread geographic area, involving 38 counties in 10 states. The spread of human cases seemed to follow avian deaths; thus, avian death surveillance and, to a lesser extent, mosquito pool surveillance became important parts of public health efforts to track the virus and predict potential human cases [21]. In addition to avian and human illness, a substantial number of equine cases were documented throughout the United States, a pattern also being observed in other parts of the world.

An eco-epidemiological critical mass has been neared in 2002. During the summer of 2002 the number of WNV cases in North America ascended, and was the largest outbreak of arboviral meningoencephalitis ever documented in the Western Hemisphere. The WNE virus expanded its geographic range from the Mississippi River area at the conclusion of the 2001 season to the Pacific Coast by the end of 2002. Virus activity considerably increased and then found expression in the following figures: 2002—1460 cases; 66 deaths; 2003—9862 cases; 264 deaths; 2004—2470 cases; 88 deaths.

13.4.4.5 Avian Influenza

During 1997, an epidemic in Hong Kong of avian influenza in chickens and ducks occurred and was—merely marginally, then—transmitted to humans. Fortunately, the virus did not move from person to person and seemingly died out after the reservoir of domestic birds was completely depleted by the killing of approximately 1.6 million chickens, ducks, and geese by Hong Kong authorities. A variant of the type A H5N1 flu virus has been identified to be the cause of that event [22].

It was but an ostensible defeat of that epidemic H5N1 variant. In actuality it silently proliferated spatially, and then catastrophic outbreaks of influenza H5N1 took place among poultry in many countries in Asia during late 2003 and early 2004. At that time, more than 100 million birds in the affected countries either died from the disease or were killed to try to control the outbreak. (Thailand 36 million, Vietnam 36 million, Indonesia 15 million, China 5 million, Pakistan 4 million) (Cambodia, Laos South Korea, and Japan have been less affected, so far.)

By March 2004, the outbreak was reported to be under control. Beginning in late June 2004, however, new deadly outbreaks of influenza H5N1 among poultry were reported by several countries in Asia (Cambodia, China, Indonesia, Malaysia [first-time reports], Thailand, and Vietnam). These outbreaks—since extended—have been ongoing, and in 2005 reached Europe. They reached Africa in 2006.

The H5N1 virus does not usually infect humans. In 1997, however, the first case of spread from a bird to a human being was observed during the outbreak of bird flu in poultry in Hong Kong. The virus caused severe respiratory illness in 18 people, 6 of whom died. Since that time, there have been other cases of H5N1 infection among humans. Most recently, human cases of H5N1 infection have occurred in Thailand, Vietnam, and Cambodia during large H5N1 outbreaks in poultry. The death rate for these reported cases has been about 50%. Most of these cases occurred from contact with infected poultry or contaminated surfaces. Remarkably, however, it is thought that a few cases of human-to-human spread of H5N1 have occurred.

So far, spread of H5N1 virus from person to person has been rare, and proliferation has not continued beyond one person. Yet, because all influenza viruses have the ability to change, there is a great concern that the H5N1 virus could one day be able to become contagious and spread easily from one person to another. Because these viruses do not commonly infect humans, there is little or no immune protection against them in the human population. If the H5N1 virus were able to infect people and spread easily from person to person, a new flu pandemic could probably begin. It is impossible to foresee when a pandemic might occur. However, experts from around the world are watching the H5N1 situation in Asia very closely

and are preparing for the possibility that the virus may begin to spread more easily and widely from person to person. Still, the H5N1 strain is but one variant within an immeasurable natural gallery of avian flu viruses. A few of them have already infected man, whereas the majority are taking their time, for now. A highly communicable derivative of them or of the H5N1 type will most probably generate the next colossal pandemic.

Until now, the most demanding flu pandemic that has been documented was the "Spanish Flu" (also known as "Swine Flu"), which killed 40–90 million people during just two years (1918–1919). The virus was of the H1N1 subtype. Later on, in 1957 a new serotype, H2N2, emerged and generated another pandemic, substituting the H1N1 virus. The next pandemic was given rise to in 1968 by the serotype H3N2, which replaced the H2N2. In 1977, a mild H1N1 virus resurfaced, bringing about another pandemic, but it did not substituted the H3N2 virus, and they are both prevailing currently. As a matter of fact, all pandemic and any other influenza virus strains are derived from avian viral strains. Moreover, at least some of them are likely preserved in perennial lake ice, mostly in the Northern Hemisphere, and may reintroduce—subsequent to ice thawing—genes or entire genomes onto the current genetic pool of that protean virus [23]. In regard to the current H5N1 strain, which is considerably virulent but noncontagious, for now, it may attain transmissibility by even a minor genetic alteration, the full essence of which is not yet clear.

In case this virus would retain its ongoing high communicability and virulence toward farm birds (currently chickens and ducks mainly) concomitantly with such genetic alteration, then an unparalleled pathogen, both pandemic and epizootic, may rise. Theoretically, it could disease pigs and horses as well, as the influenza A virus is in general infective and at times virulent toward those domestic mammals. But apparently this cannot occur in actuality, because there is, in all likelihood, some inherent viral incompetence to have such amplified affinity toward more then one host simultaneously. The remarkable potentiality of influenza A virus to attack various farm animals signifies, at any rate, its distinct candidature in the context of agroterrorism (see below). Yet even in terms of merely an anti-human bioterrorism weapon, this varitype virus has been reckoned to be an ultimate pathogen, in some respects even exceeding the formidability of the notorious smallpox virus [24].

Pandemic spread would presumably bring about 60–80 million deaths worldwide. According to US Homeland Security Council's estimates, 90 million people could be infected in the US alone in case a bird flu pandemic breaks out, of which 45 million will require medical care, 10 million will require hospital admission and 2 million people could die [25].

A British government report warns that The health service will be plunged into chaos if Britain is struck by a bird flu pandemic. Faced with a possible 4.5 million victims, demand for hospital beds would outstrip supply and doctors might have to deny treatment to the sick and elderly to save younger, fitter patients [26].

Not casually, all of the above-detailed illustrative epidemics represent, basically, bioterrorism-patterned scenarios specifically propelled by viruses. Antibiotics, the main combat-tool against germs, are of no relevance against viruses. Antiviral drugs are very limited in their scope. Vaccines are efficient against most viruses, but they cannot cope with viruses that are currently dynamically altering. Antisera against viruses are of marginal pharmacological contribution, for now. Viruses pose, then, in a sense, the ultimate biological weapon, and can be used for bio-

terrorism purposes. Still, the cultivation and handling of viruses is complicated in comparison with bacteria, due to the necessity of host tissue, whereby viruses obligatorily propagate.

13.4.4.6 Cholera

But, beyond viruses, other classes of pathogens and toxins are not at all to be depreciated, certainly. The germ causing cholera—mostly a water-borne disease—is nowadays the most epidemic and demanding bacterial pathogen, with reference being made to acute illness (parallel to the inversely lingering course of illness of tuberculosis, another remarkably demanding bacterial disease). In contrast to viruses, the cardinal characteristic marking pathogenic bacteria is their interface with various antibiotics, which is a very tangled and dynamic one. Thus, during March and April 2002, a resurgence of the causative agent *Vibrio cholerae* O139 occurred in Dhaka and adjoining areas of Bangladesh with an estimated 30,000 cases of cholera [27]. The reemerged O139 strains belong to a single ribotype corresponding to one of two ribotypes that caused the initial O139 outbreak in 1993. Unlike the strains of 1993, however, the recent strains are susceptible to trimethoprim, streptomycin, and sulphamethoxazole, but resistant to nalidixic acid. This alternating profile exemplifies a predominant intensifying property of various bacterial pathogens resisting antibacterial drugs in an unpredictable fashion.

In general, cholera is an acute intestinal infection caused by ingestion of contaminated water or food. It has a short incubation period, from less than 1 day to 5 days, and produces an enterotoxin that causes copious, painless, watery diarrhea that can quickly lead to severe dehydration and death if treatment is not promptly given. Vomiting also occurs in most patients. Man-made and natural disasters can intensify the risk of epidemics considerably, as can conditions in crowded refugee camps. Explosive outbreaks with high case-fatality rates are often the result. For example, in the aftermath of the Rwanda crisis in 1994, outbreaks of cholera caused at least 48,000 cases and 23,800 deaths within one month in the refugee camps in Goma, the Congo [28]. Although rarely so deadly, cholera outbreaks continue to be a major public health concern, causing considerable socioeconomic disruption as well as loss of life. In 2001 alone, the WHO and its partners in the Global Outbreak Alert and Response Network participated in the verification of 41 cholera outbreaks in 28 countries.

Throughout history, populations all over the world have sporadically been affected by devastating outbreaks of cholera. Records from Hippocrates (460–377 BC) and Galen (129–216 AD) already described an illness that might well have been cholera, and numerous hints indicate that a cholera-like malady has also been known in the plains of the Ganges River since antiquity.

Modern knowledge about cholera, however, dates only from the beginning of the nineteenth century when researchers began to make progress toward a better understanding of the causes of the disease and its appropriate treatment. The first cholera pandemic, or global epidemic, started in 1817 from its endemic area in Southeast Asia and subsequently spread to other parts of the world. The first and subsequent pandemics inflicted a heavy toll, spreading all over the world before receding.

In 1961, the seventh cholera pandemic wave began in Indonesia and spread rapidly to other countries in Asia, Europe, Africa, and finally in 1991 to Latin America, which had been free of cholera for more than one century. The disease spread rapidly in Latin America, causing nearly 400,000 reported cases and over 4000 deaths in 16 countries of the Americas that year [29]. In 1992, a new serogroup—a genetic derivative of the EI-Tor biotype—emerged in Bangladesh and caused an extensive epidemic. Designated *V. cholerae* 0139 Bengal (as mentioned above), the new serogroup has now been detected in 11 countries and likewise warrants close surveillance. Although no evidence is available to gauge the significance of these developments, the possibility of a new pandemic cannot be excluded. EI-Tor, for example, was originally isolated as an avirulent strain in 1905 and subsequently acquired sufficient virulence to cause the current pandemic.

The economic and social impacts of cholera are immense. In addition to human suffering caused by cholera, cholera outbreaks generate panic, disrupt the social and economic structure, and can impede development in the affected communities. Unjustified panic-induced reactions by other countries include curtailing or restricting travel from countries where a cholera outbreak is occurring or imposing import restrictions on certain foods. For example, the cholera outbreak in Peru in 1991 cost the country US$ 770 million due to food trade embargos and adverse effects on tourism.

The germ *Vibrio cholerae* is indeed a current unrestrained foe. Prominently transmissible among humans, this pathogen may readily be used for bioterrorism purposes.

13.4.5 SIGNIFICANCE OF BIOTERRORISM-PATTERNED NATURAL EPIDEMICS

The principles and practicality of differentiating between epidemics stemming from bioterrorism acts and natural epidemics are outlined, to the extent attainable. The comprehension of bioterrorism-patterned natural epidemics thus turns out to be essential, and the related factors are presented in details, so as to facilitate the analysis of abrupt outbreaks.

The occurrence of epidemics, or outbreaks, at large, is the outcome of three alternative courses:

- A natural biological process or move, such as the emergence of a new pathogenic variant, the spread of an infected vector onto a new biotope, and so on.
- An innocent, either passive or active, artificial intervention, such as the arrival of an infected person at an epidemiologically virgin area/place, with relation to the pathogen harbored by him.
- An act of bioterrorism (or a military biological war fare operation).

The significance of bioterrorism-patterned natural epidemics appears to be contributive in two major senses. It helps to appraise the profile and impact of bioterrorism scenarios, and it may facilitate the differentiation of an epidemic (or

an outbreak), being a natural or man-made—either intentional or unintentional—occurrence. Hence, the recognition of a bioterrorism act is thus facilitated as well. This paradigmatic axis is vital for the very basic classification and handling of any epidemic or outbreak of an infectious disease or poisoning. In certain cases of diseased individuals, it ought to be applied as well, so as to arrive at the respecting differentiation. Thereby, the field of forensic microbiology plays an important roll.

In practice, classification and handling of various occurrences and events of concern ought to rely on the following elements:

- Biotlogical and chemical analysis of specific markers related to the pathogen/toxin involved, so as to trace its provenance.
- Epidemiological analysis through which gauging of the event being a natural, innocently man-made, or deliberately man-made one, is allowed for.
- Information obtained or assessment made by intelligence sources regarding identified or possible perpetrators, if any.

One essential trait of bioterrorism, then, is the degree of resemblance of a natural event. The perpetrator might be trying to emulate a natural occurrence—so as to mask his act—or might be indifferent in that respect. Being an artificial intervention, bioterrorism can rarely or scarcely initiate an infectious course that would otherwise take place naturally in the same way of appearance. Yet this incriminating disadvantage would in most cases remain uncertain owing to ambiguity, let alone events of innocent human intervention. To minimize that gray area, the mechanisms underlying natural epidemiological phenomena ought to be meticulously and thoroughly recognized. In general, they are rather gradually evolving, mostly unapparent, although their outcome may be abrupt and drastic, eventually. Acts of bioterrorism, even if looking similar in their resultant impact, lack the preceding evolving links that mark the natural apparatus. Of paramount importance, then, is the formation of a formulated, multifactorial epidemiological profile with respect to every infectious disease or toxin of special concern. This is particularly important regarding the deciphering of unexplained biological invasions of new pathogens, toxins or infected vectors/carriers.

A proper case study is the totally unexpected appearance of West Nile encephalitis (WNE) in New York City, which reflected, actually, a much broader and fundamental phenomenon, namely the introduction of a pathogen prevailing for long in the Eastern Hemisphere onto the Western Hemisphere (or vice versa). In that case, inherent difficulty emerged in both identifying the etiological agent and deciphering, later on, its provenance. Although a well-known disease in the Eastern Hemisphere, it was impossible, subjectively, to clinically identify, or even suspect, WNE. This means, instantly, that the inventory of diseases being looked into ought to be, *a priori*, perfectly global, even in terms of initial symptomatology. The term “exotic” (disease or pathogen)—hence less likely, ostensibly—largely loses its essence, therefore. As the primary suspicion was that of an arthropod-borne virus (arbovirus) encephalitis, early testing was directed at common eastern North-American arboviruses. The synchronic mortality of collocated birds could have been instrumental for postulating that the concerned virus is basically an avian pathogen. Early serologic testing displayed IgM antibodies against the St. Louis

encephalitis virus by enzyme-linked immunosorbent assay, a basically correct finding that later turned to be misleading, showing a built-in limitation in identifying a pathogen new to a given locality.

Misdiagnosis is at times worse than lack of diagnosis, particularly with respect to infectious diseases, let alone in the context of epidemiological tracing intended to gauge bioterrorism-patterned events. Deliberate introduction of an encephalitic virus has been considered, among other possibilities, and has emerged to be more specific when it became clear that the etiological agent is WNE virus. It was a conjunction of three elements that propelled such assessment:

- Information indicating that Iraq cultivated WNE virus as a biological agents [30].
- An Iraqi intention to strike the United States by whatever means [30].
- Ostensible infeasibility of WNE virus natural transfer from the Western to the Eastern Hemisphere.

Sensibly, however, the possibility of bioterrorism was not regarded to be a prime one, in this case. The probability of a natural or accidental event still appeared to be higher. Although the mechanism of the introduction of the WNE virus into North America remains unknown, it seems clear that the source of the WNE virus strain detected in New York City originated in the Middle East. A similar avian epizootic among domestic geese in Israel during 1997 and 1998 had been attributed to WNE virus [16, 31]. Human cases of WNE virus occurred simultaneously in Israel and New York in August 1999, and when the genomic sequences of WNE virus isolates or infected human brain tissue from the New York City outbreak were compared with various non-U.S. strains, the greatest homology was found with a WNE virus strain isolated from a goose from the Israeli 1998 epizootic and subsequently with a strain detected in the brain tissue of an Israeli patient who died of WNE in 1999 [16]. In addition, both the pattern of high avian mortality previously not associated with WNE virus outbreaks as well as the severity of human CNS disease seen in New York City and Israel were similar during the 1999 outbreaks. In between 1998 and 1999, this specific strain of WNE virus could have probably been harbored by certain migrating avian host species (transfected by mosquitoes) along an axis extending from the Western Hemisphere, through Greenland, and, later, onto New York [32].

Deliberate introduction or release of infected birds or mosquitos compatible with the above-described natural apparatus could be equally feasible, conceivably; yet certainly extremely sophisticated, somewhat beyond the expected capacity of a terror organization or even a terrorism-sponsoring state. On the other hand, the employment of a current epidemic strain of cholera, for instance, through introducing it into food supplies or water systems, even if conducted far away from an ongoing epidemic, could generate a wide outbreak that by all means may seem natural, resembling an infected traveler that innocently took a transcontinental flight. The chain of transmission in such cases is much simpler; hence, they are liable to be followed, untraceably, in the form of an act of bioterrorism. Furthermore, concentrating on AIDS and Ebola, an elaborated analysis inquired into those aspects, and aroused certain viewpoints that illustrate the significance of bioterrorism-patterned natural epidemics [33].

Notably, a recent outbreak of mumps (June 2006, Kansas)—a viral, often epidemic disease—is expected to help health officials prepare for an act of bioterrorism or a flu pandemic [34]. The Kansas Health and Environment Department had found 761 confirmed or suspected cases of mumps around the state. In dealing with the outbreak, the department for the first time used its incident command system to spread information to agencies around the state. The same system would be used in the event of a natural or intentional disease outbreak.

Once the bioterrorism-employed pathogen has been introduced into the targeted site, the subsequent epidemiological featuring of the resultant events may expectedly be entirely futile, in terms of pointing to an act of bioterrorism, because those events would be shaped by whatever environmental, medical, and demographic circumstances prevailing at any rate in the targeted site. In the absence of direct evidence witnessing an act of bioterrorism, the only potentially incriminating indications can stem from the very specificity of the pathogenic strain involved, the particular manner of introduction, and the existence or lack of collateral factors such as natural vectors, carriers, or reservoirs, including natural abiotic vehicles, like rivers, of the pathogen in concern. Currently, the only fully reliable way to establish specificity is sequence analysis of both genomic and extragenomic DNA/RNA. This would be a necessary, yet usually insufficient, precondition/prerequisite for deciphering the provenance of a pathogen used in an act of bioterrorism.

Therefore, diligent modeling is vital. Evaluating surveillance systems for the early detection of bioterrorism is particularly challenging when systems are designed to detect events for which there are few or no historical examples [35]. One approach to benchmarking outbreak detection performance is to create semisynthetic datasets containing authentic baseline patient data (noise) and injected artificial patient clusters, as signal. This useful pattern has very recently been developed.

It has thereby been pointed out, indeed, that doctors in training had difficulties diagnosing diseases associated with bioterrorism. The study involved 631 doctors, mostly medical residents—doctors still in training—in 30 internal medicine residency programs in 16 states and Washington, D.C.; it was found that half of the doctors surveyed misdiagnosed botulism, 84% misdiagnosed plague, and chickenpox was misdiagnosed as smallpox 42% of the time [36].

Yet beyond the clinical domain, various, at times crucial, gaps still prevailing within our overall knowledge about the biology of pathogens may play a significantly negative roll in that they can possibly bring about false incrimination or, inversely, false discrimination, referring to bioterrorism-resembling events. That is but one reason, even if a major one, for deepening our research and understanding of the essence and pronunciations of the complex mechanisms underlying the emergence and prognosis of infectious diseases. Mankind, at large, would expectedly endeavor to be most familiar with its prime extraneous foes, especially as their might is currently and steadily increasing.

13.4.6 SPECTRUM OF APPLICABLE PATHOGENS AND TOXINS

A general featuring of the spectrum of pathogens and toxins applicable for bioterrorism is given. Basic distinctions among various bioterrorism warfare agents, together with the implications they bear, are thereby presented.

Basically, then, any epidemic pathogen may be regarded, potentially, as a candidate for carrying out a bioterrorism act, the germ causing plague, for example. To those agents should at any rate be added many nonepidemic—namely, incommunicable—pathogens, such as anthrax, and a large variety of toxins. The spectrum thus formed is in a way misleading in its amplitude.

In actuality, a much narrower range of pathogens and toxins that may be used, practically, as weapons is notable, although but a marginal fraction, quantitatively, of the entire class of bacteria, viruses, fungi, and other infectious agents plus numerous different toxins found in nature. This being the case, their characteristics should meet, one way or another, at least part of the following fundamental criteria:

- Infective/toxic and virulent.
- Procurable or reproducible.
- Conveyable and stable.
- Introducible into the targeted area and people.

Still, the spectrum of agents applicable for bioterrorism acts is broader than those applicable for armed conflicts, due to the greater vulnerability and wider variety of civilian infrastructures that may be targeted. Qualitatively, however, this specific offense-oriented range of pathogens and toxins is marked by very potent and aggressive biological agents, some of which are extremely contagious and medically untreatable.

Preferring, mostly justifiably, a comprehensive approach, the United Kingdom recently increased the number of biological agents that must be secured to ensure they are not obtained and used for acts of terrorism. The government boosted, thus, the number of restricted agents listed in the 2001 Antiterrorism, Crime and Security Act from 47 to 103. The list of controlled bioagents includes 45 viruses, 21 bacteria, 2 fungi, 13 toxins and 18 animal pathogens [37].

It seems, then, as if the most significant distinctions can be made between epidemic and nonepidemic agents, on the one hand, and, independently, between treatable and untreatable agents, on the other hand. Although the former distinction relates equally to bacterial and viral pathogens, the latter reflects a fundamental difference between those two major classes. Regardless of antisera, antiviral preparations are of limited efficacy, although they are expectedly being upgraded. Connectedly, within the sphere of toxins, the related spectrum may basically be divided into specifically treatable—protein toxins, hence may be coped by antitoxins—and specifically untreatable ones, which are otherwise chemically structured, like alkaloids. Vaccines, as prophylactic measures, are in principle efficient against viruses, bacteria, and protein toxins.

At the same time, it would be insensible to refer to those distinctions as absolute categorizations, because some pathogens represent intermediaries, to a certain degree. Other distinctions such as between lethal and sublethal pathogens are rather artificial, although of course not meaningless. Influenza, as one example, is generally regarded as an incapacitating disease, while potentially much more virulent, in reality. A genuine distinction, obviously, is the one categorizing self-reproducing agents—hence a multiplying mass of weapon—as against unviable

agents, meaning toxins. The former, if effectively applied, constitute an infectious apparatus that intensify itself; the latter rather resemble, in that sense, chemical warfare agents, bearing their own immense capacity.

13.4.7 BACTERIAL AGENTS

Varitype pathogenic germs may be used for bioterrorism purposes through different modes, and they are here represented by four entities: plague, brucellosis, Legionnaires disease, and tuberculosis. Their heterogeneity with respect to source of infection, impact, as well as short-, medium-, and long-term endurance is thereby accentuated.

Within the context of bioterrorism, bacterial pathogens are signified for, foremost, by the germs responsible for the diseases of plague, anthrax, and alimentary tract infections (the latter group already typified above in the form of cholera). Other bacterial pathogens, such as those causing tularemia, brucellosis, glanders, Legionnaires disease, Klebsiella-associated pneumonia, and Q-fever, are of secondary—certainly not negligible—importance. A third category of potential microbial agents may be added, in case the perpetrator chooses to employ a slow-acting, scarcely traceable type of germ. Those three categories are here visited, then, through four representatives, namely, the causative agents of plague, Legionnaires disease, brucellosis, and tuberculosis. Anthrax is separately covered.

13.4.7.1 Plague

The plague bacterium is an old, salient foe to mankind. Posing three significantly different forms of an aggressive disease—bubonic, pneumonic, and septicemic plague—this germ is chiefly marked by two hosts, prior to man infection, namely rat and flee; hence, it can in principal be employed as a bioterrorism agent through each of those three modes, namely, inhalable air-borne bacteria, infected rats, or infected flees. Naturally, the humane plague cycle is usually initiated by the bite of a rodent flea or occasionally by the human flea.

The bubonic plague is the common form, so called because of the buboes or swellings, which are the obvious visible symptom, communicated by flea bites and attacking the human lymphatic system [38]. Simple bubonic plague may kill within 5 days, if antibiotic is not applied. It is regarded as the "true" or classic form of the disease. Pneumonic plague occurs when a victim develops pneumonia as a consequence of first getting the bubonic plague. The pneumonic variant occurs when the bacilli colonize the alveoli and cause latent suppurative pneumonia. This results in hemorrhagic sputum that can spread the disease via aerosolized droplets. In that case, the infection is then communicated by exhalation and affects the bronchial system of the next host directly. The pneumonic variant kills within 1–3 days. The third variant, the septicemic plague, is extremely rare and occurs where the bloodstream is directly affected raising the concentration of bacilli in the bloodstream to a level at which it can be transmitted directly by the human flea without passing through the intermediary host of the rat. This plague variant can kill within hours and explains contemporary accounts of people who went to bed apparently well and when they awoke in the morning they were, like the biblical Assyrians (also victims of a god-sent plague), all dead men.

The bubonic form of the plague is the one most widely described by chroniclers and, contrary to popular belief, can be survived, especially if the buboes burst or are lanced, although this was not understood at the time. Both the pneumonic and the septicemic varieties were fulminant and 100% lethal. The pneumonic variety, however, could be transmitted only by close human contact, in the same way as influenza today, but it accounted for the high mortality among monks, priests, and others tending to the dying, putting their faces close to the patient. As those infected in this way were unlikely to get far in the period between infection and death, the pneumonic plague remained localized within families and communities, for example, monasteries where it could spread like wildfire. Henry of Knighton, a regular Canon in the Abbey at Leicester and opponent of the Franciscan Order, reported the death of the entire population of 150 Friars in a Franciscan monastery in Marseilles, adding as a malicious afterthought, a good thing too. The bubonic version also kills its hosts, but more slowly, especially in the case of the flea that can survive dormant for weeks, even months, in the goods of a traveling merchant. The causative agent, *Yersinia pestis*, will, however, die off when it has itself killed off all accessible and susceptible hosts, whether human, rat, or flea. To sustain itself the bacillus must find a host that is not affected by it or that reproduces faster than the bacillus can kill the host.

13.4.7.2 Legionnaires Disease (Legionellosis)

The particular significance of *Legionalla* sp. as a human pathogen was not recognized until 1976, when a mysterious epidemic of pneumonia struck members of the Pennsylvania American Legion. Indeed, the most common presentation of *Legionella pneumophila* is acute pneumonia (legionellosis); potentially any species (about 40, allover) of *Legionella* may cause the disease. Extrapulmonary disease (e.g., pericarditis and endocarditis) is rare. Less often, the disease presents as a nonpneumonic epidemic, influenza-like illness called Pontiac fever [39].

Remarkably, *Legionella* bacilli are primarily waterborne. They reside in surface and drinking water and are usually transmitted to humans in watery aerosols. The pathogenesis of *Legionella* infections begins with a supply of water containing virulent bacteria and with a means for dissemination to humans. Person-to-person transmission has never been observed, and *Legionella* is not a member of the bacterial flora of humans. Infection starts in the lower respiratory tract. Alveolar macrophages, which are the primary defense against bacterial infection of the lungs, engulf the bacteria; however, *Legionella* is, unlike most bacterial pathogens, a facultative intracellular parasite and multiplies freely in alveolar macrophages. Recruited neutrophils and monocytes, as well as bacterial enzymes, produce destructive alveolar inflammation. Direct inoculation of surgical wounds by contaminated tap water has been described.

In most cases, the initial infective link is an aerosol of water contaminated with the organisms. Evaporative condensers and cooling towers are proven sources of outdoor infection. Indoors, nebulizers, and humidifiers filled with contaminated drinking water have disseminated *Legionella* to susceptible patients. The automatic misting devices that keep supermarket produce fresh have even been fingered as culprits in outbreaks of pneumonia. Notably, aerosols are produced in numerous ways in our environment, from taking a shower to flushing the toilet. An epidemic

of Pontiac fever caused by *Legionella anisa* was associated with an ornamental fountain in a public place. Clusters of *Legionella* pneumonia have occurred after exposure to whirlpool spas in hotels or cruise ships. In most cases, the source of the infection remains unknown. Direct infection of surgical wounds has been linked to washing of patients with tap water that harbored pathogenic *Legionella* organisms.

Legionella infections may be sporadic or epidemic, community acquired, or nosocomial. There is great geographic variation in the frequency of infection even within communities, presumably reflecting the presence of suitable aquatic environments and susceptible subjects. Both sporadic and epidemic cases are more common during summer than winter months, apparently because of increased use of air-cooling equipment that generates aerosols. As a bioterrorism agent, this prominent bacterium is prone to be applied, then, in both water sources and air circulating systems.

13.4.7.3 Brucellosis

Brucellosis represents a narrow, uniquely significant category of diseases combining proximate and lingering effects altogether. This clinical profile may meet, then, certain needs of both short- and long-term warfare. In the short run, it is featured by an acute phase. After a relatively long and variable incubation period (1–8 weeks), it most often manifests as an acute bacteremic disease, and it may be complicated by secondary hematogenous localization in almost every organ [40, 41]. Inversely, chronic brucellosis is defined as a disease evolving for more than a year, without evident secondary localization. During asymptomatic infection, the pathogen is sequestered in lymphoid tissues, bone, and liver. It would tend to persist for many years, at times in a steadily debilitating incurable state. Four bacterial species are responsible for human brucellosis: *Brucella suis* (from pigs; high pathogenicity), *Brucella melitensis* (from sheep; highest pathogenicity), *Brucella abortus* (from cattle; moderate pathogenicity), and *Brucella canis* (from dogs; moderate pathogenicity). Many animals are potential reservoirs for various *Brucella* species [40, 41].

Epidemiologically, brucellosis is a zoonotic infection transmitted from animals to humans by ingestion of infected food products (milk and dairy products are the main sources for human contamination), direct contact with an infected animal, or inhalation of aerosols. This last mode of transmission is remarkably efficient given the relatively low concentration of organisms (as few as 10–100 bacteria) needed to establish infection in humans and has brought renewed attention to this old disease. Descriptions of the disease date back to the days of Hippocrates, although the organism was not isolated until 1887, when British Army physician David Bruce isolated the organism that bears his name from the spleens of five patients with fatal cases on Malta. The disease gets its additional names from both its course (undulant fever) and location (Malta fever, Crimean fever).

Given the ease of effectiveness of aerosol transmission of *Brucella* species, researchers attempted to develop it into a biological weapon beginning in 1942. In 1954, it became the first agent weaponized by the old U.S. offensive biological weapons program. Field testing on animals soon followed. By 1955, the United States was producing *B suis*-filled cluster bombs for the U.S. Air Force at the Pine

Bluff Arsenal in Arkansas. Not much later, it was weaponized and standardizes by the USSR. The pathogen may meet both large-scale and guerilla warfare purposes.

13.4.7.4 Tuberculosis (TB)

Although AIDS represents an attritional viral disease, as described, tuberculosis is, in parallel, a bacterial disease of a long-lasting debilitating course, both individually and demographically. Migration of contagion within community and the course of the disease in itself are very clumsy, yet consistent, aided by fortified stability toward antibacterial drugs. A staggering 1.9 million around the globe die of tuberculosis each year—another 1.9 billion are infected with the causative agent, *Mycobacterium tuberculosis*, and are at risk for active disease [42]. It's sobering to realize that this ancient scourge, which has been found in 2000-year-old mummies (but much earlier evolved), remains a severe global health threat despite modern medicine. In fact, TB is a leading infectious disease killer in the world, alongside AIDS and malaria.

Millions of people—fully one third of the world's population—are infected with TB. Five to 10% of those will develop the active disease, for reasons only partially understood. This is, certainly, a key trait. The bacteria can lie dormant for many years and become active when the host is weakened by factors such as stress, poor nutrition, diabetes, or HIV infection. Once active, TB destroys tissue in the lungs and becomes contagious. Because it is airborne, there is little that can be done to protect against infection.

Antibiotics and public health measures failed to wipe out TB, although until the mid-1980s its rates had been brought very low, even in the developed world. Then the TB bacteria acquired immunity to many drugs, spreading rapidly among homeless people, AIDS patients, and other vulnerable groups worldwide. Several drugs can cure TB, but only if they are taken for many months. With abbreviated treatment, bacteria that have evolved ways of evading the drugs can escape eradication and proliferate as a resistant strain. Then, even when treated with the strongest drugs for 2 years, the resistant TB is fatal about 60% of the time.

Russian prisons are a major source of multidrug-resistant TB. As tens of thousands of infected inmates reenter the civilian world every year, TB spreads when they cough and sneeze. Some experts fear that with the speed and frequency of modern travel, the resistant epidemic could spread to Europe and the United States. To counter the threat of a worldwide epidemic, the costly second-line drugs are supplied, and prison health workers are being helped to ensure that infected inmates take their entire course of drugs—even if it means the prisoners have to remain in confinement for up to 2 years past the start of treatment.

In 2005, in Japan, the Tuberculosis Prevention Law was set to be abolished so that bacteria that cause the disease can be included in counterterrorism regulations in an updated Infectious Disease [43]. The Tuberculosis Prevention Law (passed in Japan in 1951) does not contain counterterrorism provisions or regulations requiring the quick investigation of an epidemic. The change is aimed at restricting transfer of the disease (alongside with other ones), allowing inspections, and requiring registration of ownership of samples. The bacterium causing TB is regarded, in a sense, as an attritional bioterrorism agent.

13.4.8 VIRAL AGENTS

In addition to the viruses mentioned above, some other viral pathogens are noticeable, of which several are profiled herewith as varitype representatives: Rift Valley fever, yellow fever, Norwalk, and hepatitis A. The smallpox virus is presented later. Notably, the handling of viruses is much more complicated then that of bacteria; hence, it is less likely to be mastered by terrorist organizations, individuals, or perpetrators, with reference being made to the viruses mentioned below as well as others.

13.4.8.1 Rift Valley Fever (RVF)

The RVF virus typically represents a zoonotic hemorrhagic pathogen equally potent against man as well as various mammalian farm animals (such as cattle, buffalo, sheep, goats, and camels). For viruses, this wide spectrum featuring is rare, making this pathogen a biological agent of appreciable uniqueness. This trait characteristically found expression in the late 1970s, in Egypt. After an initial epizootic of RVF in Egypt in 1971, the first recorded epidemic of RVF in Egypt, in 1977–1980, inflicted an estimated 200,000 human cases, with some 600 reported deaths, plus enormous losses of farm animals [44]. An epidemic of the disease occurred again in Egypt in 1993. RVF virus is naturally a mosquito-borne pathogen, but it is adequately infective in the form of an air-borne aerosol, making it a biological agent applicable through those two modes. It is found in the Old World only, principally in Africa. In September 2000, an RVF outbreak was reported in Saudi Arabia and subsequently Yemen. These cases represent the first RVF cases identified outside Africa. Fortunately, it is not carried by migrating birds, as is the case with many other arboviruses (including the parallel mosquito-borne West Nile virus) and with influenza A virus. RVF virus, then, is basically a geographically slowly crawling virus of notable potentiality, particularly with respect to tropical and subtropical regions. It may be employed as a bioterrorism agent in the context of both antihuman bioterrorism as well as agroterrorism. Basically a mosquito-dependent tropical virus, it could doubtfully colonize temperate regions, however.

RVF is generally observed during years in which unusually heavy rainfall and localized flooding occur [45]. The excessive rainfall allows mosquito eggs, usually of the genus *Aedes*, to hatch. The mosquito eggs are naturally infected with the RVF virus, and the resulting mosquitoes transfer the virus to the livestock on which they feed. Once the livestock is infected, other species of mosquitoes can become infected from the animals and can spread the disease among other hosts, including man.

13.4.8.2 Yellow Fever

The Yellow Fever virus is another mosquito-borne pathogen, in that case affecting both man and primates. In the past, it was mass-accumulated as a biological weapon, in the form of infected mosquitoes, by the U.S. Army. Although somewhat complex, this is an effective way of employing this virus as a weapon either through guerilla or apparent warfare. It so happened that this standardized weapon-form

resembled and reestablished the first human virus ever isolated. It was in 1901 that the pathogen causing yellow fever was proved to be a filterable virus carried by mosquitoes.

Yellow fever is a viral hemorrhagic fever. There are three types of transmission cycle: sylvatic (or jungle), intermediate, and urban. All three cycles exist in Africa, but in South America, only sylvatic and urban yellow fever occur [46]. Sylvatic yellow fever occurs in tropical rainforests where monkeys, infected by sylvatic mosquitoes, pass the virus onto other mosquitoes that feed on them; these mosquitoes, in turn, bite and infect humans entering the forest. This produces sporadic cases, the majority of which are often young men working in the forest, e.g., logging.

On occasion, the virus spreads beyond the affected individual. The intermediate cycle of yellow fever transmission occurs in humid or semi-humid savannahs of Africa and can produce small-scale epidemics in rural villages. Semi-domestic mosquitoes infect both monkey and human hosts and increased contact between man and infected mosquito leads to disease. This is the most common type of outbreak observed in recent decades in Africa. Urban yellow fever results in large explosive epidemics when travelers from rural areas introduce the virus into areas with high human population density. Domestic mosquitoes, most notably *Aedes aegypti*, carry the virus from person to person. These outbreaks tend to spread outward from one source to cover a wide area.

13.4.8.3 Norwalk

The Norwalk virus is an enterovirus with pronounced eco-epidemiological traits. It causes acute gastroenteritis with nausea, vomiting, fever, and myalgia that lasts 24–48 hours. The virus is transmitted through fecal-oral contact. The Norwalk virus is well established as the chief cause of viral gastroenteritis epidemics. The disease occurs throughout the year without a seasonal predominance.

Norwalk virus was first associated with gastroenteritis in 1972. For a long time, it was an unnoticed, although extremely important, pathogen. It was identified by electron microscopy of stool samples that had been saved from a 1968 gastroenteritis epidemic that occurred in Norwalk, Ohio [47]. In a 2-day period, acute gastroenteritis developed in 50% of 232 students or teachers in an elementary school. The virus initially was labeled as a small, round, structured virus, and it was named after the city in which the outbreak occurred. The virus is transmitted through contaminated food, water, or infected contacts. After ingestion, the virus infects the mucosa of the proximal small intestine, damages microvilli, and causes malabsorption. Although no histopathological lesions can be found in the stomach mucosa, the virus causes abnormal gastric motility and delayed gastric emptying.

In the United States, the Norwalk virus is estimated to cause approximately 40% of cases of nonbacterial gastroenteritis. The Norwalk virus is, then, the leading cause of viral gastroenteritis in the United States. January 1, 2002, to December 2, 2002: Norwalk virus was attributed to 9 of the 21 outbreaks of acute gastroenteritis on cruise ships reported to the U.S. Centers for Disease Control and Pre-

vention's Vessel Sanitation Program in this time period. The Norwalk virus brings about approximately 23 million cases of acute gastroenteritis each year and is the major cause of outbreaks of gastroenteritis. An extensive outbreak has been recorded in Europe (Finland). As a bioterrorism weapon, this enterovirus is a typical incapacitating agent.

13.4.8.4 Hepatitis A

Inversely a water/food-borne virus of a relatively long incubation period (several weeks) and a causative agent of a lingering incapacitating infectious disease, hepatitis A virus (HAV), has been intended mainly for attrition warfare purposes and has apparently been employed by the Soviet army in Afghanistan, through contaminating water or food sources. Also, hepatitis A virus is reported to have been studied as a possible bioterrorism agent by South Africa.

Infectious hepatitis caused by HAV is common worldwide and is usually spread as a result of poor personal hygiene and can be a problem in day care centers, refugee camps, and among troops in the field. The virus is hardy and can withstand relatively harsh chemical treatments and can survive outside the body for days. It attacks humans only, invading the liver and generating, hence, a systemic debilitating illness.

The disease has an incubation period that is relatively long for a biological weapon at 3–4 weeks, but the onset of the disease is abrupt and victims become exhausted and develop jaundice as their livers lose function [48]. Victims typically take about 10 weeks to recover. The disease is rarely fatal, and victims have lifelong immunity. Overall, hepatitis A virus may be regarded, then, as a representative of a class of water/food borne antihuman viruses, in that case, a pathogen of a rather attritional nature. Lasting for more than 3 months, the entire course of the virus since contracted by a victim produces a fairly chronic infection.

13.4.9 TOXINS

Overall, about 400 toxins have been identified, which are certainly but a small proportion of what is actually found in nature. Out of this remarkable inventory, several are reckoned as typical bioterrorism agents. Presented here are few prominent toxins: two protein toxins (botulinum and SEB)—hence detectible and treatable by anti-toxins—and three non-protein toxins (T-2 toxin, aflatoxin and aconitine), hence hardly detectable or treatable by antidotes. Etiological diagnosis of toxins is often extremely complicated.

The realm of toxins is a very wide one. Those microbial, fungal, plant, and animal biomolecules exhibit an unthinkably diversified inventory of natural substances, all poisonous toward man, by definition. They are extremely variable chemically and physically. But dosage plays a cardinal role, both in terms of its great differential among toxins, as well as the delicate transition onto the tangential domain of toxin-based pharmacological applications. Moreover, most usable for man—as proteins, chiefly—in preparing toxoids and antisera, toxins are inwardly

inert—sometimes rather immensely beneficial—within their own toxinogenic biosystem, or extremely poisonous, outwardly, as natural toxicants. Fundamentally, they constitute the pristine form of biochemical warfare in nature, much earlier to the emergence of mankind. Thus, for instance, Hydrogen cyanide, reckoned as a classical chemical warfare agent, is found in various toxic plants, thereby equipping them with a powerful poison.

Overall, about 400 toxins have been identified, which are certainly but a small proportion of what is actually found in nature. They include, however, bacterial toxins—49; plant—36; fungal—26; algal—22; (other) marine organism—111; snake—124; insect—22; amphibian—5; and in total—395. Out of this remarkable inventory, several are reckoned as typical bioterrorism warfare agents. Presented here are few prominent toxins: two protein toxins (botulinum and SEB)—hence detectible and treatable by antitoxins—and three nonprotein toxins (T-2 toxin, aflatoxin, and aconitine), which are hardly detectable and treatable by antidotes. Ricin, an outstanding bioterrorism toxin on its own, is covered separately. Other notable toxins, such as tetradotoxin, saxitoxin, mamba toxin, and many others are not discussed, although certainly potential candidates for bioterrorism tasks, particularly state-sponsored ones. Mamba toxin, as one example, has been developed as a weapon in South Africa (see below). Also, various plant and fungal psychotoxins—part of which constitute important psychopharmacological agens—have in some countries been exploited experimentally, to the least, as a major means to attain compelled mind control over normal human beings— an act of governance regardable as bioterrorism.

13.4.9.1 Botulinum Toxin

Botulism toxin, a bacterial protein, is reputed as the most known toxic molecule. It is produced by *Clostridium botulinum*, a gram-positive spore-forming anaerobe germ that dwells in the soil. There are 7 different antigenic types of this toxin: A through G. Disease in humans is caused by types A, B, E, or F. Aerosol exposure studies in rhesus monkeys indicate that type F is the most toxic and that it is 60× more toxic than type B, the least toxic. Extrapolations from primate studies predict that the fatal dose of Botulinum toxin in humans is on the order of:

- 70 μg by mouth
- 0.7–0.9 μg via the respiratory route
- 0.09 μg by intravenous or intramuscular routes

The toxin is a 150-kDa zinc-dependent metalloproteinase that cleaves proteins involved in the docking and fusion of synaptic vesicles to the membrane at the neuromuscular junction. The toxin consists of two chains: a heavy chain (100 kDa) and a light chain (50 kDa) linked by a disulfide bond. The crystal structure of the molecule has been solved to 3.3-A resolution [49]. The protein structure revealed a 50-residue belt that partially obscures the active site access channel; the authors note that this unusual feature makes rational inhibitor design more difficult.

The deadly toxin irreversibly blocks acetylcholine release from peripheral nerves resulting in muscle paralysis. It has been developed as a biological weapon by many government research programs, including the United States, Russia, and Iraq. Currently, public health services classifies botulinum toxin as a Category A Bioterrorism Agent, indicating that it is a high-priority risk to public health. As a bioterrorism weapon, it is a potent substance that is easy to produce and transport. A large population of victims requiring intensive care could easily overwhelm health-care systems. It can be introduced into the food and water supply or be aerosolized. The toxin is unstable after a few days in surface water, and it cannot withstand chlorine treatment. Although it is more stable in packaged foods, it is inactivated by normal cooking practices (heat > 85°). Aerosolization is technically difficult but would bring about the poisoning of a large number of people.

At the conclusion of the Gulf War, the Iraqis reported that they produced 19,000 L of pure botulinum toxin to a UN team. A total of 19,000 L of botulinum toxin is estimated, just arithmetically, to be sufficient to kill three times the current human population by inhalation. Overall, 10,000 L of the toxin had been loaded into weapons. They loaded botulinum toxin into thirteen 600-km missiles and one hundred 400-lb bombs. Some of the toxin has not been accounted for. The JAMA consensus statement points out that it is "noteworthy that Iraq chose to weaponize more botulinum toxin than any other of its known biological agents."

Incubation times vary according to the amount of toxin ingested and the toxin type. The range reported from natural infections is between 6 hours and 10 days. Symptoms most commonly present between 12 and 36 hours of eating contaminated food. Inhalational exposures are predicted to progress more rapidly. Regardless of the route of intoxication, the neurological symptoms are similar. Gastrointestinal cases may also display nausea and vomiting. Botulinum toxicity presents as a febrile, descending paralysis. In cases of severe exposure, it is possible that respiratory failure will occur suddenly. Without treatment, the cause of death is respiratory failure due to obstruction from the pharyngeal muscles and failure of the diaphragm to move adequate volumes of air.

The standardized antitoxin is equine in origin, and of high efficacy, provided that it is administrated quite early. When treatment is administered promptly, the risk of death is significantly decreased. In the past 50 years, the mortality has decreased from 50% to 8%. It is important to note that the antitoxin prevents worsening of the condition, but recovery may not occur until after several weeks to months of intensive care. Complications such as long-lasting weakness, aspiration pneumonia, and nervous system dysfunction may occur. This would at any rate make botulinum toxin a deadly and/or medium-term debilitating agent. The toxoid is highly efficient as prophylaxis.

Most experts predict that a terrorist attack with botulinum toxin would attempt to distribute the agent via aerosolization to intoxicate the largest number of people. The toxin does not survive long in the water supply. In fact, there are no reported cases of water-transmitted botulism. The food supply is at some risk, but the agent can be inactivated by food preparation. Weapons programs, such as the one in Iraq, have demonstrated that it is not difficult to produce and store large amounts of concentrated toxin.

13.4.9.2 Staphylococcal Enterotoxin B (SEB)

One of seven staphylococcal enterotoxins, this bacterial protein is the best studied potential bioterrorism weapon of a group of molecules described as superantigens; others include two streptococcal pyrogenic toxins, and the toxic shock syndrome toxin [50]. Superantigens create stable bonds across class II molecules of major histocompatibility complex (MHC) and specific variable (Vß) T-cell receptors on T_H cells, causing a release of disease-producing cytokines. Naturally, SEB intoxication occurs due to consumption of contaminated foods or drinks. SEB may be aerosolized or used to sabotage food supplies. As a weapon it would induce substantial, prolonged morbidity (up to 2 weeks) with little mortality.

From 1 to 6 hours after aerosol exposure to SEB, a distinct syndrome of high fever, chills, myalgias, nonproductive cough, dyspnea, and severe substernal chest pain may appear. Headache is also common, and nausea, vomiting, and anorexia may occur. Illness usually lasts for a few days, but it is rarely fatal. Physical examination may be unremarkable or reveal inspiratory and/or expiratory rales. After SEB ingestion, symptoms are primarily vomiting and diarrhea; fever only occurs in about one quarter of ill persons and respiratory involvement is absent. Although symptoms may be quite severe and lead to dehydration or even shock, illness usually lasts less than 12 hours. Physical examination may be unremarkable or reveal inspiratory and/or expiratory rales. Were Toxic shock syndrome toxin-1 (TSST-1) or streptococcal pyrogenic exotins to be used, they would likely cause acute erythroderma followed by desquamation and multiorgan failure. Differential diagnosis is complicated by many other diseases. Yet although toxin is transient in serum, it accumulates in the urine and is detectable for several hours postexposure. Antibodies generally develop within 6 days of exposure.

SEB, a very potent and enduring protein toxin, was included in the past U.S. BW program and standardized as a powerful biological warfare agent. Although reckoned to be an effectual incapacitating agent, it has not been connected, so far, with terror organizations.

13.4.9.3 T-2 Toxin

The Soviet military discovered—and later on materialiged—the potential use of the fungal trichothecene toxins—chiefly T-2 toxin—as aggressive bioterrorism agents shortly after World War II, when many Russian civilians ate bread baked from flour, naturally contaminated with extremely toxinogenic species of *Fusarium* mold. During this vast epidemic, numerous victims developed a protracted lethal illness characterized by initial symptoms of abdominal pain, diarrhea, vomiting, and exhaustion followed within days by fever, chills, muscular pain, and an imbalance of the red and white blood cells accompanied by pus-forming or other disease-causing organisms or their toxins in the blood or tissues [51]. It was then named Alimentary Toxic Aleucia.

The trichothecene mycotoxins are nonvolatile compounds produced by molds. They are very stable and resist heat- and ultraviolet light-induced inactivation. Only after heating at 500°F for 30 minutes will the toxins inactivate.

This discussion focuses on the hemorrhagic T-2 mycotoxin, a highly toxic agent that causes several illnesses in humans and animals, as described. From the 1970s and 1980s, trichothecene mycotoxins surfaced in the press as bioterrorism warfare

agents in incidents labeled "yellow rain" attacks against civilians in Southeast Asia [52]. Although such attacks have not been verified officially, it has been observed that trichothecene mycotoxins, T-2 in particular, have been produced in the USSR, weaponized, transferred to North Vietnam, and employed by North Vietnamese airplanes. The impact was vast and terrorizing, owing to many civilians that were vulnerably exposed, and then suffered a prolonged course of conspicuous pathological effects, with high mortality rate. Somehow, the evident employment of trichothecene mycotoxins in Southeast Asia, destined for bioterrorism—as well as live human field experimentation—purposes, turned into a saga involving alternative, natural explanations for the "yellow rain" phenomenon, which are certainly legitimate but do not refute the coexistence of the two—vicious and naïve—occurrences.

Reportedly, the Egyptian Air Force employed trichothecene mycotoxins during the Yemen War (in the 1960s) against Yemenis civilians—the main impact being terrorizing [53]. Later on, the Iraqi Air Force allegedly employed trichothecene mycotoxins against Iranian soldiers during the Iraq–Iran War in 1984 [54, 55]. According to UNSCOM, the Iraqis researched trichothecene mycotoxins, including T-2 [56]; they probably weaponized the T-2 toxin.

Unlike most biotoxins and microorganisms that do not affect the skin, T-2 toxin is an aggresive dermal irritant and can severely harm an unprotected person's skin and eyes. The pain associated with the exposure occurs within seconds to minutes. Larger doses produce incapacitation and death within minutes to hours. A larger amount of T-2 toxin is required for a lethal dose than of the chemical warfare agents VX, soman, or sarin. Comparisons with blister agents such as sulfur mustard show the T-2 toxin is about 400 times more efficient in producing blisters: It takes approximately 50 ng of T-2 toxin to produce the same injury to the skin as 20 μg (20,000 ng) of mustard. The T-2 toxin has a diverse effect depending on the manner and amount of exposure with vomiting and diarrhea noted at exposure doses one fifth to one tenth the lethal dose [52].

Exposure causes skin pain, itching, redness, blisters, and sloughing (shedding) of dead skin. Effects on the airway include nose and throat pain, nasal discharge, itching and sneezing, cough, shortness of breath, wheezing, and chest pain; the victim spits blood as a result of pulmonary or bronchial hemorrhage. The T-2 toxin also produces effects after ingestion or eye contact. Severe poisoning results in prostration, weakness, jerky movement, collapse, shock, and death [57]. The only protection against T-2 toxin effects is the individual protective mask and chemical protective overgarment. No chemotherapy, vaccine, or specific antidote is available [57].

Altogether, the trichothecene mycotoxins are reckoned as primarily blister agents that, at lower exposure concentrations, would cause extreme skin and eye irritation, and at larger doses would produce considerable incapacitation and death within minutes to hours [52].

13.4.9.4 Aflatoxin

As a public health hazard, the major routes for aflatoxin exposure are inhalation, pulmonary mycotoxicosis, especially of grain dusts, and ingestion as a result of eating food made with contaminated grains. The aflatoxin problem was first

recognized in 1960, when there was a severe outbreak of a disease referred to as "Turkey 'X' Disease" in the United Kingdom, in which over 100,000 turkey poults died. The cause of the disease was due to toxins in peanut meal infected with *Aspergillus flavus*, and the toxins were called aflatoxins. The potentialities of aflatoxins as toxic carcinogens, mutagens, teratogens, and immunosuppressive agents are well documented [58]. They are produced as secondary metabolites by the fungus *Aspergillus flavus* and *A. parasiticus* on a variety of food products. Chemically, aflatoxins normally refer to the group of difuranocoumarins.

Two forms of illness have been observed:

1. (Primary) Acute aflatoxicosis is produced when moderate-to-high levels of aflatoxins are consumed. Specific, acute episodes of disease may include hemorrhage, acute liver damage, edema, alteration in digestion, absorption and/or metabolism of nutrients, and possibly death.
2. (Primary) Chronic aflatoxicosis results from ingestion of low-to-moderate levels of aflatoxins. The effects are usually subclinical and difficult to recognize. Some common symptoms are impaired food conversion and slower rates of growth with or without the production of an overt aflatoxin syndrome. In the long term, exposure to aflatoxin is thought to explain the high rates of primary liver cancer in Africa and parts of Asia. Pooled data from Kenya, Mozambique, Swaziland, and Thailand show a positive correlation between daily dietary aflatoxin intake (in the range of 3.5- to 222.4-ng/kg body weight per day) and the crude incidence rate of primary liver cancer (ranging from 1.2 to 13.0 cases per 100,000 people per year).

Iraq developed and weaponized aflatoxins, chiefly as a bioterrorism agent. It has then been noted that "The discovery (by UNSCOM, during the 90s) that Iraq was researching aflatoxin, not a traditional BW candidate, was a cause for some surprise. It is a carcinogen, the effects of which manifest themselves only after many years, and several Western experts have rationalized this Iraqi program only in terms of genocidal goals. If aflatoxin were used against the Kurds, for instance, it would be impossible definitively to prove the use of BW once the symptoms emerged. Another possible explanation is its potential use as an immune suppressant, making victims more susceptible to other agents. However, the aflatoxin declaration may also hide other aspects of Iraq's BW program: according to Iraq's depositions, the production program never encountered any mishap (as other parts of the BW program had) and, to judge from the declared time-frame for the total amount produced, production could never have stopped, even for cleaning of the equipment. This raises the suspicion that Iraq declared an excessive amount of aflatoxin in order to disguise the fact that other, more destructive agents had been produced in greater quantities [59]."

Iraq developed and produced aflatoxin as a long-term debilitating bioterrorism agent, intended to be used against the Kurds. There is documentary evidence and statements obtained by UNSCOM that Iraq was mixing aflatoxin with riot-control gas [60]. Although seemingly peculiar, some rational can be figured out regarding this type of weaponization (much more detail is given in Section 13.4.15.6).

13.4.9.5 Aconitine

This relatively unnoticed plant toxin is an intensely poisonous alkaloid obtained from aconite root. It occurs in colorless crystals. Aconite tubers are most toxic wild plants distributed from Asia to western Europe [61–64]. It achieved some notoriety in the nineteenth century as an agent for homicides and suicides. In modern times, aconite has been used as Chinese herbal medicine, which is freely purchased from herb shops and consumed as a doctation by a herbal practitioner for pain control in the Northern Hemisphere [65]. In Japan, some cases of aconite poisoning appeared as a result of committing suicide or accidental ingestion, which were mistaken for edible grass. However, aconite alkaloids have the potential for serious and even fatal cardiotoxity, which management has continued to fail save patients with therapeutic resistant fatal arrhythmia [66, 67].

Serious aconitine poisoning is characterized by hypotension, palpitations, shock, delay in myocardial conduction, and dysrhythmia beginning within 6 hours of ingestion. Respiration is progressively depressed by the effect of aconitine on the bulbar respiratory center. Tingling of the tongue, mouth, and skin, followed by numbness and anesthesia, are characteristic signs of aconitine poisoning. Excessive salivation is a characteristic sign of poisoning. The skin becomes cold, clammy, sweaty, and pale. Initial bradycardia is due to vagal stimulation. Soon after ingestion, aconite causes a tingling, burning sensation on the lips, tongue, mouth, and throat, which is followed by numbness and constriction of the throat. When applied to the skin, aconite causes a tingling sensation and then numbness. Blurring of vision occurs. Initial miosis is followed by mydriasis. There is a feeling of constriction in the throat [68].

According to some reports, Egyptian Armed Forces Commander-in-Chief Field Marshall Mohammed Abd el Hakim Amer, who headed the defeated Egyptian Army in the 1967 Six Days War, was later poisoned, institutionally, by this substance. Allegedly, he committed suicide by means of aconitine that had been introduced to him while arrested [69]. An unidentified toxicant, possibly the same plant toxin, was used to replace the antidote with which Egyptian autoinjectors were filled, for personal assassinations [70].

Another trivial, yet peculiar episode, involved an English doctor who used aconitine to murder his crippled 18-year-old nephew for his inheritance. Percy Malcolm John was a resident at Blenheim School in Wimbledon and owned a small property that would go to his uncle on his death. Lamson visited the boy, bringing a cake and a capsule that he said was medicine. A few hours later he died in agony from aconitine poisoning [71]. Reportedly, aconitine toxin has been adopted by some states for assassination purposes.

13.4.10 AVAILABILITY OF INFECTIVE AGENTS AND TOXINS

A broad spectrum of availability of pathogens and toxins is discussed, especially pertaining to potential resources worldwide. Still, the spectrum is much narrower regarding weaponized agents, making the course of the attacker complicated, unless "raw" infective agents or toxins are to be employed. Different episodes illustrating that variability are presented.

The common nonstate-sponsored scenario of a just-graduated microbiologist cultivating a pathogenic germ in a rudimentary household laboratory, so as to produce it as a weapon for bioterrorism acts, is partially feasible. It is much less likely with regard to weaponizing or engineering bioterrorism agents. A significant advantage emerges concerning state-sponsored bioterrorism, because the relevant pathogens and toxins are appreciably more procurable, reproducible, and conveyable for a state, generally speaking. Therefore, the inventory of agents, their handling and the feasibility of conducting bioterrorism are scaled up when a state is involved, either intending to carry out an act of bioterrorism on its own or to assist a terror organization. Any step made by a country may basically be institutionalized, hence be more legitimate compared with an unaffiliated or noninstitutionalized body, element, or person.

Overall, the wide range of bioterrorism agents is reflected by considerably varying degrees of availability. Ricin toxin can readily be produced, roughly, by unqualified saboteurs. Conversely, an expedient way to meet the need for high-leveled know-how often faced by terror organizations would be in the form of "scientific mercenaries." At large, varitype availability of pathogens and toxins is demonstrated though the following episodes (and further ones mentioned in Sections 13.4.14, 13.4.15 and 13.4.16).

In Japan, in 1965, outbreaks of typhoid and dysentery were intentionally induced by a local bacteriologist, with professional direct access to those germs [72].

In 1972 two men affiliated with the U.S. group "Order of the Rising Sun," who eventually fled to Cuba, had conspired to contaminate the water supplies of some large U.S. Midwestern cities with stocks of typhoid fever germs cultivated by one of them. Up to 40 kg of bacteria cultures were found in a college laboratory [73].

In 1973, the American leftist terrorist group, the Weather Underground, reportedly attempted to blackmail a homosexual officer at USAMRIID into supplying organisms that would be used to contaminate municipal water supplies in the United States. The plot was discovered when the officer requested several items "unrelated to his work."

In 1975, the Symbionese Liberation Army was found in possession of technical manuals on how to produce bioterrorism weapons.

Moving to Europe, in 1980, police raided a German Red Army Faction apartment in Paris and found a miniature laboratory containing a culture medium of the germ that produces botulinum toxin. Notes about bacteria-induced diseases were found in the apartment as well [74]. Once again in Europe, several Muslim terrorists affiliated with the Algerian "Armed Muslim Group" were arrested in Belgium, holding a lot of information about biological (and chemical) weapons and about the World Cup football games [75].

Outstandingly, protesters claimed to have taken infected soil from the Scottish island of Gruinard and placed it at the Microbiological Defence Establishment at Porton Down, Britain. The island has been closed to the public since germ warfare experiments on sheep were conducted there in 1941. The anthrax spores used in the experiments can remain dangerous for decades.

The American Type Culture Collection (ATCC) has often been approached. Two Canadians attempted to procure botulinum and tetanus cultures from the ATCC. Reportedly the first phone order, of less deadly cultures, was fulfilled, and

it was not until the second order that ATCC employees became sufficiently suspicious to notify authorities [76].

A member of the white supremacist Aryan Nation acquired freeze-dried bubonic plague bacteria from the ATCC [77]. In May 1995, in the United States, Larry Wayne Harris was arrested for illegally obtaining the plague bacteria *Yersinia pestis*. Using his previous employer's certification, Harris obtained the samples through the mail from the ATCC. He was sentenced to 18 months probation and 200 hours of community service. Harris was again arrested in 1998 when he and another individual were found allegedly in possession of anthrax cultures, which were later determined to be anthrax vaccine. Due to the ease of obtaining dangerous pathogens, the CDC established rigorous guidelines for shipment of specific pathogens that may be used as bioterrorism agents.

Yet, as a matter of fact, a wide variety of pathogens and toxins serving the Iraqi BW program during the 1980s has been freely procured from different Western and Eastern sources, mostly the ATCC. The Iraqi case study provides remarkable demonstration, indeed, of repeated procurements of highly dangerous pathogens and toxins that readily took place albeit an integral part of the past Iraqi BW program [78]. And beyond, paradoxically, anti-bioterrorism programs worldwide bring about academic, commercial, and industrial institutionalization of numerous new pathogens-holdings labs which constitute potential resources for pathogens seekers. It so happened, that 245 facilities are now authorized to work with live anthrax in the US, and about 100 actually do so , compared to roughly 12 prior to the 2001 anthrax mailings [79].

Inadequately secured state-held stockpiles of BW constitute a potential resource. Reportedly, bin Laden's associates managed to receive anthrax and plague cultures or weaponized agents, from former Soviet facilities in Kazakhstan, or elsewhere. This has not been evidenced, although attempts to obtain those and other germs have certainly been made by al-Qaeda, perhaps fruitlessly. Still, assuming that al-Qaeda is responsible (together with Iraq) for the Sept. 2001 anthrax letter attacks, its members were at least involved in the final step of the envelope posting, thus possessing, temporarily, this pathogen [80]. Also, aerosol-released bioterrorism weapons were often in the possession of Spetsnaz operatives (Soviet Special Forces) who were believed to be involved with terrorists, especially those associated with bin Laden.

A typical example demonstrating an endeavor to exploit an institutionalized researcher as a 'scientific mercenary' was the case in which al-Qaeda had direct connections with a senior Pakistani microbiologist, Dr. Abdur Rauf, who attempted to support al-Qaeda's pursue of BW [81].

Adriana Stujit, an acknowledged Dutch journalist, contended that radical Muslims have gotten control over South Africa's biological weapons stockpiles. Quantities of anthrax, Ebola, Congo fever, and other agents are missing from South Africa, with the only explanation being theft. There has been no explanation or accurate documentation of the amounts, locations, and contents of the stockpiles [82]. This is not at all surprising, considering the picture described below regarding South Africa.

Obtaining pathogens and toxins from their natural environment is another sensible, though skill-demanding mode. In 1993, the Japanese cult Aum Shinrikyo sent a group of 16 cult doctors and nurses to Zaire, on a supposed medical mission. The

actual purpose of the trip to Central Africa was to learn as much as possible about and, ideally, to bring back samples of Ebola virus. In early 1994, cult doctors were quoted on Russian radio as discussing the possibility of using Ebola as a bioterrorism weapon. The attempt was fruitless. Also, they attempted to purchase a Q-fever culture from a Japanese academic researcher but were rebuffed. But they did obtain botulinum germs from earth in Japan, anthrax germs, and cholera germs. The anthrax strain was consistent with strain Sterne 34F2, which is used in Japan for animal prophylaxis against anthrax [83].

Domestic naive facilities may readily be contributive. In Israel, much concern was raised that regular microbiological laboratories—whether private or institutionalized, and particularly those located in the Palestinian-occupied territories—may be used as minifactories for producing biological agents in quantities sufficient for bioterrorism purposes [84].

A broad spectrum of resources of pathogens and toxins is notable, then, especially pertaining to potential resources worldwide. Still, it is much narrower regarding weaponized agents, making the course of the attacker complicated, unless "raw" infective agents or toxins are to be employed in an act of bioterrorism. But, on the other hand, dozens of biotech firms now offer to synthesize complete genes from the chemical components of DNA, making it feasible, seemingly, that a bioterrorist, armed with only a fake e-mail address, could probably order such deadly biological components online and receive them by mail [85]. He would doubtfully be able to transform, however, those components into a weapon, if not substantially assisted.

13.4.11 TECHNICAL FEASIBILITY OF BIOSABOTAGE ACTS

Pragmatically, biosabotage acts are featured by high technical feasibility, making them attractive, in that sense. Various operational options allowing for such feasibility are presented and discussed. Still, an appreciable level of know-how is needed for all preparatory stages preceding the in-effect act of bioterrorism.

The most plain, nearly self-evident, act of bioterrorism is demonstrated by one person emptying a tube into a water source so as to contaminate it with a waterborne pathogen. Against such an act stands mainly the level of water chlorination, which does not interfere, practically, with the distinct technical feasibility of this deed. It is, indeed, a simple thing to do.

But the technical feasibility of bioterrorism may extend much further. A fairly sophisticated practice involves the preparation and dispersing of a toxin or pathogen in an inhalable aerosol form, either dry or wet. Various advanced aerosol technology-based devices structured to dispersing inhalable aerosols of pharmacological quality are available and may likewise release a pathogen or toxin. Alternatively, dissemination may be achieved by infected insects. During an infamous biowarfare attack in 1941, the Japanese Military released an estimated 150-million plague-infected fleas from airplanes over villages in China and Manchuria, resulting in several plague outbreaks in those villages [86]. The victims were, deliberately, merely civilians. The same principle may be applied for disseminating plague by the release of infected rats in an enemy's settlements. Another example, similarly complex, yet plainly feasible act of bioterrorism, rabid, pre-symptomatic dogs or

other canines infiltrated covertly, steadily, and untraceably in the wild through borderlines, may then bring about the spread of rabies onto local dogs and farm animals plus humans, gradually elevating the overall level of rabies endemicity.

Currently, effective worldwide dissemination is achievable through postal systems. The following recent incident, although certainly a naïve one, illustrates the technical feasibility of biosabotage acts at large, as one, outstanding example:

Thousands of scientists were scrambling at the urging of global health authorities to destroy vials of a pandemic flu strain sent to laboratories in 18 countries as part of routine testing. The rush, urged by the World Health Organization, was sparked by a slim, but real, risk that the samples could spark a global flu epidemic. The vials of virus sent by a U.S. company went to nearly 5000 laboratories, mostly in the United States [87].

Referring to the incident, WHO's influenza chief, Klaus Stohr contended that "The risk is relatively low that a lab worker will get sick, but a large number of labs got it and if someone does get infected, the risk of severe illness is high and this virus has shown to be fully transmissible. The risk is low but things can go wrong as long as these samples are out there and there are some still out there."

The 1957 pandemic strain, which killed between 1 million and 4 million people, was in the proficiency test kits routinely sent to laboratories. This strain has not been included in the flu vaccine since 1968, and anyone born after that date has no immunity to it.

Most samples were sent at the request of the College of American Pathologists, which helps laboratories do proficiency testing. A private company, Meridian Bioscience Inc. of Cincinnati, Ohio, is paid to prepare the samples. The firm was told to pick an influenza type A virus sample and chose from its stockpile the deadly 1957 H2N2 strain. The reason for choosing this past, mighty strain, and not a current strain, remains unclear [88]. Still, some other test kit providers besides the college also used the 1957 pandemic strain in samples sent to laboratories in the United States.

The majority of the laboratories that got the test kits are in the United States. Fourteen were in Canada, and 61 samples went to laboratories in 16 other countries in Europe, Asia, the Middle East, and South America, according to the WHO. The test kits are used for internal quality control checks to demonstrate that a laboratory is able to correctly identify viruses or as a way for laboratories to get certified by the College of American Pathologists. The kits involve blind samples. The laboratory then has to correctly identify the pathogen in the vial in order to pass the test. Usually, the influenza virus included in these kits is one that is currently circulating, or at least one that has recently been in circulation. The WHO then notified the health authorities in all countries that received the kits and recommended that all samples be destroyed immediately. That same day, the College of American Pathologists faxed the laboratories asking them to immediately incinerate the samples and to confirm in writing that the operation had been completed.

Unintentionally, this demonstration of the technical feasibility of biosabotage operations marks both simultaneous, wide-range distributable shipment of a virulent—in that case, rather recoverably pandemic—pathogen in a stable infective form, as well as specifically, on-spot targeted sites intended to be attacked biologically. The two options are equally feasible.

Actually, two events of unintentional postal distribution of smallpox—yet in that case generating epidemics in effect—happened to occur already in 1901. Smallpox had developed in a woman in Saginaw, Michigan, after she received a letter form her sweetheart, a soldier in Alaska.

He had written it while recovering from this disease. The infection subsequently spread to 33 other persons in Saginaw [89]. Also in 1901, an outbreak of 5 cases of smallpox was recorded at the Mormon headquarters in Nottingham, England, apparently after receipt of "letters or other fomites" from Salt Lake City, Utah, where smallpox was widespread [90].

Heavily crowded facilities single out the technical feasibility of bioterrorism. Thus, the British army tested model bacilli spore powder released (1963) from a window of a tube train traveling in the London Underground [91]. The trial concluded that the spores can be carried for several miles on the tube system, and locally can persist as an aerosol of high concentration for a considerable period. Also, widespread dispersal of bacteria was found in a May 1965 secret release of innocent bacilli at Washington's National Airport and its Greyhound bus terminal, according to declassified military reports. More than 130 passengers who had been exposed to the bacteria traveled to 39 cities in seven states in the two weeks following the mock attack [92]. By 1966, in a similar trail in New-York Subway, bacilli powder-carrying light bulbs were dropped [93].

Water is an easy target, basically. The feasibility of water contamination has been pointed out to be concrete in Israel: Deliberate influx of sewage from Judea and Samaria hills onto the Israel Coast Plain was been observed during the 1990s, according to the Israel Minister for Environment Quality, causing the contamination of Israeli water systems [94, 95]. Objectively, this may become much more feasible as a result of the 2005 Israeli disengagement. It should be mentioned that, in the past, outbreaks of cholera occurred in Judea and Samaria as a result of sewage being routinely and innocently used for the irrigation of vegetables. Connectedly, the factual situation is that most streams found in Israel stem from the mountainous aquifers, which are mostly located in the Judean and Samarian Hills, parts of which are now outside of Israeli territorial control. The other Israeli water sources stem from the Golan Heights and Southern Lebanon.

Furthermore, rather unusual modes illustrating the technical feasibility of biosabotage acts have been noted in Israel:

In the body of one person who survived suicide bomber sabotage, bone fragments were discovered that are believed to come from a suicide bomber. The bone fragments tested positive for hepatitis B. Medical experts believe "This is possibly the first report of human bone fragments acting as foreign bodies in a blast injury, and consequently all survivors of these attacks in Israel are now vaccinated for hepatitis B." The experts suggested that bone fragments embedded in attack victims should be routinely tested [96]. Theoretically, bone fragments might also spread other diseases including HIV, dengue fever, syphilis, and Creutz–Jakob disease [97].

In August 2004, an Iranian-made unmanned drone launched from southern Lebanon by the Iranian-supported Shi'lte militia, the Hezbollah flew for about 15 minutes along Israel's northern Mediterranean coast until it reached the coastal resort of Nahariyah. "Iran has not only supplied Hezbollah with these UAVs but

has also trained 30 of the group's members to operate them," an official (a senior commander in the Iranian Revolutionary Guards) told the London-based Arab daily *al-Sharq al-Awsat* 11 Nov 2004 [98]. The efficiency of UAVs as aerosol disseminators of biological agents is well known.

Drifted saboteurs may even be full residents of the country to be attacked. A terrorist state or organization might use such residents, particularly extremists, to carry out bioterrorism acts, thus considerably elevating the technical feasibility of those operations. The attacked might catch the extremists, but not understand they were minor figures, and present them instead as major figures. All in all, the practicability of bioterrorism is fairly plain, although a degree of professional knowledge is needed for planning and preparations.

It is also possible to disseminate infected insects or infected animals (like rats, for instance). Also, deliberate infection of contacts by an infected individual harboring a contagious disease (AIDS, for example—a plot already carried out not infrequently) is, in a sense, an act of bioterrorism. Water and ventilation systems may be targeted. During the First Gulf War, there were serious concerns in the United States, that the ventilation systems of buildings might be attacked by terrorists using BW agents [99].

According to Norqvist, terrorists might effectively and easily disseminate biological agents through water systems, resulting in a high number of casualties, the terrorism focusing either on large cities or military facilities. It has thereupon been pointed out that chlorination can be neutralized by using naturally chlorine-resistant microorganisms or constructing bacteria resistant to chlorine concentrations normally used in the municipal drinking water systems [100]. Simple devices might be used to deliver biological agents into the ventilation systems of buildings. Open-air experiments carried out in the 1960s demonstrated that throwing a light bulb filled with biological agent before an incoming subway train during rush hour is sufficient to infect tens of thousands of people [101]. Plausibly, state-supported terrorist groups would be the most likely of all terrorist groups to get a hold of biological weapons by the supporting government transferring entire systems from their national programs [5].

13.4.12 OPERATIONAL MODES

A wide variety of modes that may serve for operating bioterrorism is described. Essentially aimed at attaining advantage through asymmetric warfare, they may lead, at most, to an impact equaling catastrophic terrorism. They might be limited, inversely, to merely assassination. Hoax acts are visited as well. One-man operational mode can bring about any of the mentioned outcomes.

The operational modes marking bioterrorism are closely related to asymmetric and catastrophic warfare. Asymmetric warfare is a military term to describe warfare in which the two belligerents are mismatched in their total capabilities or accustomed methods of engagement such that the inferior side must press its special advantages or effectively exploit its enemy's particular weaknesses if they are to have any hope of *prevailing* [102–104]. Thus, asymmetric warfare is a recipe for engaging an opponent who has superior military power at his disposal and where

the main target is not the armed forces but the fabric of society itself. Catastrophic terrorism differs from the more traditional forms of terrorism because it has no closely defined political aim. It is based on the belief that the current world order is dominated by certain "universal values" that the terrorists despise and that this order must be destroyed.

Consequence management roles vary depending on whether the attack is a terrorist event or an act of war. Yet, the distinction between terrorist and military use of WMDs is increasingly problematic. State adversaries, perhaps acting through terrorist surrogates, may be inclined to use WMDs early, unconventionally, and if possible, anonymously. They may use WMDs against such military targets as ports, airfields, staging areas, and overseas bases to prepare the military battlefield by slowing logistics and power projection. Similarly, they may psychologically undermine public support or politically divide a coalition for an operation by attacking domestic or allied civilian targets. Eager to deter regional involvement while avoiding an overwhelming retaliatory response, perpetrators may try to obscure their identity. Under these circumstances, the line between terrorism and symmetric warfare may then vanish.

The stealthy qualities of BW further complicate the distinction between terrorism and war. An adversary with effective agent dissemination capabilities could employ BW as part of a covert attack nearly impossible to detect until casualties appear. Depending on the agent used, the attacked might not know whether an outbreak was natural, a terrorist attack, or the opening assault of a war. For all the legitimate concern about bioterrorism, systemized weapons are mostly still difficult to employ effectively without access to state-developed technology. Rogue states and well-financed terrorists with access to state-developed technology remain the most serious danger from the effective, large-scale use of biological agents through guerilla warfare.

The repertoire of bioterrorism modes is potentially an incredible one, extending from ricin-based assassination of one person to a worldwide smallpox pandemic, even if not aimed, a priori, to reach such magnitude. Those two edges may each take shape in actuality due to a seemingly slight act carried out by a single perpetrator. The former mode has practically been materialized through the murder of Markov, the Bulgarian journalist in London, whereas instead of ricin the lethal toxin used could variedly be of another type, as detailed above. The latter mode is a continuously floating menace, the possible realization of which is attentively being faced, in terms of both preventive measures and preparedness for handling such occurrence. The one-man mode was exemplified in 1998, when the British government issued a warning to all ports about an Iraqi attempt to bring large quantities of the deadly germs of anthrax into Britain (and other countries) inside cosmetics bottles, cigarette lighters, and perfume sprays, disguised as duty-free goods [104].

A bioterrrorism attack could consist, then, of nothing more than a person deliberately coughing on people and surfaces after being infected with a pathogen, as correctly pointed out in a study conducted by the Australian Strategic Policy Institute. This could happen by a terrorist knowingly infected and incubating an infection flying to Australia and then walking around a crowded shopping center for some hours, coughing near people and over surfaces. The study found that even without their knowledge, infected individuals could likewise be used as carriers for bioterrorism acts [105].

One major operational mode of massive bioterrorism may focus on endpoints of collective source reservoirs right before their physical division into much smaller to individually consumed portions. Such reservoirs may include blood, sera, or other preparations intended to be introduced into the body as well as foods, drinks, and water. Thus, certain collective infusion fluids may be contaminated before being packed: AIDS, hepatitis B, hepatitis C, arboviruses, and other blood-adapted pathogens.

Milk supplies, as another example, meet that very same biosabotage principle and have aroused much worry. About a third of an ounce of botulism toxin poured by bioterrorists into a milk truck en route from a dairy farm to a processing plant could cause hundreds of thousands of deaths and billions of dollars in economic losses, according to a scientific analysis [106].

The analysis considered what might happen if terrorists poured into a milk tanker truck a couple of gallons of concentrated sludge containing as much as 10 g of botulinum toxin. Because milk from many sources is combined in huge tanks holding hundreds of thousands of gallons, the toxin would get widely distributed in low, but potentially lethal, concentrations and within days be consumed by about 568,000 people, the report concludes. The researchers acknowledge that their numbers are very rough. But depending on how thoroughly the milk was pasteurized (which partially inactivates toxins) and how promptly the outbreak was detected and supplies recalled, about 400,000 people would be likely to fall ill, they conclude. Although only 6% of victims would generally be expected to die, the death rate could easily hit 60%, they conclude, because there would not be nearly enough mechanical ventilators or doses of antitoxin to treat so many victims.

A different mode of bioterrorism may aim to bring about the outward leakage of infectious microorganisms by physically damaging facilities containing them. A variety of installations may serve for such a mode, including P-3 and P-4 laboratories, vaccine factories, and institutionalized depositories. Such sabotage may questionably be regarded as bioterrorism, particularly if directed toward a facility engaged in biological warfare, even if but defensive. Yet the consequences and ultimate impact may be very severe. Hardly accusable may as well be bioterrorists choosing a mode of amplifying an ongoing outbreak or epidemic, especially if the very same causative pathogenic strain is concurrently employed by them for that purpose.

The various options of bioterrorism conducted as a sole operative mode or in conjunction with other sabotage acts add a further dimension. Bioterrorism acts may on the spot be accompanied by simultaneous conventional and/or unconventional—mostly chemical or radiological—sabotage. Such synchronism may form camouflage and be misleading, making the bioterrorism component scarcely thinkable or detectable. Spatial diversity may concomitantly increase the blurring effect. Combined employment of WMDs indeed drew the Pentagon's attention. The Pentagon has implemented, thus, a plan to expand its support of civilian authorities in the event of multiple domestic attacks involving chemical, biological, radiological, or nuclear weapons, The Virginia-based Joint Task Force-Civil Support was previously the Pentagon's only force dedicated to such a mission [107].

"We have identified capabilities within our force structure—beyond Joint Task Force-Civil Support—in order to ensure that we could respond not simply to a domestic attack involving a WMD, but to multiple attacks at diverse locations,

several cities perhaps at once where terrorists might have employed weapons of mass destruction," Paul McHale, deputy assistant secretary of defense for homeland defense, said. "It is now the established policy of the Department of Defense that we will train and equip for the mission requirement of multiple WMD response," said McHale [107].

Two overt modes are notable:

1. Suicide by a person carrying a detectable contagion.
2. Bioterrorism combined with conventional terrorism, simultaneously serving for two advantages:
   a. Temporary misleading (until infected cases present).
   b. Increasing vulnerability to bioterrorism agents by conventional wounding.

Opposite in polarity to the extreme mode involving in-effect bioterrorism in conjunction with multi-WMDs, are bioterrorism hoaxes. Bioterrorism hoaxes—whether consisting of unviable or viable substances that are benign—constitute an increasing mode of bioterrorism. The anonymously angry of the world are creating serious trouble today with just a stamp, an envelope, and a household product. It takes only moments for someone to send a package containing a suspicious but ultimately harmless powder. Moreover, hoaxers often see the powder-filled letters as a way to send a message, without considering that they are committing a crime. The act, however, can force entire buildings to be locked down and tie up emergency personnel for hours. Each incident must be taken seriously in case the contents turn out to be anthrax rather than crushed aspirin.

It so happened that the uncertainty prevailing around a hoax caused Australian Prime Minister John Howard to say in the early hours of a crisis thereupon created due to an powder containing envelope received in the Indonesian Embassy (June 2005): "This is a very serious development for our country, and I can't overstate the sense of concern I feel that such a recklessly criminal act should have been committed." He added he believed the threat was meant as retaliation for the 20-year prison sentence Australian national Schapelle Corby received in Indonesia for smuggling drugs. Such acts could damage relations between the two nations and invite retaliations against Australians in Indonesia [108].

Actually, however, people were putting powder in the mail to scare others years before someone sent envelopes laced with anthrax that killed five American people in the fall of 2001. There were 22 incidents reported worldwide in 2000 involving faked biological agents, according to the Monterey Institute's Center for Nonproliferation Studies. The count jumped to about 730 in 2001, due largely to Clayton Lee Waagner's campaign against abortion providers [109].

Waagner was arrested late that year after sending roughly 550 powder-filled letters, and the number of bioterrorism hoaxes dropped to 70 in 2002. However, excluding his count, both 2001 and 2002 saw significant increases in such incidents from 2000, spurred by the anthrax mailings and the resulting media coverage, according to Sundara Vadlamudi, research associate for the center's WMD Terrorism Research Program.

Although certainly the most relentless, Waagner was not the first anti-abortion bioterrorism hoaxer or the last. More than 20 letters containing fake anthrax were

mailed to abortion providers and abortion rights organizations in January 2002, several weeks after his arrest. Currently, however, the trend is increasing; notable receiving powder-filled envelopes since April 2005: the Israeli Embassy in Washington, D.C., the Danish embassies in Stockholm and Vienna, the New Mexico state capitol, a Slovenian government office, the office of Quebec Premier Jean Charest, a Vermont multimedia company, Israel Army Radio, the Bank of Israel, and NATD's Joint Warfare Center, Norway.

13.4.13 SPATIALLY AND TEMPORALLY VARYING IMPACTS

The expected impact of bioterrorism acts, together with the featuring of their spatial and temporal variance, are configured. A typical multifactorial system is thus formed, the handling of which is remarkably complicated, demanding, and vital. It includes a far-reaching range of bioterrorism scenarios, some evident, some tentative, beginning with hoaxes scenarios, and ending in the form of a pandemic.

The impact of bioterrorism acts is appreciably varied, both spatially and temporally. Its variability is shaped by the following factors:

- Initial area coverage (via air, water, food, or animal vectors/carriers)
- Duration of pathogenetic course
- Curability
- Environmental stability of the pathogen/toxin
- Contagiousness
- Demographic conditions
- Climatic conditions
- Conduction and effectiveness of preventing measures (before and after the act of bioterrorism)

The multifactorial integral thus formed is complex. For automating the testing and validation of spatial and temporal cluster detection algorithms, and enabling the ready creation of datasets for benchmarking outbreak detection systems, a specific software tool has been developed [35]. It allows for the creation of simulated clusters with controlled feature sets, varying the desired cluster radius, density, distance, relative location from a reference point, and temporal epidemiological growth pattern. This tool does not require the use of an external geographical information system program for cluster creation. Based on user-specified parameters describing the location, properties, and temporal pattern of simulated clusters, it creates clusters accurately and uniformly.

The impact is pronounced within several domains:

- Personal illness that may lead to death
- Paralyzed manpower
- Logistical efforts needed to medically support and isolate the infected/sickened victims
- Meticulous, extremely demanding managing of the apparently uninfected population

- Demoralization that may ascend to total panic
- Overall instability

The remarkable psychological responses subsequent to a bioterrorism attack were summarized as follows: horror, wrath, panic, paranoia, demoralization, magical thinking about germs and viruses, fear of invisible pathogenic agents, fright of contagion, anger at terrorists, government, or both, attribution of arousal symptoms to infection, scapegoating, social isolation, and loss of faith in social institutions [110]. Panic is a power multiplier in itself. Some plead that the use of biological agents can cause severe panic and hysteria among the civic population. For example, during the Sept. 2001 anthrax letter attack, thousands of civilians came to hospitals, although only few of them were found to be suffering from exposure to the anthrax powder. When BW agents are used, there is a great fear that the number of civilians turning to get medical help will overload the health service systems and those who really need treatment will not be able to get it. This overload, besides keeping treatment from those who need it, will also cause mass hysteria. Mass hysteria is very significant. In case of contagious diseases, there is a grave concern that the mass hysteria and the urge to flee the scene will only cause the disease to spread. That is contrary to the proper way of fighting it, namely, closing and isolating the contaminated area.

A typically acute bioterrorism episode would be featured by a toxin or pathogen of a short incubation period, pronounced illness, recovery or death, absence of secondary epidemic waves, and the creation of long-lasting immunity of the surviving population, which would inhibit relapsing occurrences. Such a prototypic episode may at times not exceed a week, just as it had been designed by the perpetrator. But, contrastingly, attritional or demographically debilitating impact may result from a delayed, relapsing, or slowly progressing pathogenetic course that may prevail for many years in a given population.

Spatially, however, any combination with the above-mentioned temporal variations is possible, basically. This means that in a relatively confined area a several-weeks transient bioterrorism episode or a lingering impact stemming from a bioterrorism act lasting for years, may take place. Equally, a vast territory may be afflicted by a swiftly moving epidemic or, alternatively, by a clumsily evolving pathogen, in terms of epidemic rate and virulence, whether it is an incapacitating or deadly agent. The dynamics underlying this complex variability is foremost shaped by the nature of the toxin or pathogen employed in-effect, and the countermeasures to be specifically taken against it. Fundamentally, this fluctuating dynamics is well illustrated, both spatially and temporally, through the varitype bacteria, viruses, and toxins presented within the above corresponding sections. It prevails, thereby, for both the dimension of the individual victim as well as the demographic dimension at large.

On the other hand are the bioterrorism hoax incidents, of which the spatial and temporal impacts, though, are still significant. Even an absolutely empty post envelope bearing but one word, like "biohazard," would bring about those undesirable impacts. If not empty, it may contain but paper and/or innocent chemical, toxin, non-infective microorganism, infective yet attenuated microorganism, or pathogenic microorganism. In this order of possibilities, there is an ascending line of spatial and temporal impacts. (The envelope content may as well comprise insects, infected or naïve.)

Three recent examples are herewith mentioned, then, resembling the spatial and temporal variance of impacts:

After a harmless bacillus powder was found in an post envelope sent to the Indonesian Embassy in Australia, the Australian capital of Canberra sustained a barrage of bioterrorism hoax mailings beginning 1 June 2005 to its Parliament building, Prime Minister and Cabinet Department, and the embassies of Indonesia, the United States, United Kingdom, Japan, Italy, and South Korea [111]. Emergency personnel in Canberra had to decontaminate 46 staffers at the Indonesian Embassy when it appeared some form of powered toxin had been sent to the building, according to Australian media reports. Tests later indicated the substance was not dangerous [112].

Some days later, continuation took place far away. On 10 June 2005, an employee in the collections department of Imperial Parking in Vancouver, British Columbia, opened an envelope containing a similarly suspicious white powder. Vancouver emergency services were quickly alerted [113]. The affected section of the building was locked down—the air-conditioning system and elevators were shut off, and no one was allowed to enter or leave. Twenty-five workers were quarantined for several hours until tests determined the substance was not dangerous. Forty-eight emergency workers and 18 pieces of equipment were sent to the powder scare at the Imperial Parking office. Firefighters suited up in protective gear to retrieve a sample, whereas others managed the quarantine and organized decontamination for the hazardous materials workers. Emergency medical personnel examined firefighters before they entered the building and after they exited, and waited to see whether they would have to take anyone to the hospital. Police officers handled crowd control and traffic and provided an escort when the sample was taken for further testing at a laboratory. This occurred, unfortunately, while the city's emergency services were also handling a hotel fire, an injured person, and the nearby appearance of the Aga Khan, spiritual leader of Shia Imami Ismaili Muslims.

A third episode followed soon. An Israeli embassy employee in the United States checking mail at 5 p.m. 16 June 2005 opened one envelope that contained a small amount of a white powder. A section of the building was closed, and some employees remained inside until tests indicated at 11 p.m. that the substance was benign. The letter, which reportedly contained anti-Semitic language, was traced to a man jailed in North Carolina, according to the FBI [113]. The logistical, mental (and medical) impacts would be much worse, certainly, both temporally and spatially, in case a mailed envelope contains a living pathogen, as was the 2001 anthrax letter attack (presented below).

13.4.14 HISTORY AND EVOLUTION

An old tool of mankind, the chronology of bioterrorism from 1500 BC to now is presented. It demonstrates the gradual, consistent transition from intuitive bioterrorism to knowledge-based bioterrorism. It shows, as well, the past, recent, and present trends of bioterrorism as an evolving course, the extrapolative featuring of which is troublesome.

The evolutionary course of biological warfare at large is fascinatingly long. Almost as soon as humans figured out how to make arrows, they were dipping them in animal feces or sick persons so as to contaminate them. Practically, bioterrorism

agents were the earliest weapons of mass destruction ever used by mankind. Long before having any idea regarding the in-effect nature of poisonous and infectious substances, man used toxins, feces, carcasses, and the like as effective weapons, in order to disease, kill, and terrorize opponents and enemies, thus following, from the very beginning, the three very basic fundamentals: incapacitating, killing, and intimidating. Rather a sort of intuitive bioterrorism, primarily.

Still, most of the ancient world liked to believe it fought with a code of honor. According to Adrienne Mayor, "Archers were disdained because they shot safely from afar: long range missiles implied unwillingness to face the enemy at close range. And long range missiles daubed with poisons seemed even more cowardly." Yet Odysseus, hardly a coward, returns home to kill his wife's suitors with poison arrows [1].

The roots of repugnance toward contaminated weapons are deep. Such weapons were singled out for disdain more than 2000 years ago in Greek and Roman codes of conduct, as well as in Hindu writings. But the course of using pathogens and toxins for terrorism continued. The rulers of ancient India were no less conflicted than the Greeks about arrows "barbed, poisoned or blazing with flame." These instruments violated the "traditional Hindu laws of conduct for Brahmans and high castes, the Laws of Manu." But in the Arthashastra, the Brahman military strategist Kautilya advised his king to use whatever means necessary to attain his military goals, including poisons.

In the Near East, it was after the mythic Greek hero Hercules slew the multi-headed Hydra that he developed a technology at the heart of today's most pressing international issue. In her illuminating history of warfare, the acknowledged folklorist Adrienne Mayor argues, in a sense, that "by steeping his arrows in the monster's venom, Hercules created the first biological weapon [1]."

Amazingly, then, the ancient world already made an important distinction between using disease weapons for purely defensive purposes as opposed to "first strikes." Although this constraint was rooted partially in ethics, Mayor contends it also reflected a shrewd understanding of epidemiology: "The principle of summoning plague for self-defense may be related to the reality that invaders are 'immunologically naïve' and therefore more vulnerable to epidemic diseases in foreign lands than the local population." Mayor is intrigued with the often fantastic devices the ancients used in war, but "Greek Fire" also excavates ancient attitudes toward biological arms and terrorism tools that are startlingly relevant today. Poisonous arrows were the Bronze Age's terror weapons. "Almost as soon as they were created," Mayor writes, "poison weapons set in motion a relentless train of tragedies for Hercules and the Greeks—not to mention the Greeks' enemies, the Trojans."

Similar, unrecorded biotterorism-like events followed, most probably. Yet, beyond Greek mythology, even earlier, the ancient world also contained examples of bioterrorism warfare against settled populations stretching back to 1500 BC, when the Hittites sent plague victims into the lands of their enemies. Later, it was in about 600 BC that Solon of Athens put hellebore roots in the drinking water of Kirrha to kill the inhabitants. At about the same time, the Assyrians used to poison enemy wells with a fungus that would make the enemy delusional. Around 500 BC, Socrates was poisoned by the juice of Conium, which was the state poison of the Athenians. Necrotizing germs were intuitively employed in 400 BC, whereas Scythian archers systematically used arrows dipped in blood and manure or decom-

posing bodies to prevent wounds from healing. There are accounts from 300 BC of parts of the dead bodies of humans or animals being used by the Romans to poison water supplies. There have also been instances of the dead bodies of those who died from plague being catapulted into besieged cities. Later on, by 200 BC, Carthaginians used Mandrake root left in wine to sedate the enemy. Furthermore, in 184 BC, Carthaginian leader Hannibal is credited with an interesting use of bioterrorism weapons. In anticipation of a naval battle with the Pergamenes at Eurymedon, he ordered his troops to fill clay pots with snakes. During the battle, Hannibal sent the pots crashing down on the deck on the Pergamene ship. The confused Pergamenes lost the battle, having to fight both Hannibal's forces and a ship full of snakes. The act brought about panic and injured enemy sailors. Pergamenes, a king in Asia Minor, remarked that "he did not think any general would want to obtain a victory by the use of means which might in turn be directed against himself [1]." Honey bees are known to have been used as weapons since Roman times, as was then the case of Lucullus, who defeated Mithridates (74 BC) via bees.

As man expended onto the Far East and, later, the Americas, tropical plants became a common source for toxins. Thus, poisoned arrows are used widely throughout the jungles of Burma, Malaysia, and Assam. The principal sources of arrow poison are varieties of *Antiaris, Strychnos*, and *Strophanthus* [114]. *Antiaris toxicaria*, for example, is a tree of the mulberry and breadfruit family, common in Java and the neighboring islands. The active agents in all of these are either contained within the milky sap or the juice of crushed seeds. This is smeared behind the arrow point on its own, or mixed with another plant latex. When introduced into the bloodstream, the active ingredient (either antiarin, strychnine, or strophanthin depending on the species) acts quickly, attacking the central nervous system causing paralysis, convulsions, and cardiac failure.

The story of the *Strychnos*-derived toxin Curare is remarkable, in that it perfectly embodies a complete bivalent evolutionary line, starting with a very old arrow-poison—still in its very same traditional use presently—and ending, for the time being, as an important muscle relaxant. Contemporarily, curare is usable for selected assassinations just like "modern" toxins. In the sixteenth century, a group of Spanish explorers traveled the Amazon River. During the voyage, one explorer was hit in the hand by an arrow and died soon after. The culprit was curare, used widely as an arrow poison by many Amazon Indian groups (as it is still used by a few today). The complex processes used to make curare were a guarded secret. Often 30 or more ingredients could be found in one recipe. Indigenous Amazonians often mixed plants of different genera to concoct their potent toxins; their skill and knowledge in safely preparing these poisons is a testimony to their incredible ingenuity. Amazonian curares are divided into two groups based on the container the plant is stored in: pots or tubes. Pot curare in the East Amazon is predominately from the species *Strychnos guianensis*. Tube curare in the West Amazon is from *Chrondrodendron tomentosum*. (The curare in modern medicine is made from the latter species, therefore, its name: tubocurarine.)

For many centuries, the exact content of curare remained a mystery to Western observers; not until 1800 did Alexander Von Humboldt witness and document the preparation of curare by the Indians from the Orinco River. In 1814, an explorer named Charles Waterton injected a donkey with curare. Within 10 minutes, the donkey appeared dead. Waterton cut a small hole in her throat and inserted a pair

of bellows, and then pumped to inflate the lungs. The donkey held her head up and looked around. Waterton continued artificial respiration for 2 hours until the effects of curare had worn off. Curare was found to block the transmission of nerve impulses to muscle, including the diaphragm muscle, which controls breathing.

Back to Europe, the Middle Ages, the use of infectious diseases to break sieges of castles and fortified towns is widespread. The most common method is to use catapults to hurl dead human or animal bodies over walls to spread disease. This same method is used to poison water sources. Plagued rats and infected flies were employed as well for introducing and disseminating the contagion. This was the case in 1155, when Barbarossa uses dead bodies to spread pathogens among the enemy during the battle of Tortona [115]. About 200 years later, in 1340 attackers hurled dead horses and other animals by catapult at the castle of Thun L'Eveque in Hainault, in what is now northern France. The defenders reported that "the stink and the air were so abominable . . . they could not long endure" and negotiated a truce.

In 1346, Tartar forces led by Khan Janibeg attacked the city of Kaffa (now Feodossia, Ukraine), catapulting the plague-infected bodies of their own men over the city's walls, and forcing the defending Genoese to abandon it when plague spread. Connectedly, ships carrying plague infected refugees (and possibly rats) sailed to Constantinople, Genoa, Venice, and other Mediterranean ports and are thought to have contributed to the second plague pandemic. (The first plague pandemic in 541 AD spread from Egypt to other parts of the world and killed 50–60% of the world population). It was perhaps the trigger of a subsequent outbreak of Bubonic plague that swept medieval Europe, causing 25 million deaths. Using dead bodies and excrement as weapons continued in Europe during the Black Plague of the fourteenth and fifteenth centuries. Even as late as 1710, Russian troops fighting Sweden resorted to catapulting plagued bodies over the city walls of Reval.

During that era, three peculiar events took place, as well:

In 1422, at Karlstein in Bohemia, attacking forces launched the decaying cadavers of men killed in battle over the castle walls. They also stockpiled animal manure in the hope of spreading illness. Yet the defense held fast, and the siege was abandoned after 5 months. In 1495, the Spanish tried wine infected with leprosy patients' blood against the French near Naples, and, in 1650, Polish artillery General put saliva from rabid dogs into hollow spheres for firing against his enemies.

In between, a sort of bioterrorism came to the New World in the fifteenth century, aimed to defeat the Indians. Spanish conquistador Pizarro gave clothing contaminated with the smallpox virus to natives in South America. During the French and Indian War (1754–1767) Sir Jeffrey Amherst, commander of British forces in North America, suggested the deliberate use of smallpox to "reduce" Native American tribes hostile to the British [116]. An outbreak of smallpox at Fort Pitt results in the opportunity to execute Amherst's plan. On June 24, 1763, Captain Ecuyer, Amherst's subordinate, gives blankets and a handkerchief from the smallpox hospital to the Native Americans and records in his journal, "I hope it will have the desired effect." This was followed by an epidemic of smallpox among Native American tribes in the Ohio River valley, which may also have been spread by contact with settlers. Transmission of smallpox by fomites (on blankets) is inefficient compared with respiratory droplet transmission.

Still, although the ancient world's arsenal of primitive bioterrorism weapons was trivial compared with the horrors of the modern world, those weapons raised the same terrifying moral and political dilemmas then as now. Thus, the absence of brought out events whereby BW were employed throughout the nineteenth century was possibly the latency preceding proliferation. Let alone that the nineteenth century marked the first isolation of germs in science.

During the twentieth century, then, an ascending course took place. In modern times, BW was used first for sabotage by Germany during WWI. German forces reportedly spread glanders and anthrax to debilitate enemy cavalries (detailed above).

In 1918, the Japanese formed a biological weapons section in the Japanese Army (Unit 731). Later on, in 1931, Japan expanded its territory into Manchuria and made available "an endless supply of human experiment materials" (prisoners of war, mostly civilians) for Unit 731. Biological weapons experiments in Harbin, Manchuria, continued until 1945. A post-World War II autopsy investigation of 1000 victims revealed that most were exposed to aerosolized anthrax. It is estimated that up to 3000 more prisoners and Chinese nationals may have died in this facility. During an infamous biowarfare attack in 1941, the Japanese Military released an estimated 150-million plague-infected fleas from airplanes over villages in China and Manchuria, resulting in several plague outbreaks in those villages. Overall, the Japanese Imperial Army experimented with and operated about 16 biological agents as tools of warfare and terrorism between 1932 and 1945. This took place in numerous locations in Asia, and it has been estimated that a total of 10,000 Chinese prisoners, U.S. prisoners of war, and British detainees were killed by some of the most gruesome human experimentation in history. The Japanese used BW agents such as anthrax, plague, tularemia, and smallpox [117, 118].

During World War II, another effort, taken by Britain, was the production of over 5 million anthrax infected cattle cakes, which would have been dropped over Germany in an attempt to decrease meat stocks by some 30%. Events overtook plans to put these into operation [119].

Ken Alibek, formerly a chief scientist of the Soviet offensive biological warfare program, has alleged that the Soviets employed the germs causing tularemia during World War II. In his book *Biohazard*, he states that there is evidence tularemia was used by the Soviet troops to help stop the German panzer troops in the Battle of Stalingrad. The resulting tularemia outbreak may have halted the Nazi advance, but the Soviet troops also developed the disease because of what Alibek suspects was a sudden change in wind direction. Over 100,000 cases of tularemia were reported in the Soviet Union in 1942, a 10-fold increase in incidence experienced in 1941 and 1943. Seventy percent of the cases were the respiratory form of the disease, which is the form that would have been expected from a BW rather than a natural outbreak of the disease [120]. Nonetheless, this episode may constitute a good example of biological warfare, rather than bioterrorism.

Avner Cohen, an expert on unconventional weapons proliferation, has catalogued reported uses of bioterrorism weapons by Jewish forces during the 1948 War of Independence in Palestine. Connectedly, the Israeli historian Uri Milstein alleged that "in many conquered Arab villages, the water supply was poisoned to prevent the inhabitants from coming back." Milstein states that one of the largest of such covert operations caused the typhoid outbreak in Acre in May 1948 [121]. Within

that context, the Palestinian Arab Higher Committee reported in July 1948 that there was some evidence that Jewish forces were responsible for a cholera outbreak in Egypt in November 1947 and in Syrian villages near the Palestinian–Syrian border in February 1948. Furthermore, in May 1948, the Egyptian ministry of defense stated that four “Zionists” had been captured while trying to contaminate artesian wells in Gaza with “a liquid which was discovered to contain germs of dysentery and typhoid.”

A pause took place for almost two decades (apart from minor or marginal incidents), but since 1965, the trend significantly changed. Multiple bioterrorism occurrences have been observed, as follows.

1965—In Japan, outbreaks of typhoid and dysentery were deliberately induced by a local bacteriologist [72].

1970—In Canada, several students became badly ill after eating food deliberately contaminated with the eggs of parasitic ringworm [122].

During the 1970s, the Soviets used mycotoxins in Laos and Cambodia and hepatitis A virus in Afganistan.

1972—Two men affiliated with the U.S. group “Order of the Rising Sun,” who eventually fled to Cuba, had conspired to contaminate the water supplies of some large Midwestern cities with stocks of typhoid fever germs cultivated by one of them. Up to 40 kg of bacteria cultures were found in a college laboratory [73].

1975—The Symbionese Liberation Army was found in possession of technical manuals on how to produce bioweapons.

1980—Assassination of CIA agent Boris Korczak in McLean, Virginia, Tyson’s Corner, using a ricin weapon, possibly in umbrella configuration [75].

Police raided a German Red Army Faction apartment in Paris and found a miniature laboratory containing a culture medium of the germ that produces botulinum toxin. Notes about bacteria-induced diseases were found in the apartment as well [74].

Protesters claimed to have taken infected soil from the Hebridean island of Gruinard and placed it at the chemical defense establishment at Porton Down. The island has been closed to the public since germ warfare experiments on sheep were conducted there in 1941. The anthrax spores used in the experiments can remain dangerous for decades [75].

1983—The FBI obtained one ounce of ricin in a 35-mm film canister from an individual in Springfield, Massachusetts, who had manufactured it himself. This is believed to be one of several confiscations of ricin [75].

Some 750 people were sickened due to typhoid fever, consequent to bacterial contamination of restaurant salad bars in Oregon, conducted by a local cult attempting to affect the outcome of a local election [73].

1984—Australian authorities received an anonymous threat warning that foot-and-mouth disease virus would be released among livestock if reforms in Queensland Prison were not implemented [123].

A Cuban expert defected and testified that one third of the United States could have been contaminated if a stockpile of toxins held by Cuba were to be “strategically placed in the Mississippi River [75]”.

Two Canadians attempt to procure tetanus and botulism cultures from ATCC. Reportedly the first phone order, of less deadly cultures, was fulfilled, and it was not until the second order that ATCC employees become sufficiently suspicious to notify authorities [71].

1990–1995—Japanese cult Aum Shinriky attempted at least three times to disperse aerosolized botulinum toxin and anthrax in downtown Tokyo and at U.S. military installations in Japan. All attempts failed.

1990—In Scotland, a limited outbreak of giardiasis occurred as result of deliberate water contamination [124].

1991—During the Gulf War, there were serious concerns in the United States, that the ventilation systems of buildings might be attacked by terrorists using BW agents [98].

1993—An Arkansas man with survivalist group connections attempted to smuggle 130 g of ricin from Alaska into Canada to use as a weapon [125].

1994—An Iraqi scientist specializing in genetic engineering and implanted in New York by Saddam Hussein's regime intended to conduct an act of bioterrorism, due to having access to various local laboratories [126].

1995—Two members of the Minnesota Patriots Council were convicted of conspiracy to assassinate a deputy U.S. Marshal and International Revenue Service agents by ricin [127].

A member of the white supremacist Aryan Nation acquired freeze-dried bubonic plague bacteria from the ATCC [76].

1996—In Texas, 12 laboratory workers at a medical center became ill as a result of eating muffins and doughnuts intentionally contaminated by dysentery germs type 2 [185].

1998—An Iraqi terrorist network was maintained in the United States, intending to conduct acts of bioterrorism and reportedly furnished with BW agents by Iraqi women that smuggle agents filled vials into the United States within their bodies [128].

The British government has issued a warning to all ports about an Iraqi attempt to bring large quantities of the deadly germs of anthrax into Britain (and other countries) inside cosmetics bottles, cigarette lighters, and perfume sprays, disguised as duty-free goods [104].

Several Muslim terrorists affiliated with the Algerian "Armed Muslim Group" were arrested in Belgium, holding a lot of information about biological and chemical weapons and about the World Cup football games [129].

1999—A group of medical workers, mostly Bulgarian, employed in the Benghazi children's hospital, Libya, were detained, subsequent to an explosive AIDS epidemic that apparently started in 1998 in that hospital, and involved, thereupon, hundreds of children. By the year 2000, the medics were charged with deliberately infecting 393 Libyan children in their care with HIV, by injecting them with infected products. The HIV type was the same in each case—a rare and previously unrecorded strain that originated in West Africa when two existing viruses combined [130]. An

analysis conducted by European experts suggested that the outbreak has the hallmarks of accidental cross-contamination, where poor hygiene and ineffective sterilization procedures allowed contaminated blood to be spread between patients from a single infected child. Highly involved in the affair, the charged medics were then sentenced to death, however. Libyan leader Muammar Gadhafi said he believes the medics are guilty.

2001—The anthrax letters were sent in the USA, containing highly sophisticated militory-grade spore powder (details are given bellow).

2003—Former Texas Tech professor Thomas Butler said that 30 vials of plague bacteria were missing from the university. In fact, he stole, smuggled, and illicitly transported the bacteria to Tanzania [131].

Further episodes have been discussed above. All in all, the various above-described episodes are at any rate but a small segment of the entire picture. By 1998, Carus undertook a comprehensive inventory and assessment of bioterrorism (together with biocrimes) in the twentieth century. He has documented 222 cases, categorizing the cases and number of reported cases [132]:

- Confirmed use of bioterrorism agents—24
- Probable or possible use—28
- Threatened use (probable or confirmed possession)—11
- Threatened use (no confirmed possession)—121
- Confirmed possession (no known attempts or threats to use)—5
- Probable or possible possession—6
- Possible interest in acquisition (no known possession)—13
- False cases and hoaxes—14

Surprisingly, there have been only 222 bioterrorism-related incidents in a 100-year period and in only 24 cases have there been confirmed attacks—an average of 1 every 4 years worldwide. Most were abortive. Fourteen of the 24 confirmed cases of bioterrorism or biocrimes are food or agriculture-related; of these cases, 11 involved food poisoning and only 3 targeted commercial animals or plants. Of the 222 documented incidents, only 6 appear to be clearly linked to attacks on commercial plants and animals.

Significantly, yet, the survey made by Carus points at 144 incidents that occurred in the 1990s, meaning nearly two thirds of the total. This may reflect better incident tracking and record keeping in recent years, or it may indicate a dramatic increase in the propensity of terrorists or criminals to employ bioterrorism agents. Available evidence supports the latter premise. For example, FBI statistics indicate that U. S. incidents involving weapons of mass destruction using chemical, biological, radiological, or nuclear materials have soared from 37 in 1996 to over 200 in 1999, with three fourths of the cases involving bioterrorism agents—usually the threatened release of anthrax. Notably, the vast majority of incidents have been directed against individuals or small groups, not mass populations. On the whole, if any sort of extrapolation can be made, then the next decade is supposed to be a disturbing one, at the least.

13.4.15 STATE-SPONSORED BIOTERRORISM

State-sponsored bioterrorism may be carried out by saboteurs either affiliated with the concerned state or acting on their own but institutionally assisted by some country specifically aware of the ultimate outcome. Biosabotage programs and projects, in part realized, have been identified mainly in Germany, Japan, USSR, the United States, South Africa, and Iraq. They are here presented in detail, illustrating the conceptual and practical paradigm of state-sponsored bioterrorism.

States running a methodical biological weapons program would usually adopt a collateral subsystem dealing with bioterrorism means and operations. But the opposite equation remains open, in that the absence of a methodical program may not at all impair an effectual framework in charge of developing, manufacturing, and deploying of terrorism-oriented biological agents. The perpetrators tasked for carrying out the biosabotage acts may equally be affiliated with the involved state, or with another state, be it a friendly or a hostile state, including the target country itself. State-sponsored bioterrorism may as well be directed against domestic opponents and carried out internally. Another variance lies between bioterrorism initiated by a state and such that is initiated by a terror organization (or a second state) but is crucially and knowingly assisted by the concerned state. All those modes may be categorized as state-sponsored bioterrorism and are looked into through the following case studies.

13.4.15.1 Germany

From 1915 to 1918, Germany waged an ambitious campaign of covert biosabotage on animals being shipped from neutral countries to the Allies. The program used the germs causing glanders and anthrax, and employed secret agents to administer the bacterial cultures to animals penned for shipment. The cultures were sometimes injected using needles dipped into the cultures, sometimes poured onto feed, or (later in the war) contained in capillary tubes embedded in lumps of sugar that were fed to the animals. Horses and mules were the main targets, but in some cases sheep and cattle appear to have been targeted as well.

The programs were initiated nearly simultaneously in Romania and the United States. The Romanian campaign was administered by Major Nodolny of the German General Staff, through his Military Attaché in Bucharest. The agents disseminating the cultures were Bulgarian, run by the Bulgarian embassy. Cultures were shipped from Berlin. The program lasted until the August 1916 Romanian declaration of war against Austro-Hungary and the expulsion of German diplomats.

The campaign in the United States was operated by a U.S.-born, German-raised, physician, Anton Dilger. Dr. Dilger brought seed cultures with him to the United States in 1915 and set up a culture facility in the suburban Washington, D.C. home that he rented. He supplied cultures to the German merchant-ship captain Hinsch, stranded in the United States by the British naval blockade, who ran the agents, largely stevedores. Dr. Dilger returned to Germany in early 1916, and the campaign came to a halt a few months later [133, 134]. Similar campaigns were conducted concomitantly in Argentina, Mesopotamia, and Norway. During WWII, the only known conduction of biosabotage by Germany was the contamination of a

large reservoir in Bohemia with sewage, in 1945. Throughout that war, however, the Nazis routinely used non-German-captured civilians for induced infection experimentations.

13.4.15.2 Japan

Civilians were the main object of mass terror attacks launched by the Japanese bacteriological Unit 731 on multiple Chinese targets during the 1930s and 1940s, various bombs and other disseminating devices being thereupon applied. Furthermore, if terrorism at large is a term of relevance with respect to enemy civilian prisoners, then the vast biological experimentations conducted by Unit 731 on thousands of arrested civilian Chinese during the 1930s and 1940s are certainly a sort of an extremely brutal bioterrorism. First-hand accounts testify the Japanese infected civilians through the distribution of contaminated foodstuffs, such as dumplings and vegetables. There are also reports of contaminated water supplies. Such estimates report over 580,000 victims, largely due to plague, anthrax, tularemia, smallpox, and cholera outbreaks [135]. Plague was often induced through infected flees, as well. In addition, repeated seasonal outbreaks after the conclusion of the war brought the death toll to much higher. On one occasion at least (1939), the Japanese military contaminated Soviet water sources with typhoid bacteria at the former Mongolian border.

13.4.15.3 United States

Declassified documents reveal the past existence of at least two bioterrorism operations worked out, if not conducted, by the CIA against Cuba:

Operation FULL-UP, the objective of which was to destroy confidence in fuel supplied by the Soviet Bloc by indicating it is contaminated. The operation was to be accomplished by introducing a known biological agent into jet fuel storage facilities. This agent flourishes in jet fuel and grows until it consumes all the space inside the tank [136].

Operation MONGOOSE: A document entitled “Project Cuba”, dated 18 January 1962, sets forth the aims and the 32 original tasks of what subsequently became known as “Operation MONGOOSE [137].” For task 21, it states that, on 15 February 1962, the CIA would submit a plan to disrupt the harvest of food crops in Cuba. The following two sections of the declassified text of this document, which might be expected to clarify the method to be used in pursuit of this objective, appear to be censored: Clearly their content was so repugnant that even the officials responsible for declassifying the document saw fit to keep that part of it secret. However, in materials provided to the U.S. Senate Select Committee on Intelligence Activities by the CIA during the mid-1970s, the CIA acknowledged that it had developed methods and systems for carrying out a covert attack against crops and causing severe crop loss. The CIA denied that it had ever employed such systems [138].

The United States has repeatedly been accused by Cuba of biosabotage acts that allegedly occurred. Reportedly, in 1977, a U.S. intelligence source admitted that the United States used the swine-fever virus as biological warfare against Cuba. The agent told U.S. media he was ordered to transport the virus from a U.S. Army Base and CIA training center in the Panama Canal Zone to a group of right-wing

Cuban exiles who in turn delivered it to operatives inside Cuba in March 1971 [139]. This may seemingly be connected to the outbreak of swine-fever virus in Cuba on 6 May, 1971—its first appearance in the Western Hemisphere. The highly contagious virus is lethal to pigs. Six weeks into the epidemic, the Cubans were forced to slaughter a half-million pigs to stem the spread of the epidemic. Also, the *New York Times* reported in 1983 how the head of a Miami-based anti-Cuban terrorist group admitted in a U.S. court that he had taken germs to Cuba in 1980.

Furthermore, Project MKNAOMI is notable as well. In the 1970s, the CIA publicly revealed that a U.S. Army team called the Special Operations Division (SOD) at Fort Detrick, Maryland, developed biological and chemical weapons for the CIA under a Top Secret project that would last almost 20 years [140]. This project, MKNAOMI, was practically unknown at the CIA due to the extreme sensitivity of its mission. Few written records were kept. CIA personnel working at Fort Detrick used the cover of Special Support Staff of the Department of Defense. Indeed, on 23 October 1962, the U.S. Patent Office granted patent 3,060,165 to four persons "as represented by the Secretary of the Army." The patent was first filed 3 July 1952, Serial Number 297,142 for the use of ricin as a biological weapon. The strikingly honest descriptive language used to apply for this U.S. patent, in 1952, is very revealing: "Ricin is a protoplasmic poison prepared from castor beans after the extraction of castor oil therefrom. It is most effective as a poison when injected intravenously or inhaled. A very fine particle size was necessary so that the product might be used as a toxic weapon." Also, in the early 50s the SOD conducted—as revealed in a document partially declassified by the FBI—a biosabotage experiment, using the Pentagon building as a model target, so as to prove that all persons present therein would be unknowingly exposed within a relatively short period of time [141]. Additional model targets where selected to simulate biosabotage operations, for example the Washington's National Airport and the New-York Subway during the 60s (details given above). The CIA and possibly other elements within the U.S. intelligence community apparently persisted in holding bioterrorism agents after the United States destroyed its biological weapons arsenal. Besides, an increasing debate has aroused as to the shear innocence of the US outstandingly growing research of virulent pathogens, referring to the fragile borderline separating between defensive- and offensive-oriented implications. However, the very same debate may equally pertain, in principle, to other states.

13.4.15.4 South Africa

Rather unexpectedly, an extremely meticulous biosabotage program has been uncovered in South Africa. Apparently, it constitutes an outstanding case of a state-sponsored bioterrorism paradigm that has been fairly brought out in details [142].

The most characteristic feature of the South African biological (and chemical) terrorism program was undoubtedly the development, testing, and utilization of a wide array of hard-to-trace agents to assassinate "enemies of the state [143]." As insider testimony and the notorious "sales list" of 1989 (Telemedicine Research Center document 52) indicate, several of the highly poisonous substances produced at both Delta G and Roodeplaat Research Laboratories (ad hoc front companies)

were actually deployed by clandestine units ADF and SAP "death squads," above all the Security Branch's C[ounterinsurgency]1 section (later renamed C10), housed at the Vlakplaas base, in covert assassination operations [144].

There is no doubt whatsoever that high-ranking officers within the SADF and SAP and other "securocrats" within the government were generally aware of these activities, many of which they in fact authorized. Some civilian Afrikaner paramilitary groups, whose pro-apartheid members remain violently opposed to black majority rule, have even publicly threatened to attack their enemies with biological and chemical agents [145, 146].

In the mid-1980s, a higher level and more formalized assassination program formed when the Teen-Rewolusionêre Inligting Taakspan (TREWITS: Counter-Revolutionary Intelligence Task Force) was created. Then, on the verbal instructions of a senior cardiologist, Colonel Dr. Wouter Basson—head of Project Coast: Apartheid's Chemical and Biological Warfare Program—a host of freeze-dried pathogens and highly toxic substances that had been produced either at Delta G or RRL—was secretly transferred and thereafter stored in a refrigerator inside a fireproof and bombproof walk-in safe in his own office to military and police personnel through various channels. The deadly agents were passed on, either to the aforementioned persons in innocuous public places like restaurants or to Basson himself in the latter's office at South African Medical Services (SAMS) headquarters in Centurion. The specific recipients of these lethal substances and contaminated items were operatives of the "death squads," officers who either deployed some of them personally or later distributed them to the so-called "hit team" members; an ex-psychologist who in 1988 assumed control over Systems Research and Development; a bioengineering company set up in part to manufacture special "applicators," i.e., arcane assassination devices such as rings, screwdrivers, walking sticks, and umbrellas that had been transformed into weapons by means of the addition of poison compartments and injectors or firing mechanisms for poisoned pellets; and Basson himself. Furthermore, holes were drilled in cans of Game orange soda, into which some substance was injected, and then closed by means of soldering so that they were no longer visible.

The actual substances included the viruses of Ebola, Congo, and Marburg; lethal toxins such as mamba toxin, botulinum, and ricin; bacterial agents such as plague, anthrax, brucellosis, salmonellosis, and bottles of cholera bacteria; and a wide variety of foodstuffs, beverages, household items, and cigarettes that had been contaminated with these biological agents [147]. There can be little doubt that several of these materials, items, or devices were subsequently often used to murder or sicken opponents of the apartheid regime. If one excludes the hundreds of drugged and secretly disposed guerrilla opponents, the total number of victims appears to have been in the dozens.

International ties formed as well within that dark context. Dr. Wouter Basson, or other Coast personnel, may have transferred dangerous biological warfare materials and know-how to elements of a loose international network of right-wing extremists. Fears have been expressed that Basson and other Coast scientists were associated with an even broader international right-wing network, purportedly known as Die Organisasie (The Organization), among whose members are said to be expatriate Rhodesians and South Africans who emigrated to other countries both during the apartheid era and as the apartheid system was collapsing [148]. Basson also had strong bonds with Arabic elements, particularly Iraqi and Libyan.

Connectedly, according to a pair of Federal Bureau of Investigation (FBI) informants, in the mid-1980s, the American doctor Larry Ford transferred a suitcase full of dangerous "kaffir-killing" pathogens to Surgeon-General Knobel at the Los Angeles residence of the South African trade attaché, Gideon Bouwer [149]. It has also emerged that at Knobel's request Ford lectured Coast scientists about the contamination of household items with biological agents [150–153]. The whole apparatus was dismantled during the 1990s. Still, such a complex state-sponsored bioterrorism program, operating both inside South Africa and beyond, all over, has not elsewhere been uncovered publicly, yet certainly not an isolated one, worldwide; the Soviet, and later Russian parallel system did not—and apparently does not—lag far behind.

13.4.15.5 USSR and Russia

Two bioterrorism affairs, one momentary—the planned assassination of an opponent by ricin toxin in London—and the other one lasting for years—the relapsing employment of fungal toxins against civilians in South East Asia—were sponsored, in effect, by USSR, whereas Bulgaria and North Vietnam were involved as partners, respectively. Not singular (referring to the Soviet apparatus at large), those two affairs attracted much attention. Although the latter has been surreptitiously—yet massively—conducted by the Soviet MOD (details given in Section 13.4.9.3), the former was a fine product of the KGB.

Various modes of biosabotage have been specifically encountered with regard to the USSR and Russia, in the book titled *Biological Espionage*, written by former KGB officer Alexander Kouzminov who worked for the so-called "Department 12, Directorate S (the KGB Operational Technical Support Directorate) [154]." This directorate oversees Moscow's "illegals" (i.e., Russian agents posing as Westerners, operating under deep cover). Department 12 (and Department 8) of the KGB were tasked with preparing "clandestine acts of biological sabotage against 'potential strike targets' on the enemy's territory." These potential targets include military research laboratories, combat units, weapon stockpiles, public drinking water, food stores, vaccine repositories, pharmaceutical plants, and the overall economy of the target country. These two departments would also assassinate, incapacitate, or kidnap foreign officials, political enemies, and "important persons" (where "important" is determined by the exigencies of war).

Department 12 was referred to in intelligence circles as the "Chamber" or "Kamera." KGB General Viktor Chebrikov, Andropov's closest subordinate in the KGB, was then the Director of this department. The "Chamber" developed, among many technical devices and substances various toxins, such as ricin, which is but one example. The work of Department 12 "has grown" since the collapse of the Soviet Union. Genetic engineering has brought forth new bioterrorism horrors. And these are to be unleashed in the event of something called "Day X," which signifies, conceptually, the beginning of the next world war—a large-scale war. Soviet military thinkers believe that such a war will tentatively involve the mass use of nuclear as well as biological weapons, concomitant with multiple bioterrorism operations. The KGB thus had its own R&D centers for special toxic matters including bioterrorism toxins and pathogens for use in espionage aims and sabotage (so-called "Fleita" program). In parallel, aerosol-released bioterrorism weapons were often in the possession of Spetsnaz operatives (Soviet military Special Forces).

Connectedly, the manners of the KGB are well illustrated in detail through the Soviet–Bulgarian ricin plot. Georgi Ivanov Markov was born 01.03.1929 in Sofia, Bulgaria and died in London due to induced ricin intoxication. He was executed by DS (Durzhavna Sigornost—Bulgarian State Security) in London on 11.09.1978, thanks to vital assistance knowingly afforded by the KGB. A totally independent journalist, Markov was Bulgaria's most revered dissident and Bulgarian Communism's arch enemy. Bulgarian Communist dictator, Todor Zhivkov, was very well informed about Markov's activities by the DS [155]. In 1977, Zhivkov asked the KGB to help him silence Markov. The Russians did not hesitate. Both President Yuri Andropov and Vladimir Krutchkov, head of KGB, personally approved and ordered General Sergei Golubev (Chief of the Security Service and specialist on "murder") to cooperate with DS. The KGB granted DS access to the resources in the "Chamber."

Golubev received instructions in the KGB headquarter relevant "Chamber," and the next week he flew to Sofia with Ivan Surov. Surov's job was to transmit the Bulgarian Intelligence Service practical know-how in the use of special poisons, which could not be traced after the victim's death. Golubev and Surov discussed with the Bulgarian's intelligence officers the various options of killing Markov. They worked out one plan to use a poison that could be surreptitiously dissolved in tea, coffee, or any liquid that Markov might drink. In 1978, Gen. Golubev traveled to Sofia three or four times to help DS with planning of the secret operation. Three attempts to assassinate Markov followed. The first attempt was made in Munich in the spring of 1978 when Markov was visiting friends and colleagues at Radio Free Europe. Someone put a toxin into Markov's drink at a dinner in his honor. The attempt to kill him failed. The second assassination effort occurred on the Italian island of Sardinia, where Markov was on vacation with his family. The plan also failed for reasons unknown.

Golubev returned to Sofia to work out a new plan to kill Markov. The KGB decided to use a camouflaged weapon. A folding umbrella was adapted with a firing mechanism and silencer to shoot a small pellet at close range, one and a half to two meters. Golubev requested that the KGB Residency in Washington purchase several U.S.-manufactured umbrellas and send them to the Center. The KGB head resident in Washington bought several umbrellas and sent them to the KGB, and an OTU operational technical unit rebuilt the umbrellas. The "Chamber" then adapted the umbrella tip to enable it to shoot the victim with a tiny metal pellet containing ricin. Golubev then took the converted umbrellas to Sofia to instruct the assassin on how to use this weapon. The pellet was supposed to penetrate the clothing and be lodged in the upper skin layer. Consequently, the final, and successful, attempt was staged in London 07.09.1978, on Bulgarian's Communist dictator Todor Zhivkov's sixty-seventh birthday. Before his assassination, Markov received a threatening anonymous phone call: "Not this time," said anonymous caller. "This time you will not become a martyr. You will simply die of natural causes. You will be killed by a poison that the West cannot detect nor treat." The tasked ricin toxin did the job, indeed.

On the day of his assassination, Markov worked a double shift at the BBC. After finishing the early morning shift, he went home for rest and lunch. Returning to work by car, he drove to a parking lot on the south side of Waterloo Bridge. It was his habit to take a bus across the half-mile Waterloo Bridge to the BBC head-

quarters in the Bush House. After parking his car in a parking lot near the Waterloo Bridge, Markov climbed the stairs to the bus stop. As he neared the queue of people waiting for the bus, he experienced a sudden stinging pain in the back of his right thigh. He turned and saw a man bending to pick up a dropped umbrella. The man who was facing away from Markov, apologized. The assassin then hailed a taxi and departed. Although in pain, Markov boarded the bus to work. But the pain continued.

Markov noticed a small blood spot on his jeans. He told colleagues at the BBC what happened and showed one friend a pimple-like red swelling on his thigh. By evening, he had developed a high fever. He was hospitalized and treated for an undetermined form of blood poisoning. His condition fast worsened. He was not responding to doctor's efforts. The next day he went into shock, and after three days of agony and delirium, he died on 11.09.1978.

An autopsy was performed at Wandsworth Public Mortuary. The doctors found a tiny metal sphere the size of a pinhead in the wound. When they attempted to extract the "pin," a tiny pellet fell on the table. The police took the pellet to the Chemical and Microbiological Warfare Establishment at Porton Down, commonly called the "Germ Warfare Center." There, a team of the England's foremost specialists in forensic medicine, and, reportedly, Dr. Christopher Green of the CIA examined the pellet. The pellet was 1.52 mm in diameter, embedded in his calf, and composed of 90% platinum and 10% iridium [156]. They found that two 0.34-mm holes had been drilled in the pellet, possibly using a high-technology laser at right angles to each other, producing an X-shaped cavity. The holes were empty.

This prevented investigators from establishing the type of substance that had been used, but it was sufficient to determine that Markov had "not died of natural causes." BATS (British Anti-Terrorist Squad), detectives then joined the Scotland Yard investigating team. After weeks of research and experimentation, in January 1979, a Coroner's Inquest in London Gavin Thurston ruled that Georgi Markov had been killed via ricin toxin. Traces of ricin were possibly found later thereupon.

But several years later, two former top KGB officers, Oleg Gordievsky and Oleg Kalugin, publicly admitted Soviet complicity in Markov's murder by means of ricin toxin. The case was dormant until after the arresting of Communist dictator Todor Zhivkov and the fall of the Communist government in Bulgaria in 1989. Although the DS act about the case Markov is destroyed or has been sent to Moscow, there is no doubt that some DS and KGB officers know the true about his death.

In 1991, former chief of Bulgarian Foreign Intelligence Vasil Kotsev, who was identified as the person in charge of the Markov operation, died in a questionable and mysterious automobile accident. A second suspect, General Stoyan Savov, preferred to commit suicide on 09.01.1992 rather than face trial also for destroying the documents. In 1994 the British Parliament asked Russia to help them find 15 past KGB agents who might have been involved in or had knowledge of the murder. The request remains unanswered. The Markov murder case remains officially unsolved. No one has been brought to justice for the murder of Markov, although *prima facie* evidence points fairly clearly at the involvement of Soviet and Bulgarian elements, chiefly the KGB.

The Russian KGB officially ceased to exist in November 1991, but its successor organization, the FSB, is functionally extremely similar to the KGB. Even after

many details about the related bioterrorism mechanisms were revealed, during the 1990s, and although many alterations took place in Russia, this system did not substantially change.

13.4.15.6 Iraq

In the past, Iraq conducted bioterrorism in the following cases:

In 1988, the Iraqi army deliberately introduced typhoid bacteria into the water supply of the Kurdish city of Sulaimaniyah, bringing about an outbreak [157].

In 1989, outbreaks of cholera were generated as a result of BWA being experimented with on Kurdish populations by Iraq [158].

In 1990, an apparent, severe malaria outbreak that exceptionally occurred in the Kurdish Biharka concentration camp in Iraq has been attributed to Iraqi experimental employment of a BWA [159].

Also, Iraq developed and produced aflatoxin (at least 2200L) as a long-term debilitating bioterrorism agent intended to be used against the Kurds. It has thereupon been noted that:

> The discovery (by UNSCOM, during the 1990s) that Iraq was researching aflatoxin, not a traditional BW candidate, was a cause for some surprise. It is a carcinogen, the effects of which manifest themselves only after many years, and several Western experts have rationalized this Iraqi program only in terms of genocidal goals. If aflatoxin were used against the Kurds, for instance, it would be impossible definitively to prove the use of BW once the symptoms emerged. Another possible explanation is its potential use as an immune suppressant, making victims more susceptible to other agents. However, the aflatoxin declaration may also hide other aspects of Iraq's BW program: according to Iraq's depositions, the production program never encountered any mishap (as other parts of the BW program had) and, to judge from the declared time-frame for the total amount produced, production could never have stopped, even for cleaning of the equipment. This raises the suspicion that Iraq declared an excessive amount of aflatoxin in order to disguise the fact that other, more destructive agents had been produced in greater quantities [59].

Being a very potent, although typically slow-acting hepatotoxin and nephrotoxin, aflatoxin may have been developed as a BWA by the Iraqis for purposes of long-term terrorism, or some short-term acute impact of yet unknown nature [5]. Iraq was unable to justify the weaponization of aflatoxin from the research data obtained from its own experimentation. One bomb that by Iraq's account should have contained aflatoxin instead tested positive for botulinum toxin and negative for aflatoxin [160]; this indicated another mode of weaponization. And indeed, there is documentary evidence and statements obtained by UNSCOM that Iraq was mixing aflatoxin with riot-control gas. They note that it would not be unthinkable for a leader who has used chemical weapons on part of his population. "It is a great way to keep colonels from becoming generals," said an UNSCOM inspector familiar with the searches. "Saddam Hussein hasn't made any weapon that he hasn't used on his own population, with the exception of Scud missiles [60]." Doubtfully, the entire, tainted past Iraqi–Kurdish interface has been revealed by him since being in prison.

Notably, the Iraqi Intelligence Service provided the BW program with security and participated in bioterrorism research, probably for its own purposes, from the beginning of Iraq's BW effort in the early 1970s until the final days of Saddam Hussein's regime. The Iraqi Intelligence Service had a series of laboratories that conducted bioterrorism work including research into BW agents for assassination purposes until the mid-1990s. The Iraqi Survey Group found that the Iraqi Intelligence service produced ricin and tested it on political prisoners. ISG has not been able to establish the scope and nature of the work at these laboratories or determine whether any of the work was related to military development of a BW agent [161]. But they could certainly suffice to sponsor and support the 2001 anthrax letters' sabotage, together with al-Qaeda, as has previously been suggested [80]. All in all, the option for bioterrorism operations was persistently maintained by Iraq until its collapse in 2003 [162].

13.4.15.7 Iran

According to Eisenstadt, Iran has probably deployed BWs, which it could deliver via terrorist saboteurs, aerosol tanks mounted on aircraft or ships, or via missiles [163]. Taking care, thus, of the entire spectrum of BWs, Tehran did not ignore their importance in the context of terrorist actions; it equipped itself with micro-warfare means destined to employ bioterrorism agents by on-spot spraying and by contaminating water systems. Iran, as well as Muslim BW possessors like Sudan and Syria, can readily be assisted by some Muslim terror organization, in case they want to carry out bioterrorism acts through nonresidential saboteurs. More concretely, such cooperation between Iran and its terror organization ally—the Hezbollah—has been feared.

Other states runing BW programs that may potentially support of sponsor bioterrorism acts include, mainly, Syria, North Korea and Cuba.

13.4.16 NONSTATE-SPONSORED BIOTERRORISM

Persisting organizations, temporary communes, or sporadic individuals may initiate and conduct bioterrorism acts, without there being any institutionalized assistance from any country. The following section deals with those three types of elements, practically or potentially involved in bioterrorism-related activities. Also, it presents in detail prominent episodes of in-effect bioterrorism (further episodes are included in Section 13.4.14, 13.4.17 and 13.4.18).

13.4.16.1 al-Qaeda

This terror organization has been, and still is, the most significant one worldwide, in terms of bioterrorism, especially that it was involved, most probably, in the Sept. 2001 anthrax letter attack. In the mid-1990s, while being sheltered in Sudan, its head, Osama bin Laden, financed, in part, the construction of BW (and CW) facilities in Sudan. Later on, members of al-Qaeda were apparently trained in Iraq (by its intelligence apparatus) for BW (and other nonconventional weapons) employment. In 1998, relationship with Iraqi intelligence was established, so as to obtain

poisons—appatently toxins—and gases training. After the USS Cole bombing in 2000, two al-Qaeda operatives were sent to Iraq for CBW-related training beginning in Dec. 2000. Iraqi intelligence was "encouraged" after the embassy and USS Cole bombings to provide this training [164].

Moreover, in August 2002, reports have emerged that Ansar al-Islam, an al-Qaeda affiliate active in Iraqi Kurdistan since September 2001 as a militant group, has been involved in testing various poisons including ricin [165]. According to an ABC News report, the group tested ricin powder as an aerosol on animals such as donkeys and chickens, and perhaps even an unwitting human subject. The experiments were ordered and financed by a senior al-Qaeda official, who was providing money and guidance from elsewhere in the region.

Also, selected al-Qaeda terrorists were guided as to the methods of cultivating germs and preparing toxins to be used as bioterrorism agents and how to convert them into weapons, exploiting easily available equipment and materials. Those who plotted in the caves of Afghanistan have left behind diagrams of American cities and landmarks. Also, manufacturing instructions have been posted on the Internet. One of the simulated operations in Kandahar, Afghanistan, was contaminating a water main of a European city (apparently London) using equipment that could fit inside a backpack. Several al-Qaeda cells have been trained in Afghanistan, where they have learned to use bioterrorism agents, including anthrax, ricin, and botulism toxins. Later, after the fall of the Taliban regime, those groups continued their experiments in the Pankisi Gorge, on the territory of Georgia, bordering Chechnya [166, 167]. Not too far away, in Fallugah, Iraq, an improvised laboratory belonging to Iraqi al-Qaeda-directed rebels was revealed in 2004. It was found to contain materials for making chemical blood agents, as well as a "cookbook" on how to produce a deadly form of anthrax [168]. Two months earlier, notably, the very same Abu Musan al-Zarkawi's derivative group of al-Qaedat ("Tahwid and Jihad"—"Oneness of God and Holy War") tried hard to take care of two women known as the Iraqi anthrax masterminds. It kidnapped two Americans and a British man, threatening to kill them if Iraqi women prisoners were not released. The two Iraqi masterly women were not set free, and the three kidnapped men were then killed [169].

Another training base was located at Zenica, Bosnia. It is not clear, however, whether any experimentation practically included, beyond toxins, in-effect living germs. Reportedly, bin Laden's associates managed to receive anthrax and plague biological weapons from former Soviet facilities in Kazakhstan. Records and operations manuals captured in Afghanistan and elsewhere disclose that bin Laden has devoted money and personnel to pursue smallpox, among other biological weapons. Furthermore, uncorroborated testimony in a high-profile Egyptian trial in 1999 indicated that al-Qaeda had equired Ebola virus and Salmonella germs.

al-Qaeda, and particularly its second in command, Ayman al-Zawahiri, a physician, had long been eager to acquire biological agents, particularly anthrax, according to Khalid Shaikh Mohammed, one of Osama bin Laden's top lieutenants. Also, al-Qaeda agents had inquired about renting crop-dusters to spread pathogens, especially anthrax. During interrogations with terror suspects in custody, it has come to light that the al-Qaeda terror group has been actively seeking weapons-grade anthrax [170]. According to an article by Milton Leitenberg, computer hard drives and handwritten notes seized at the home where Mohammed was arrested included

an order to buy anthrax, along with other evidence of an interest in acquiring anthrax and other dangerous germs [171]. Until the American invasion of Afghanistan, launched after the Sept. 11, 2001 attacks, al-Qaeda's anthrax program was based in Kandahar, Afghanistan, and was led by two men: Riduan Isamuddin, known as Hambali, and Yazid Sufaat, a Malaysian member of Jemaah Islamiyah, an al-Qaeda-affiliated group. Although Sufaat tried to acquire anthrax, there is no evidence that he was able to procure the appropriate strain used for the 2001 attacks (Ames strain). This does not mean, yet, that al-Qaeda did not obtain that deadly strain through other channels. Hambali had been trying to open a new BW project for al-Qaeda in the Far-East, when he was arrested. Reportedly, anthrax powder was found, eventually, in March 2006 in a house occupied by the Taliban in Afghanistan [172].

A London-based offshoot was engaged in preparing ricin and botulinum toxins. In January 2003, British authorities arrested six Arab men that intended to produce ricin in their north London apartment, led by Kamel Bourgass, who had been trained in al-Qaeda terror camps in Afghanistan and was specially selected for instruction in making poisons [173]. Accurate recipes and ingredients for poisons including botulinum and ricin (plus cyanide), and the blueprint for a bomb were found in the apartment, in addition to castor beans.

Nonetheless, after the 2001 anthrax letter attack (covered bellow in special subchapter) and the U.S. military operations against al-Qaeda in Afghanistan, on many occasions repeated bioterrorism warnings emerged, stemming from intelligence information and from various announcements made by al-Qaeda. Just as one example, six flights bound for America, including four from Britain, were cancelled after intelligence suggested that al-Qaeda was planning a spectacular attack using a hijacked airliner and weapons of mass destruction, particularly BWs [174]. Alongside with cases of in-effect bioterrorism-oriented activities, like the ricin affair in London, various bioterrorism hoaxes that could not be identified may probably be attributed to al-Qaeda. At any rate, al-Qaeda certainly wants to use biological weapons and widen the scope. The British M15 recently reported, thereby, that al-Qaeda operatives are training in germ warfare, and trying to recruit university students with access to microbiological laboratories, so as to steal virulent pathogens [175].

13.4.16.2 Jemaah Islamiah

A Southeast Asian Islamic militant group affiliated with al-Qaeda, this organization does not lag far behind the latter. Connectedly, Dr Rohan Gunaratna, who heads the terror unit at Singapore's Institute of Defence and Strategic Studies, has warned Australia of a new, global generation of Islamist terrorists "armed, trained financed and ideologicised" to use biological weapons. In declaring that part of this new global terror wave would come out of Southeast Asia, he added he found the Jemaah Islamiah group had come extremely close to developing bioterrorism-chemical weapons, recounting an alarming analysis of a Jemaah Islamiah biological-terror rudimentary training manual that was taken from a Philippines safe house in late 2003. His further generalization is notable, saying "It is only a question of time that a group that has these intentions will have the capability to develop them. We are seeing a new generation of terrorists being trained in the use of biotlogical

weapons. We rarely saw this in the 1990s but today we are seeing increasingly this kind of training. Groups are being trained to use these agents, though the probability of attack is still low [176].”

13.4.16.3 Hezbollah

Former CIA director James Wolsey described the Hezbollah as a potential tool for bioterrorism. That threat has been accentuated and is particularly realistic, because the Hezbollah is a radical terror organization, directly supported and encouraged by Iran, which possesses biological weapons. The evident acquisition and successful employment of unmanned drones by the Hezbollah, as well as its access to the sources of the Jordan River, may increase a potential bioterrorism threat posed by this dangerous organization. In 1998 the Hezbollah attempted to obtain biological and chemical weapons through two businessmen situated in Switzerland [177]. Elements of Hezbollah and al-Qaeda joined forces to plan a series of attacks using toxic substances, apparently chemicals and toxins. Groups of al-Qaeda and Hezbollah activists from the Sidon area of Lebanon met in Africa in December 2002, to set up the needed preparations there or in Sidon [178]. The 2006 confrontation between Hezbollah and Israel, demonstrated effective operational capacities of the Hezbollah to employ a variety of Iranian rockets and missiles, some of which are tipped—in Iran—with biological warheads.

13.4.16.4 Radical Palestinian Terror Organizations

An article appeared on the 13 August 2001 edition of the Lebanon-based Palestinian weekly, *Al-Manar*, stating that there is “serious thinking” among the Palestinians about obtaining BWs. It says regarding BWs that “obtaining its primary components is possible without too much effort, let alone the fact that there are hundreds of experts who are capable of handling them and use them as weapons of deterrence, thus creating a balance of horror. Anyone who is capable, with complete self-control, of turning his body into shrapnel and scattered organs, is also capable of carrying a small device that cannot be traced and throw it in the targeted location [179].” It has been pointed out that Palestinian organizations are inclined to resort to the acquisition and introduction of nonconventional capabilities—in particular biological and chemical—mainly for deterrence purposes. According to that source, many Palestinians believe that biological and chemical weapons are a legitimate and desirable means in the struggle against Israel [180]. Basically, a radical terror organization, like the Hamas, is apt to acquire BWs, although so far it is not known to have obtained them, in that case.

Notably, a novel mode of infection with hepatitis B virus has been suggested, following penetrating human bone fragments due to the explosion of a Palestinian suicide bomber [96]. Connectedly, perhaps, the Tanzim planned to use a suicide-bomber arrested with explosives bearing AIDS-infected blood, the thinking being that anyone who survived would get AIDS. The operation was foiled [181]. Another Palestinian body, the al-Aqsa Martyrs’ Brigades (affiliated with the Palestinian Fatah political party) sent an announcement in 2006 to the Ramattan News Agency, stating: “we are pleased to say that we succeeded in developing some 20 different

types of biological and chemical weapons, this after a three-year effort", adding that those agents might be employed under certain circumstances [182].

13.4.16.5 Aum Shinrikyo Cult

The Aum Shinrikyo Cult ("religion of supreme truth"), a Japan-based apocalyptic religious sect, produced biological agents and tried to use them. The Japanese police discovered that the Aum included among its members skilled scientists and technicians, including some with training in microbiology, who attempted to generate weapons using anthrax, cholera, botulinum toxin, Q-fever, and even Ebola virus [183]. These accounts also suggest that there were four separate attempts to use biological agents, including anthrax once and botulinum toxin three times:

- In April 1990, the Aum Shinrikyo outfitted an automobile to disseminate botulinum toxin through the engine's exhaust. The car was then driven around Japan's parliament building.
- In early June 1993, the cult attempted to disrupt the planned wedding of Prince Naruhito, Japan' s Crown Prince, by spreading botulinum toxin in downtown Tokyo using a specially equipped automobile.
- In late June 1993, the cult attempted to spread anthrax in Tokyo using a sprayer system on the roof of an Aum-owned building in eastern Tokyo. The anthrax was disseminated for four days.
- On March 15, 1995, the Aum planted in the Tokyo subway three briefcases designed to release botulinum toxin. Apparently, the individual responsible for filling the botulinum toxin had qualms about the planned attack and substituted a nontoxic substance. The failure of this attack led the cult to use sarin in its March 20, 1995 subway attack. A helicopter and two UAVs were purchased by the cult and intended to be equiped with sprayers.

Fortunately, the Aum scientists apparently made mistakes in either the way they produced or disseminated the agents, and no one became ill or died from the attacks.

13.4.16.6 Bhagwan Shri Rajneesh Cult—Typhoid Epidemic

As the summer of 1984 waned, a cult led by the Bhagwan Shri Rajneesh near the town of The Dalles, Oregon, used a biological agent to sicken hundreds in an apparent dress rehearsal to sway the outcome of a local election. Three years earlier, the Bhagwan brought followers with him from India when he immigrated in 1981. The hard-working Rajneeshees were isolationist, with some 150 armed people to keep outsiders away from their ranch. When the Bhagwan decided to enlarge his ranch and his flock, he took over the small town of Antelope, christening the new town Rajneesheepuram.

Oregon's attorney general stated, however, that the municipality was unconstitutional because it did not separate church and state. To outmaneuver the attorney

general, the cult's hierarchy hatched a plan to make the Wasco county residents too sick to vote in November 1984, enabling the Rajneeshees to seat their favored candidate on the county court. The cult's nurse was the scientific brain behind attempts to put a bioterrorism plan into action [184].

Although the cultists considered additional organisms (AIDS and *Salmonella typhi*), the Rajneeshees decided upon *Salmonella typhimurium*, so as to bring about a massive food contamination. The cult bought bactrol disks from a Seattle medical supply company under false pretenses. A trio of cult members worked in a laboratory equipped with an incubator and freeze dryer to brew what they called a "salsa." Several more Rajneeshees were involved in distributing the agent on various occasions. Starting on 29 August 1984, the Rajneeshees began sprinkling their *S. typhimurium* in personal drinking glasses, on doorknobs, and urinal handles; on produce at the local supermarket; and on salad bars in 11 restaurants.

Soon, a steady stream of patients was reporting to local physicians and hospitals, with symptoms ranging from nausea and diarrhea to headache and fever. In total, 751 fell ill. Wasco County commissioners and ordinary citizens were among the victims. Within 4 days, local health-care providers were able to identify the *S. typhimurium* as the source, but over a year passed before there was confirmation that a single strain caused all of the illnesses and the Centers for Disease Control filed its report. No one died in this test to see whether a ballot box could be fixed, but the Bhagwan reportedly observed that one should not worry if a few perished. Law enforcement authorities thought that the Rajneeshees were practicing to poison the water system of The Dalles. Cult members had already put dead rodents and perhaps raw sewage and salmonella salsa into The Dalles' water supply.

Several cult members were involved in the planning and execution of the salmonella attacks, but only two of the Baghwan's chief lieutenants were prosecuted. This pair received multiple concurrent 20 year sentences, among other penalties. According to one analyst who studied the Rajneeshees carefully, the cult did not work its way up the ladder of violence to bioterrorism. Rather, the Rajneeshees appear to have abruptly embarked on their salmonella spree as a means to a specific end.

An epidemiologic analysis was then done. Cohort and case-control investigations were conducted among groups of restaurant patrons and employees to identify exposures associated with illness. All 751 persons with Salmonella gastroenteritis were associated with eating or working at area restaurants. Most patients were identified through passive surveillance; active surveillance was conducted for selected groups. A case was defined either by clinical criteria or by a stool culture yielding *S. typhimurium*. It has been found that the outbreak occurred in two waves, September 9 through 18 and September 19 through October 10. Most cases were associated with 10 restaurants, and epidemiologic studies of customers at 4 restaurants and of employees at all 10 restaurants implicated eating from salad bars as the major risk factor for infection. Eight (80%) of 10 affected restaurants compared with only 3 (11%) of the 28 other restaurants in The Dalles operated salad bars (relative risk, 7.5; 95% confidence interval, 2.4–22.7; $P < 0.001$). The implicated food items on the salad bars differed from one restaurant to another. The investigation did not identify any water supply, food item, supplier, or distributor common to all affected restaurants, nor were employees exposed to any single common source. In some instances, infected employees may have contributed to the spread of illness by inadvertently contaminating foods. However, no evidence

was found linking ill employees to initiation of the outbreak. Errors in food rotation and inadequate refrigeration on ice-chilled salad bars may have facilitated growth of the *S. typhimurium* but could not have caused the outbreak. A subsequent criminal investigation revealed that members of a religious commune had deliberately contaminated the salad bars. An *S. typhimurium* strain found in a laboratory at the commune was indistinguishable from the outbreak strain [184].

Although the above information pertains to organizational or cultist bioterrorism, the following episodes represent individual bioterrorism.

13.4.16.7 Shigella Dysenteriae Type 2 Outbreak

Another case of intentional contamination of food with a bacterial pathogen occurred in 1996, involving clinical laboratory workers infected with *S. dysenteriae* type 2 [185]. *S. dysenteriae* type 2 is a rare organism, and outbreaks are seldom seen in the general population. After consumption of muffins and donuts anonymously placed in the break room of a Texas laboratory, 12 of 45 laboratory workers developed severe, acute diarrheal illness. Rapid onset of symptoms allowed investigators to retrieve a muffin sample, later cultured and found to contain *S. dysenteriae* type 2, matching those cultured from infected workers. Laboratory reference cultures were found in disarray, and cultures were missing, indicating laboratory cultures had been taken, grown, and used to contaminate foodstuffs. All case patients reported having eaten muffins or doughnuts placed in the staff break room on October 29. Isolates from nine case patients were indistinguishable from *S. dysenteriae* type 2 recovered from an uneaten muffin and from the laboratory's stock strain, a portion of which was missing.

13.4.16.8 Hepatitis A Outbreak

Another instance of apparent intentional contamination of food with hepatitis A virus was documented in 1965. Twenty-three cases of hepatitis were reported among personnel at a Naval Air Station in 1961 [186]. The course of disease among those infected was moderately severe with no deaths. At the time, hepatitis A (infectious hepatitis) and hepatitis B (serum hepatitis) diagnoses were made on clinical and epidemiological grounds. To determine the cause of the infections, an extensive investigation of risk factors was conducted. Dining hall records and food questionnaires identified potato salad as the most likely contaminated food source. Questioning of the sole salad cook revealed that he had experienced symptoms resembling hepatitis, and a background investigation revealed aberrant social behavior. Connectedly, two incidents of inappropriate urination gave investigators a possible route of contamination of the potato salad when coupled with the individuals' symptomology.

13.4.16.9 Ascaris Suum Outbreak

The last instance of intentional contamination involved four college students who were peculiarly exposed to a massive dose of embryonated *Ascaris suum* eggs (a large ringworm infecting pigs) while attending a Winter Carnival in Canada during February 1970. The most likely source of infection was a meal served to the students during the Winter Carnival [187].

More episodes, mostly of secondary importance, are mentioned below in Section 13.14.4.

13.4.17 THE ANTHRAX LETTERS

A colossal event generated by means of a minute amount of anthrax powder, the September 2001 anthrax letter attack, is discussed in detail. The remarkable potentiality of anthrax as a bioterrorism agent in general, and within the context of the letter attack in particular, is demonstrated. Resultant short- and long-term impacts are accentuated, alongside with the severe inability to point at the provenance of the anthrax powder contained in the letters.

The germ *Bacillus anthracis* is the etiological agent of anthrax, a disease primarily of herbivores, but one that humans occasionally acquire through contact with infected animals or with contaminated animal products. The mode of infection may be cutaneous, intestinal, or pulmonary. The latter represents, as well, a distinct form of employing anthrax germs as an inhalable bioterrorism agent, either sprayed (wet aerosol) or powdered (dry aerosol). The efficacy of the aerosol thus generated is shaped by a variety of inherent attributes largely depending on the way the aerosol material has thereby been structured. In general, the aerosol material contains anthrax germs spores—a resilient form of life typifying all species of the genus *Bacillus* sp.—plus various, most vital, additives.

Under optimal meteorological conditions, producing 50% fatalities over a one-square-mile area would require about just 10 g of anthrax spores, in case there is no medical intervention, whatsoever [188]. Additional data show the impact of anthrax in terms of some 20,000 to 80,000 casualties afflicted by 30 kg of this biological agent, as compared with 400 to 6000 casualties afflicted by 300 kg of sarin nerve gas, and 80,000 casualties afflicted by 20 kiloton of a nuclear weapon [189]. Moreover, official U.S. estimates for casualties produced by an airplane, flying upwind of a city, releasing successfully a cloud of anthrax germs, range from 100,000 to three million dead. An individual driving a car around a medium-sized city spewing anthrax out the tailpipe would cause some 70,000 fatalities, and two individuals in two cars in two cities, 140,000 (referring to an unprotected population). These are, of course, traditional theoretical estimates; yet they illustrate the proportional impact of a biological agent, in this case, anthrax—a noncontagious bacterial pathogen. Still, even by 2003, it was held that a little more than two pounds of anthrax spores efficiently spilled into the air over a city the size of New York could be expected to kill more than 120,000 people unless state and federal officials respond much more aggressively than they currently plan to, according to the first comprehensive computer model of such a terrorist act [190].

The September 2001 anthrax letter attack marked an outstanding, most significant milestone in the course of bioterrorism. It was a quantum leap, scarcely expected in practical terms, albeit with a lot of indicative intelligence preceding the event. Overall, this bioterrorism campaign has been, operationally, complicated, assuming that the spore powder was produced outside the United States. A most comprehensive picture has been presented by the School of Public Health, Department of Epidemiology, University of California. It meticulously covers the technical, epidemiological, medical, and logistical aspects altogether. Seven letters

containing anthrax spores were probably mailed, with similar written messages from Trenton, NJ. Five letters were sent on September 18 (postal facilities [191, 192] [probable cross-contamination]), one going to American Media in Boca Raton, Florida [193, 194] (not recovered); a second to the *New York Post* (recovered) [195–197]; a third to Tom Brokaw of NBC News (recovered) [198, 199]; a fourth to ABC News (not recovered) [200]; and a fifth to Dan Rather of CBS News (not recovered) [201]. On October 9, two more letters were sent from Trenton, NJ. (probably cross-contamination) [202–206] via Brentwood mail processing facility [207–210], one to Senator Tom Daschle (recovered), and the other to Senator Patrick Leahy (recovered) [211]. Letter(s) cross-contaminated with the Daschle and Leahy letters were sent from Trenton, NJ to Wallingford, CT, with at least one letter probably going to Oxford, CT [212]. The final anthrax case in the outbreak remains a mystery, but possibly arose from contact with the September 18 letters or cross-contamination with the October 9 Leahy letter in Trenton, NJ. To do so, spores from the Leahy letter would need to have adhered to an envelope of another letter destined for the Bronx, New York City [213]. In summary, the 22 cases (one was removed by the CDC) that comprised the American Anthrax Outbreak of 2001 likely had contact with one or more of seven spore-laden envelopes.

Four letters laden with anthrax spores were discovered, all dated by an unknown author as "09-11-01," and all sent from Trenton, NJ. Two letters were postmarked September 18, 2001 in Trenton, one of which was sent to the *New York Post* where it was handled by several staff members, and the other to Tom Brokaw of NBC, opened September 19–25 but not found until October 12, 2001 in case 2's file drawer [198]. The *New York Post* letter, handled but not opened, was found on October 19, 2001. It was dampened before being discovered, turning the spore contents into a granular or clumped state.

The second two letters were postmarked on October 9, 2001 and mailed to the Washington, D.C. offices of Senator Tom Daschle of North Carolina, Majority Leader, and Senator Patrick Leahy of Vermont, Chair of the Judiciary Committee. Both letters went though Washington, D.C.'s Brentwood mail processing facility, which handles all incoming federal government mail. Both letters contained the same anthrax strain and were of the same potency.

The Daschle letter was opened in the sixth floor office at 9:45 a.m. by an aide in the Senator's Hart Senate Office Building suite on October 15, 2001. It was believed to contain about 2 g of powder comprising 200 billion to 2 trillion spores. Based on nasal swabs, all 18 persons who were in the area of Daschle's sixth floor office tested positive for anthrax exposure, as did 7 of 25 (i.e, 28%) in the area of the Senator's fifth floor office (an open staircase connected the two offices).

The Leahy letter never arrived at his office. Instead an optical reader misread the handwritten 20510 ZIP code for the Capitol as 20520, which serves the State Department. As a result, the letter was routed to the State Department, where it arrived on October 15, infecting a State Department postal worker (case 20) [211]. Shortly thereafter, all mail was isolated and sealed in plastic bags for a later search.

On November 16, 2001, the Leahy letter was found; then after special preparation, it was opened on December 6 in a laboratory setting. It contained about 1 g of anthrax, made fresh no more than 2 years before it was sent. The contents of the enclosed letter were identical to the wording of the Daschle letter. The anthrax

spores in the Daschle and Leahy envelopes were uniformly between 1 and 3 μm in size, and were coated with fine particles of frothy silica glass. More investigation is underway.

Also processed at the Trenton, NJ postal facility was a small number of letters sent to the Southern Connecticut Processing and Distribution Center in Wallingford, CT. Here letters arrived on October 11 that had been cross-contaminated with anthrax spores from the October 9 Daschle or Leahy envelops. Anthrax spores were found on mail-sorting equipment in Wallingford. One letter that went through the Wallingford distribution center was found in Seymour, nearby to Oxford where case 23 resided. Likely case 23 was infected via a similar cross-contaminated letter that came in contact with mail in the distribution center in Wallingford (not discovered) [212].

Most uncertain is the origin of case 22, although there is a connection between case 22's neighborhood and the Trenton, NJ post office [213]. A printout from the post office showed that an unrelated letter went to a shop around the corner from case 22's home. This unrelated letter was processed 2 minutes after the Leahy letter and 18 minutes before the Daschle letter. Thus the mail sent to case 22 might also have been cross-contaminated with spores from the Leahy or Daschle envelopes. Alternatively, case 22 might have had contact with one or more of the unrecovered September 18th letters following their disposal in Manhattan, similar to case 19 and case 21 [196].

But the anthrax letters affair was not limited to the US. The American embassy in Vilnius, Lithuania, was likewise concurrently targeted. Also, Three businesses in Karachi, Pakistan, were targeted, and received anthrax letters. Anthrax spores were found in a letter sent from Europe to a doctor's surgery in Chile, according to Chilean officials [214].

For the time being, the culmination of bioterrorism worldwide has been this act of distributing mail envelopes containing anthrax spore powder. It reflected noticeable supremacy of a simple act of bioterrorism (irrespective of preparing the anthrax powder in itself, which was very sophisticated), in several senses:

a. Uncontrollable preparing of the postal envelopes containing the anthrax powder
b. Uncontrollable, repeated mailings
c. Undetectable conveying of the mailed envelopes until reaching their various destinies
d. Untraceable footprints of the perpetrators
e. Inability to even postulate whether the sabotage was state or nonstate sponsored

Despite or, rather, because of those points of supremacy, the leading agencies responsible for foreseeing or, at the least, deciphering in retrospect such strikes—FBI, CIA, DIA, and the like—were after nearly 2 years still reluctant to grant public access to an unclassified report on lessons learned from the anthrax letter attacks of 2001; the Pentagon has finally released a redacted version of the document [215]. "The anthrax attacks revealed weaknesses in almost every aspect of U.S. bioterrorism-preparedness and response," the report said. "As simple as these

attacks were, their impact was far-reaching." The report, authored by David Heyman of the Center for Strategic and International Studies, is based on a day-long forum convened by CSIS under contract to the Defense Threat Reduction Agency in December 2001.

It provides a detailed and informative but hardly unsuspected inventory of shortcomings in emergency preparedness and response. Ironically, the Defense Department's two-year denial of repeated requests for release of the document exemplifies one of the central problems identified in the report: "The failure to communicate a clear message to the public was one of the greatest problems observed during the anthrax attacks . . . [including] failure to provide timely and accurate information." The Department's inability to efficiently process requests for this document suggests that it still has a long way to go to remedy this particular failure. The redacted version of the report was finally released in response to a Freedom of Information Act (FOIA) appeal [215].

Also, the Pentagon did not contend that the withheld portions of the anthrax report are classified (exemption 1), even though they are said to concern "vulnerabilities and capabilities of the US Government to respond to another . . . attack." Rather, in an expansive interpretation of the law, it said that release of the redacted portions would make it possible to "circumvent Department of Defense rules and practices. . . ." (exemption 2). See the March 15 transmittal letter from H.J. McIntyre of the DoD FOIA Policy Office here: Mike Denny Senior Force Protection Consultant Guardian Group International (GGI) [216].

In the long run, the impact of the anthrax letter attack still prevails in several respects:

- Individually, those who survived the infection have not been fully cured.
- Globally, the short-run impact encouraged terror-oriented entities to persistently explore or increase bioterrorism options.
- Practically, numerous consequent hoaxes of bioterrorism threats through powder containing post envelopes extremely proved burdensome to wide logistical systems.
- Environmentally, even as of 2005, rooms contaminated in 2001 are repeatedly disinfected.
- Publicly, the interface with institutional classified information holders sharpened.
- Strategically, the provenance of the anthrax powder has not been deciphered, although somewhat traced [217].

Thus, since the anthrax attacks in 2001, work at the nation's post offices has been disrupted by more than 20,000 incidents of suspicious powder leaking from envelopes and packages. All but a few have turned out to be nothing more than soap, dust, talc, or other nonlethal substances. Sand was the culprit in one incident included in wedding invitations for a beach ceremony. Still, the scares have taken a toll in nerves, lost time, and money. Postal workers have been instructed, if they see something like that to consider it dangerous. The area then is sealed off, and local hazardous materials teams and the Postal Inspection Service are called in. Leaking suspicious powders that turned out to be harmless include powdered Alfredo sauce, ground lentils, pudding mix, and coffee creamer, officials said.

Other cases have included leaking samples of detergent, sugar, or baking soda [218].

In November 2003, a secret cabinet-level "tabletop" exercise, designed to be very stressful to the system was thus conducted, which simulated the simultaneous release of anthrax in different types of aerosols in several American cities. The drill, code named Scarlet Cloud, found that the country was better able to detect an anthrax attack than it was 2 years ago, said officials knowledgeable about the exercise. But they said the exercise also showed that antibiotics in some cities could not be distributed and administered quickly enough and that a widespread attack could kill thousands; particularly, enormous difficulties stopping the spread of contamination through the country and into Canada were observed [219].

The drill was notable for the top-level attention it drew and the gaps it showed in the effort to protect against bioterrorism. About three dozen senior officials involved in domestic defense, including two cabinet officers—the secretary of homeland security, and the secretary of transportation—as well as the head of the White House's Homeland Security Council, participated in the exercise at the Pentagon's National Defense University.

Moreover, the contents of the former American Media Inc. building in Boca Raton, FL—namely, thousands of boxes—exposed to anthrax in 2001, were set to be decontaminated for a second time to ensure all of the pathogen is eliminated, given the approval of the Environmental Protection Agency and the Palm Beach Country Health Department [220].

Overall, the impact of the anthrax letter attack was colossal. In a sense, the very fact that the anthrax letter attack has not been deciphered since 2001 is no less meaningful and important than this unprecedented act of bioterrorism itself. In contrast to the wealth of empirical data collected and published with respect to the specific Ames strain of the 2001 anthrax letter attack and the resultant medical cases, a relative paucity of information has been brought out regarding the chemical and physical properties of the substance contained in the mail envelopes, namely the anthrax spore powder. Primarily its provenance has not yet been deciphered. This peculiar powder certainly reflects an outstanding assortment of different disciplines: microbiological, technological, medical, political, and strategic. Connectedly, it still poses, in parallel, an enigmatic, extremely complex intelligence issue that ought to be elucidated, for numerous reasons. Although the anthrax germs used for this act of bioterrorism have been fully identified to be indistinguishable from the strain Ames—a remarkably virulent strain initially isolated in 1981 in Texas but later shared with laboratories outside the United States—it is still not even known whether the anthrax powder contained in the envelopes has been structured in the United States or elsewhere [221]. Various indications point at Al-Qaeda together with Iraq as being the perpetrators [80].

Overall, dozens of buildings were contaminated with anthrax as a result of the five mailings, which contained, altogether, about 18 gr. of the sabotage spore powder. The decontamination of the Brentwood postal facility took 26 months (and cost US$130 million). The Hamilton, NJ postal facility remained closed for 41 months (its cleanup cost US$65 million). The Environmental Protection Agency spent US$41.7 million to clean up government buildings in Washington, D.C. [222]. One FBI document said the total damage exceeded US$1 billion [223].

13.4.18 THE RICIN COURSE

Various traits making ricin the toxin of choice for bioterrorism purposes are discussed. The actual outcome of that appeal, as shown, has for long been relapsing episodes involving ricin, worldwide. Clear tendency emerges of al-Qaeda and affiliated groups, at the least, to persist in deploying ricin, and is doubtfully controllable.

Ricin molecules contain a heterodimeric type 2 ribosome-inactivating enzyme (32 kDa), also known as the A chain. It is a very potent cytotoxic RNA N-glycosidase that inactivates eukaryotic ribosomes. It is linked by a disulfide bond to the galactose/N-acetylgalactosamine-binding lectin (34 kDa), also called the B chain. Weakness, fever, cough and pulmonary edema occur 18–24 hours after inhalation exposure, followed by severe respiratory distress and death from hypoxemia in 36–72 hours. Direct administration into the blood system brings about a similar picture, whereas food poisoning is basically slower, certainly dose-dependent [224].

This protein plant toxin may be regarded, foremost, as the prime toxin for bioterrorism, owing to the integral formed by several different characteristics, altogether:

a. High toxicity
b. Atypical symptomatology
c. Effective contraction through respiratory and alimentary tract
d. Effectual administration through blood stream
e. Availability of the raw material (castor beans)
f. Typical dual usability of the raw material
g. Easiness of manufacturing

Ricin's properties have been known since ancient times, and it has a long history of accidental and intentional intoxication [225]. Ricin was studied as a possible weapon in World War I, and the United States, Canada, and the United Kingdom developed it as a field weapon during World War II, also known as Agent W [226]. The World War II effort led to refined ricin in a crystalline form, although it was the amorphous form that was used in high-explosive bombs and shells and in more specialized delivery systems, such as plastic containers and cluster bombs. Attaining effective particle sizes with ricin powder is difficult, and use of the material in water or suspended in glycerol or carbon tetrachloride is more effective [227]. The agent is difficult to detect. It is fairly stable in clear, dry weather, persisting in the soil or environment for up to 3 days [228].

But the perfect usability of ricin-oriented for sabotage acts, in parallel, has not at all been ignored. The course of ricin oriented sabotage began long before 1978; yet its in-effect emergence took place in that year. It was the successful ricin-based assassination of the Bulgarian anticommunist reporter Georgi Markov that then occurred in London (full details given above). Two years later, an assassination of CIA agent Boris Korczak occurred in McLean, Virginia, Tyson's Corner, ricin being used as weapon, possibly repeatedly in umbrella configuration [76].

The attractiveness of ricin did not diminish because it found new grounds in the United States. In 1983, the FBI obtained one ounce of ricin oriented in a 35-mm film canister from an individual in Springfield, Massachusetts, who had manufactured it himself. This is believed to be one of several confiscations of ricin [76]. In 1993, an Arkansas man with survivalist group connections attempted to smuggle 130 g of ricin from Alaska into Canada to use as a weapon [164]. Later, in 1995 two members of the Minnesota Patriots Council were convicted of conspiracy to assassinate a deputy U.S. Marshal and International Revenue Service agents by ricin [127].

Syria and Iran acquired ricin as a weapon during the 1990s. Also, the Iraqi Survey Group concluded that the Iraqi Intelligence Service produced ricin contemporarily, and tested it on political prisoners. The toxin subsequently became an agent of increasing interest within some Muslim terrorist organizations. Thus, in August 2001, the FSB (Russian Federal Security Service) claimed it had intercepted a recorded conversation between two Chechen field commanders about instructions on the “homemade production of poison” for use against Russian soldiers. Russian authorities reportedly then seized materials, including confiscated papers also containing instructions on how to produce ricin from castor beans. The Russian response did not take place too late, employing the lethal castor molecule. In March 2002 the FSB apparently continued its long tradition of poisoning, while killing Chechen rebel Amir Khattab, by sending him a letter impregnated with ricin [229].

al-Qaeda got into action. Traces of ricin and instructions on its use were discovered in 2002 in an al-Qaeda house in Afghanistan [230]. The head of an al-Qaeda affiliate network, Abu Massab al-Zarqawi, was trained in the use of ricin in Afghanistan before he relocated to Iraq in 2002. It was regarded to be an ideal bioterrorism weapon for terrorists. An al-Qaeda suspect arrested in Italy before the 2003 Iraq War told his interrogators that members of the al-Zarqawi network had purchased toxins from Iraq [231]. Ricin, botulinum, and gas-gangrene toxins were the main toxins possessed by Iraq.

And, indeed, in August 2002 reports have emerged that Ansar al-Islam, an al-Qaeda affiliate active in Iraqi, has been involved in testing poisons and chemicals including ricin. The toxin powder has been tested as an aerosol on animals such as donkeys and chickens, perhaps even on an unwitting human subject.

The outcome has first surfaced in London, marking the ricin route from Asia onto Europe: London, 5 January 2003. British authorities arrested six men suspected of producing ricin in their north London apartment. All six, including two teenaged asylum seekers and four individuals in their twenties and thirties, are believed to be Arabs from Algeria or other North African countries. On 8 January, a seventh man, age 33, was also arrested in connection with the case [232]. The next day sources in Whitehall indicated that at least one of these seven men had attended an al-Qaeda training camp in Afghanistan, whereas others appear to have received terrorist training in Chechnya and the Pankisi Gorge region of the Newly Independent State of Georgia [233–235].

In the apartment where the six original arrestees resided, the authorities found several castor oil beans and equipment that could be used to process those beans. The toxin has not been detected. Five other locales were subsequently searched in conjunction with this incident, and on 13 January, Scotland Yard officials arrested

five more men and a woman in Bournemouth. One day later, another Islamist who was being arrested by Manchester police attacked them with a knife, killing one officer and wounding four others [236]. British antiterrorist investigators soon identified this same 27-year-old Algerian, "Kamel Bourgass" (also known as Nadir Habra), as "a very senior player" in the network thought to be behind the ricin plot [237].

These events occurred after a series of arrests of other Islamist radicals in Rome, Paris, and London. Because some of these individuals, particularly those in the Rome case, were allegedly planning to carry out terrorist attacks using poisons, the most recent incident in London raised several potentially worrisome questions [238]. One is whether the arrestees actually intended to employ the deadly toxin as an assassination or mass casualty weapon. A second is whether they were linked to components of the al-Qaeda network, such as the Groupe Salafiste pour la Predication et le Combat (GSPC: Salafist Group for Preaching and Fighting—see footnote) in Algeria, or were instead affiliated with some other Islamist terrorist organization such as the Algerian Groupe Islamique Armée (GIA: Armed Islamic Group). A third is whether certain states that have previously produced and tested ricin as a potential weapon played any role at all in transmitting their technical expertise or unused stocks of ricin to violent anti-Western Islamist groups. Iran, Syria, and Iraq (until occupied, if not later) are known to possess ricin.

Still in Europe, ricin was then discovered in Paris, two months later. Traces of the toxin have been found at a railway station in Paris, according to the French interior ministry. Two vials of the potentially deadly substance were found inside a locker at the Gare de Lyon, according to ministry officials. The locker contained two vials with a powder, a bottle filled with a liquid and two smaller bottles also containing a liquid. The two smaller bottles contained traces of ricin in a mixture that turned out to be a highly toxic [218].

The United States was repeatedly the next station of the ricin course, chronologically, although apparently involving but domestic American perpetrators questing to achieve influence. In October 2003, a metallic container was discovered at a Greenville, SC postal facility with ricin in it. The small container was in an envelope along with a threatening note. Authorities did not believe this was a terrorism-related incident. The note expressed anger against regulations overseeing the trucking industry. But one month later, the target was the White House.

The U.S. Secret Service intercepted a letter addressed to the White House in November 2003 that contained sparkled ricin powder, but it never revealed the incident publicly and delayed telling the FBI and other agencies; the affair was disclosed in February 2004. It was addressed to the U.S. Department of Transportation. The letter—signed by "Fallen Angel" and containing complaints about trucking regulations—was nearly identical to one discovered in October 2003 at a Greenville, SC, mail-sorting facility. But the existence of a similar letter sent to the White House was not disclosed until yesterday, and then only by law enforcement

[1] The name *Salafi*, which derives from the Arabic verb *salafa* (to precede), refers to the original companions of Muhammad, who are collectively known as al-Salaf al-Salih (the virtuous forefathers of the faith). In this context, a Salafi is a traditionalist who demands that all Muslims follow the exemplary, pious, and uncorrupted behavior of Muhammad and his trusted original companions. Note also that the GSPC is a breakaway faction of the GIA that later allied with al-Qaeda.

officials who asked not to be identified by name. Until then, the whole thing was absolutely kept under wraps on a national security basis.

Although seemingly—at the least—purely domestic, Secret Service spokeswoman declined to comment on details of the case or why it was kept secret, citing the ongoing investigation. He also declined to comment as to whether workers at the mail facility were tested or underwent decontamination procedures, and said the facility's location was kept secret for security reasons. Officials have previously noted that one mail facility used by the White House is located at Bolling Air Force Base. The letter is believed to have been sent from the Chattanooga area as it passed through a mail facility there [240]. The subsequent and last link in the United States, for now, has been a ricin-containing postal enveloped mailed in Feb. 2004 to the U.S. Senate office of the Majority Leader. Federal investigators have examined about 20,000 pieces of mail in hopes of finding the source of the ricin discovered on Capitol Hill, but so far they have turned up nothing to lead them to a suspect in the case [241].

One month later, possibly by sheer coincidence, FBI agents searching Miron Tereshchuk's home in March 2004 found firecrackers, chemicals, recipes for ricin, and a postcard with the message "Here is your poison—enjoy," according to documents filed in the Virginia court. Back to Iraq, the same month, the U.S. Army staged raids in Baghdad, uncovering evidence of an attempt to produce ricin, so as to put some in mortar rounds [242]. And again, in the United States, in November 2005, plans for producing ricin, along with bomb materials and diagrams were found in the home of Sergio Maldonado, a 20-year-old man known as a criminal [243].

In a markedly similar event (June 2006), a jar containing ricin derived form castor beans, along with ricin residue in a bowl, gun silencers, pipe bombs and bomb-making materials, were found in a shed in Nashville, Tennessee [244].

Most probably, the ricin course did not reach an endpoint.

13.4.19 THE SMALLPOX COMPLEX

The unique properties and particular importance of smallpox virus are discussed, both as a bioterrorism threat and as a major biohazard in general. It appears to pose, potentially, a colossal menace, which ought to be intensely coped with. The issues of renewed vaccination and ongoing research are then addressed, showing the complexity related to that singular pathogen.

The virus causing smallpox appears to be, objectively, the most devastating pathogen ever faced—as far as known—by humanity. Presumably, many billions of people lost their life due to smallpox during human history (an estimated 300-million people worldwide in the twentieth century alone). The virus has been effectively used for bioterrorism purposes (details given above). It has successfully been eradicated worldwide, primarily thanks to the fact that it is infective toward man only, hence not having the capacity to endure within any other creature. This plainly means that the absence of this pathogen from human populations signifies for its final elimination, except for persisting in the frozen state in laboratories or, perhaps, in nature. Moreover, the lacking of alternative hosts, apart from man, considerably restricts—both quantitatively and qualitatively—the overall gene pool

of this virus and, therefore, its ability to markedly evolve and give rise to novel variants capable of evading human herd immunity, which has extremely been fortified in the past by mass inoculations. Resultantly, the magnitude of susceptible unvaccinated segments of human populations was, at the time, too small to sustain the virus. Consequently, the virus vanished.

Furthermore, the genetic distance between *Variola major*, the virus that generates smallpox, and the monkey-pox virus, which is sometimes regarded as a possible future reproducer of a new variant of human pox, is still appreciable. But the genetic distance from certain viral strains held in some laboratories over the world is zero. And, at the same time, human herd immunity against smallpox is steadily diminishing, since inoculations were stopped (around 1980). The temporal equation thus formed seems to be formidable. Moreover, the sound, natural equilibrium between the spatial distribution of immunized and nonimmunized segments of human populations worldwide has substantially been impaired as a result of vaccinations, particularly since the elimination of the virus (as a natural selection factor) from the wild. Objectively, favoring for a moment an authentic natural perspective, this seems to be, then, a sort of anomaly. Such circumstances may immensely increase the vulnerability of mankind to the impact of an act of bioterrorism involving the smallpox virus.

If not held in some laboratories until now, it would apparently be, then, a nonrevivable creature. But in actuality, things are different. The story begins in that there are no clear data as to the overall local attempts to isolate—and, hence, preserve—the virus during the occurrences of natural smallpox epidemics over many countries worldwide throughout the twentieth century, until the last 1972 epidemic. Still, even if assuming the total and complete destruction of this virus worldwide, it is apt to be recreated, based on the knowledge attained on its full genome.

Smallpox (also known by the Latin names *Variola* or *Variola vera*) is a highly contagious disease unique to humans. The causative virus has two variants called *Variola major* and *Variola minor. V. major* is the more deadly form, with a typical mortality of 20–40% of those infected. The other type, *V. minor*, only kills 1% of its victims. Many survivors are left blind in one or both eyes from corneal ulcerations, and persistent skin scarring—pockmarks—is nearly universal. Smallpox was responsible for an estimated 300–500 million deaths in the twentieth century. In 1967, for instance, still prevailing worldwide in spite of massive inoculations, the WHO estimated that 15 million people contracted the disease and that 2 million died in that year [245].

Transmission is by droplets, and infection in the natural disease will be via the lungs. The incubation period for obvious disease is around 12 days. In the initial growth phase, the virus seems to move from cell to cell, but around the twelfth day, lysis of many infected cells occurs and the virus will be found in the bloodstream in large numbers. The initial or prodromal symptoms are essentially similar to other viral diseases such as influenza and the common cold—fevers, muscle pain, stomach aches, etc. The digestive tract is commonly involved, leading to vomiting. Most cases will be prostrated.

The smallpox virus preferentially attacks skin cells, and by days 14–15, smallpox infection becomes obvious. The attack on skin cells causes the characteristic pimples associated with the disease. The pimples tend to erupt first in the mouth, then the arms and the hands, and later the rest of the body. At that point, the

pimples, called macules, should still be fairly small. At this stage, the victim is most contagious.

By days 15–16 the condition worsens; at this point, the disease can take two vastly different courses. The first form is of classic ordinary smallpox, in which the pimples grow into pauples, and then fill up with pus (turning them into pustules). Ordinary smallpox generally takes one of two basic courses. In *discrete* ordinary smallpox, the pustules stand out on the skin separately—there is a greater chance of surviving this form. In *confluent* ordinary smallpox, the blisters merge together into sheets that begin to detach the outer layers of skin from the underlying flesh—this form is usually fatal. If a victim of ordinary smallpox survives for the course of the disease, the pustules will deflate in time (the duration is variable), and will start to dry up, usually beginning on day 28. Eventually the pustules will completely dry and start to flake off. Once all of the pustules flake off, the patient is considered cured.

In the other form of smallpox, known as hemorrhagic smallpox, an entirely different set of symptoms starts to develop. The skin does not blister, but it remains smooth. Instead, bleeding will occur under the skin, making the skin look charred and black (this is known as black pox). The eyes will also hemorrhage, making the whites of the eyes turn deep red (and, if the victim lives long enough, eventually black). At the same time, bleeding begins in the organs. Death may occur from bleeding (fatal loss of blood or by other causes such as brain hemorrhage), or from loss of fluid. The entry of other infectious organisms, because the skin and the intestine are no longer a barrier, can also lead to multiorgan failure. This form of smallpox occurs in anywhere from 3% to 25% of fatal cases (depending on the virulence of the smallpox strain).

Edward Jenner developed a smallpox vaccine by using cowpox fluid (hence the name vaccination, from the Latin *vacca*, cow); his first inoculation occurred on May 14, 1796. After independent confirmation, this practice of vaccination against smallpox spread quickly in Europe. The first smallpox vaccination in North America occurred on June 2, 1800. National laws requiring vaccination began appearing as early as 1805 [245]. The cowpox virus is still the immunogenic tool, dismissing, fortunately, the need to use the smallpox virus itself for vaccine preparation, as is the case with many pathogens. Compulsory vaccinations were increased, and the virus has been wiped out globally.

The last case of wild smallpox occurred on September 11, 1977. One last victim was claimed by the disease in the United Kingdom in September 1978, when Janet Parker, a medical photographer in the University of Birmingham Medical School, contracted the disease and died, and the Professor responsible for the unit killed himself. A research project on smallpox was being conducted in the building at the time, although the exact route by which Ms. Parker became infected has never been fully elucidated.

After successful vaccination campaigns, the WHO in 1979 declared the eradication of smallpox, although cultures of the virus were kept by the Centers for Disease Control and Prevention (CDC) in the United States and at the Vector Institute in Koltsovo, Novosibirsk in Siberia, Russia, where a regiment of troops guard it. Under such tight control, smallpox would, it was thought, never be let out again. All other known stocks of smallpox were ostensibly destroyed. Smallpox vaccination was discontinued in most countries in the late 1970s; the risks of vaccination include death (~1 per million), among other serious side effects.

Nonetheless, after the 2001 anthrax attacks took place in the United States, concerns about smallpox have resurfaced as a possible agent for bioterrorism. As a result, there has been increased concern about the availability of vaccine stocks. Moreover, President George W. Bush has ordered all American military personnel to be vaccinated against smallpox and has implemented a voluntary program for vaccinating emergency medical personnel. Vaccination is seriously being reconsidered over many countries. It is also feared that additional stocks of the virus may exist in research collections, the product of the accumulatory nature of microbiologists. Additional collections of the virus almost certainly exist as the result of certain military and biologicol warfare programs, particularly in Russia. Iran, Syria, Israel, China, North Korea, and Cuba have been mentioned as current possessors, as well. The possibility that the virus is currently being held by a terrorist organization has not been excluded.

In light of those circumstances, and considering the extremely undesirable possession of this virus by various countries—hence its expected migration to terror elements, as well—the final and complete destruction of virus stocks held anywhere, and particularly in the CDC and Vector, was ordered in 1993, 1994, 1995, and 1996, but they have not yet been destroyed in those two facilities. Yet the continuation of this actuality has been approved. The World Health Assembly has passed resolutions (WHA52.10) (WHA 55.15) authorizing temporary retention of the existing stocks of variola virus for the purpose of further essential research [246].

The program of research is overseen by the WHO Advisory Committee on Variola Virus Research, composed of members from all WHO regions and advised by some 10 scientific academic experts from such areas as public health, fundamental applied research, and regulatory agencies. Current reports are submitted to the World Health Assembly and are worth detailing due to the uniqueness of the topic at large, as follows.

Articles summarizing recent research overseen by the WHO Advisory Committee on Variola Virus Research

- Exploring the potential of variola virus infection of cynomolgus macaques as a model for human smallpox [pdf 564 kb] [247]
- The host response to smallpox: Analysis of the gene expression program in peripheral blood cells in a nonhuman primate model [pdf 897 kb] [248]

Abstracts summarizing recent research overseen by the WHO Advisory Committee on Variola Virus Research—2004

- Diagnostic Development at the CDC: Update 2004
- Inferring the Phylogeny of Variola from Genomic SNPs Analysis
- Variola Morphogenesis effected by an erb-B Tyrosine Kinase Inhibitor: Possible therapeutic functions
- The WHO Collaborating Center for Smallpox and other Poxviruses at the Centers for Disease Control and Prevention Atlanta: 2004 report on the variola repository [249]

Abstracts summarizing recent research overseen by the WHO Advisory Committee on Variola Virus Research—2003

- Analysis of Nucleotide Sequences of Individual Orthopoxvirus Genes
- Comparative restriction analysis of genomic DNAs of the variola virus strains from the Russian collection
- Human Combinatorial Antibodies against Orthopoxviruses
- Update on variola and orthopoxvirus diagnostic development and use
- Update on search for antivirals against human-pathogenic orthopoxviruses
- Viability estimation of variola virus isolates from the Russian collection [250]

Abstracts summarizing recent research overseen by the WHO Advisory Committee on Variola Virus Research—2002

- Capillary-electrophoresis restriction fragement length polymorphism. A new method for poxvirus fingerprinting [251]
- Cidofovir Treatment of Variola (Smallpox) in the Hemorrhagic Smallpox Primate Model and the IV Monkeypox Primate Model [252]
- Genome-wide analysis of the host response to variola infection [253, 254]
- Lethal infection of primates with variola virus as a model for human smallpox [255]
- New PCR assays for identification of smallpox virus [232]
- Variola virus genomics [256]

So far, so reasonable, perhaps. But a dangerous shift might have taken place. American scientists are now awaiting World Health Assembly approval to begin experiments to genetically modify the smallpox virus. Researchers have already been given the go-ahead by a technical committee (WHO Advisory Committee on Variola Virus Research), which accepts the argument that the research could bring new vaccines and treatments for smallpox closer. Still, in the debate during the full assembly of the WHO, whose representatives from 192 member states met from 16 to 25 May 2005, WHO said it will ensure that any research will only be conducted after detailed proposals have been thoroughly examined on a case-by-case basis by the Advisory Committee, paying particular attention to biosafety and biosecurity issues [257].

Some 200 tons of smallpox virus have been produced by the USSR as a weapon and inherited by Russia. Their fate is unclear. However, details of the development of smallpox as a weapon by the Soviets became available. A report was elicited from General Prof. Peter Burgasov, former Chief Sanitary Physician of the Soviet Army and a senior researcher within the BWP. Admitting that development of BW by the Soviets did take place, in the form of live field tests, he described a "smallpox incident" that happened in the 1970s, and was then hashed up: "On Vozrazhdenie Island in the Aral Sea, the strongest recipes of smallpox were tested. Suddenly I was informed that there were mysterious cases of mortalities in Aralsk. A research ship of the Aral fleet came 15 km away from the island (it was forbidden to come

any closer than 40 km). The lab technician of this ship took samples of plankton twice a day from the top deck. The smallpox formulation—400 gr. of which was exploded on the island—'got her' and she became infected. After returning home to Aralsk, she infected several people including children. All of them died. I suspected the reason for this and called the Chief of General Staff of Ministry of Defense and requested to forbid the stop of the Alma-Ata—Moscow train in Aralsk. As a result, the epidemic around the country was prevented. I called Andropov, who at that time was Chief of KGB, and informed him of the exclusive recipe of smallpox obtained on Vozrazhdenie Island" [258].

Actually, it was a new lethal strain of smallpox that traveled far and away from the island-based BW testing facility in the Aral Sea, to infect people downwind on a ship. Most of the adults exposed to the strain contracted smallpox despite being immunized. Promptly, remarkably extensive countermeasures, including vaccination, disinfection, and quarantining were conducted [259].

In March 2003, smallpox scabs were found tucked inside an envelope in a book on Civil War medicine in Santa Fe, New Mexico [260]. The envelope was labeled as containing the scabs and listed the names of the patients that were vaccinated with them. Assuming the contents could be dangerous, the librarian who found them did not open the envelope. This was fortunate, as unlike bacteria (with the exception of those that produce spores), viruses can theoretically survive for many years. The scabs ended up with employees from the National Center for Disease Control, who responded quickly once in-formed of the discovery. The discovery raised concerns that smallpox DNA could be extracted from these and other scabs and used for a bioterrorism attack.

Nevertheless, the chances of successfully doing that seem to be slim, for now. Notably, Ramses V, who lived some 3000 years ago, is the earliest known victim of smallpox, based on an analysis of his mummy [261]. Many virus-like particles were revealed by electron microscopy and identified serologically as smallpox virus in a 400-year-old mummy from Italy. The antigenic structure of the particles was well preserved [262]. The virions in the mummy's skin had lost their viability. Viral antigen was not be detected by EIA or RPHA, and its DNA was not detected by molecular hybridization [263]. Attempts to recover the virus from the frozen bodies of persons who died of smallpox continue in Arctic sites in Siberia [264], and in Canada [265].

The *Variola major* virus is very stable and survives in exudates from patients for many months. The virus is unlikely to survive in dried crusts for more than a year [266]. Yet, it can be preserved in sealed ampules at 4°C for many years, and indefinitely by freeze-drying. This leads to the presumption that the virus still may be preserved alive within bodies of victims buried in permafrost. Much more feasible, however, the practical employment of smallpox virus for bioterrorism purposes is remarkably worrisome and reckoned to be a prime threat.

The current, perpetual phase along the smallpox virus course is facilitated, in effect, by an informal Russian–American status quo, one that has virtually been established lately, acknowledging the nontermination of BWs, for the time being. In a sense, the cardinal, unsolved issue of the smallpox virus constitutes an illustrative reflection of that much broader, not as yet untied, tangle. Sheltered by seemingly acceptable justifications of essential ongoing research into the most dreadful pathogen of mankind is thus still being kept in Russia, the United States, and most

likely, some other places. It perfectly symbolizes the bivalent potential of further, extremely ominous pathogens held, militarily, by Russia and additional states. In Russia, it is retained, probably, as a stockpiled weapon, alongside with an arsenal of various pathogens and toxins. The argument that full acquaintances with pathogens reckoned as BWA—and, likewise, with their aggressive attributes, in terms of bioterrorism threats—are necessary for achieving effective protection, is a very reasonable one, and may hardly be debated. It is therefore, objectively, a salient dual-purpose factor; particularly as engineered pathogens and bioterrorism menaces are becoming common. Concurrently, and perhaps genuinely, this attitude is applied within the U.S. Army as defensively oriented "bioprofiling" [202]. At any rate, the U.S. Army Medical Research Institute of Infectious Diseases, at Fort Detrick, has accumulated "credible evidence" that several terrorist groups and nations have obtained, or are trying to obtain, clandestine stocks of smallpox and are actively trying to produce weaponized armaments based on the virus [267].

Connectedly, an international exercise in dealing with a series of international terrorist attacks involving smallpox virus has shown that the impact would be catastrophic for almost the entire world, and that the lives of millions of people could be lost. This outcome of the "Atlantic Storm" session seems all the more alarming given all the measures taken to combat bioterrorism since the 2001 anthrax letters attacks [268]. The fictitious scenario of "Atlantic Storm" centered on a wave of attacks with the smallpox virus. The exercise was held at a hotel in Washington, D.C., with some 150 observers present to see how 11 former government officials and leaders of inter-governmental organizations, all with the necessary experience, would deal with such a calamity.

13.4.20 AGROTERRORISM

The essence and characteristics of agricultural terrorism (agroterrorism) are presented. Reference is here made to infective agents only, meaning pathogens of farm animals and cultivars. Mention is not made here of bioterrorism warfare agents common to man and animals, such as anthrax (those are discussed above). Accordingly, various episodes of agroterrorism that took place since WWII are reveiwed.

Agroterrorism is the deliberate introduction of pathogens or chemicals (toxic/radioactive), either against livestock or crops, for the purpose of causing economic losses, undermining stability and/or generating fear. The direct impacts are economical, logistical, and demographical (up to hunger). Agroterrorism may be conducted in the form of state-sponsored or nonstate-sponsored acts. The outcomes show in the form of epizootics (animal epidemics) or epiphytotics (plant epidemics).

The United States, the USSR, Germany, Iraq, and Iran. foremost, are known to have had programs that included potential agroterrorism pathogens (in Russia and Iran, at least, this inheritance presently persists), as follows:

United States: The viruses causing fowl plague (epizootic avian influenza), rinderpest (cattle plague), hog cholera (swine contagion), and Newcastle disease (poultry contagion), plus late blight of potato fungus, were explored by the United States as candidates for agroterrorism. Weaponized have been the

fungal causative agents of wheat rust and rice blast [269], making the former, explored ones, of no less importance. A wealth of British scientific experience has thereupon been exploited by the US. One salient finding has been in that 3 g of the rice blast fungi per hectare could infect between 50% and 90% of the crops exposed [270]. Other fungal agents evaluated—in that case against drug crops, mainly poppy and coca fields—were *Fusarium oxysporum* and *Pleospora papaveracea*.

Germany: Explored: foot and mouth disease, potato beetle, potato stalk rot, potato tuber decay, wheat fungus, turnip weevils and antler moths.

USSR: Explored: African swine fever virus, rinderpest virus, and the fungi casing wheat stem rust and rice blast [271]. An uncertain part of those pathogens have been weaponized, plus, apparently, cow pox and sheep pox viruses [272].

Iraq: Explored: sheep pox, goat pox, camel pox, and foot-and-mouth disease viruses; wheat smut and cereal rust fungi. Weaponization of the fungus causing weat smut has been evidenced [30].

Iran: Rinderpest and foot-and-mouth disease viruses, as well as crop fungal pathogens apparently have been explored and possibly weaponized [273].

Those lists exhibit, basically, the severity of agroterrorism, although principally the spectrum of potential agents is much broader. Thus, mention should be made, in addition, of some further examples. For instance, a 2005 GAO report accentuates the special significance of Asian soybean rust [274]. In an experts meeting “Biosystems and Bioterrorism: Can Arthropods Be Used as Agents of Destruction,” the immense importance of arthropods as disease disseminators has been pointed at, with reference being made, among other, to the glassy-winged sharpshooter scare, the Mediterranean fruit fly and the potential for Tsetse and Trypanosomosis reinfestation or establishment in free areas [275].

Illustratively, the devastating New World screwworm fly, regarded to be the most serious insect pest of cattle in the New World, appeared for the first time in the Old World in Libya, during 1988. It aroused, justifiably, great fear, and the countermeasure conducted was an act of biological warfare in itself, namely the sterile male technique: from December 1990 and until October 1991, sterile male flies at the rates of 3.5 building up to 40 million per week were released so as to suppress the fertile male invaders [276]. The release of sterile flies was terminated 6 months after the last detected case of screwworm myiasis in Libya. Notably, Libya accused the United States of intentionally delivering the initial, reproductive pest, although it was the Mexican-American Commission for Eradication of Screwworms that thereafter carried out the eradication campaign.

Peculiarly, an outstanding agroterrorism-related interface evolved between Cuba and the United States. Cuba has blamed the United States for attacking Cuban crops and livestock on as many as 21 different occasions. According to Raymond Zilinskas, of the few incidents for which information is available, agents include Newcastle Disease (1962), African wine sever (1971, 1979–1980), Tobacco Blue Mold Disease (1979–1980), Sugarcane Rust Disease (1978), and Thrips insect infestation (1997). Only in the case of the Thrips did Cuba make a formal complaint. According to the Cuban account, the United States flew a crop-duster

operated by the State Department over Cuba and released the insects. The United States has denied the allegation, and while U.S. agriculture experts discount Cuban claims, the United Nations has undertaken an investigation. Considering the above-mentioned information on the U.S. programs as presented in this section and the Section 13.4.15.3, there is support for some Cuban allegations. Yet, according to Zilinskas, the most likely explanation for all these incidents was nature or accidental human transmittal through commerce [5]. Connectedly, a Florida university professor informed the CIA that a Florida citrus canker outbreak was the result of a Cuban bioterrorism weapons program. Although the CIA could not substantiate the claim, it did investigate the case. During that same time period, Cuba claimed that an outbreak of Thrips Palmi disease on the island was bioterrorism warfare introduced by the United States [277]. Apparently, no final conclusion can be reached concerning those issues.

At any rate, the Cuban file was not the only one within the context of agroterrorism affairs. Since 1915, a variety of agroterrorism-related incidents have taken place, worldwide [278], and included, mostly, the following events involving animal and plant pathogens/toxins:

Richard Ford, a prominent British naturalist, has made the accusation that Germany dropped Colorado Potato Beetles on the United Kingdom during WWII, accounting for their unusual appearance in parts of the United Kingdom. According to Ford the bombs were made of cardboard and contained 50 to 100 beetles. The allegation has not been verified or refuted.

In a Ministry of Forestry report dated June 15, 1950, the East German government accused the United States of scattering Colorado Potato beetles over potato crops in May and June of 1950 [279, 280].

The Mau Mau, a nationalist liberation movement, poisoned some 33 steers at a British mission station, using what is believed to be a local toxic plant known as "African milk bush" [281–285].

Ken Alibek, First Deputy Chief of the Russian Biopreparat system, alleged he was informed by a senior Soviet military officer that the Soviet Union attacked the Afghan Mujaheddin with glanders on at least one occasion. According to Alibek, this would have the dual effect of sickening the Mujaheddin and killing their horses, their main mode of transportation [120, 280, 286].

Sometime from 1983 to 1987, a Tamil militant group threatened to use bioterrorism agents against Sinhalese and crops in Sri Lanka. The communiqu' threatened to introduce foreign diseases into the local tea crop and to use Leaf Curl to infect rubber trees [287–290].

Queensland's State Premier received a letter threatening to infect wild pigs with foot-and-mouth disease (FMD), which was feared might spread to cattle and sheep, unless prison reforms were implemented within 12 weeks. Ultimately, this incident proved to be a hoax as the perpetrator turned out to be a 37-year-old murderer serving a life sentence in a local jail. In December 1984, Queensland's premier received a similar letter from an unidentified individual [120, 280, 286].

An outstanding pattern emerged regarding the spread of the Mediterranean fruit fly, a major threat to agriculture in California, in 1989. Despite heroic attempts to eradicate this insect, new infestations repeatedly appeared in odd and unexpected places. Concomitantly, the Mayor of Los Angeles received several letters from a group calling itself The Breeders, which claimed to be spreading the insect to protest California's agricultural practices [287–290].

In 2003, Israel has been blamed for spreading foot-and-mouth disease in the Palestinian Authority territory [291, 292].

It so happened that the majority of antihuman bioterrorism agents are basically and currently pathogens of animals, making them zoonotic. The sense lying in that phenomenon is in that, naturally, those pathogens rarely infect humans; hence human herd immunity against them is marginal, bringing about considerable vulnerability. Some of those zoonotic pathogens are important as both antihuman and anti-animal agents, like Rift Valley fever, epiornithic avian influenza ("fowl-plague"), glanders, anthrax, and brucellosis. They are potentially usable for both agro-and bioterrorism. But another class of pathogens includes specifically livestock attackers. The FMD virus is seemingly their best representative. It is, indeed a formidable agroterrorism agent.

It was again, thus, a viral epidemic—rather an epizootic—this time belonging to the category of livestock attacking agents, which exhibited the aggressiveness of an agroterrorism-patterned course, in that case—the FMD virus. Although very rarely infective toward humans, it is extremely contagious and virulent for mammalian farm animals. It is therefore a prime candidate for agricultural bioterrorism and a very effective one.

Great Britain was the arena, 2001. Despite a single outbreak of FMD in cattle on the Isle of Wight, Hampshire in 1981, there had been no outbreaks of FMD in Great Britain since 1968, until 2001. On 20 February 2001 an outbreak of FMD caused by the O1 Pan Asia strain of virus was confirmed in pigs in an abattoir in Essex. The source of the infection was traced to a pig unit in northeast England where disease was believed to have been introduced at the beginning of February. The provenance of the causative agent could not be identified. Deliberate introduction has not been ruled out. Sheep on a neighboring holding became infected by airborne spread from the pig unit. These sheep were subsequently moved through markets in Northumberland and Cumbria between 13 and 22 February 2001. Disease was then disseminated to many other parts of Great Britain and Northern Ireland as a result of movements through markets and dealers before the existence of disease in the country was recognized. Notably, between 20 February and 30 September 2001, a total of 2025 apparently resultant FMD outbreaks were confirmed in Great Britain; a further 4 were confirmed in Northern Ireland. Over 4 million animals were killed as part of the FMD control program. The epidemic was essentially sheep based, other classes of livestock becoming infected through direct contact with infected sheep or through the movements of people, vehicles, and fomites [293].

The impact of the epidemic was colossal. The overall economic costs in the food and farming sectors of the U.K. economy totaled an estimated £5 billion, roughly $10 billion [9]. This figure compares with an annual gross output of the entire U.K. agricultural sector of £25 billion [10]. The U.K. economy suffered other economic costs associated with the outbreak of FMD. Outside the agricultural sector costs, the United Kingdom endured additional losses to the leisure and tourism sector of the economy. The U.K. Department of Environmental Food and Rural Affairs estimated that the leisure and tourism sector of the economy lost £5–6 billion pounds as a result of the outbreak of FMD in 2001 [11].

Finally, an image of a list of livestock diseases found in a cave in Afghanistan was used as evidence that terrorists are considering attacks on agriculture. It has been accentuated, in connection, that there are many operatives that were planning such acts [180].

13.4.21 NARCOTERRORISM

The nature and specific features of narcoterrorism are discussed. Various connotations of narcoterrorism, which are compatible or concerned with biosabotage-related activities, are presented. The main terrorist organizations involved in narcoterrorism worldwide are outlined.

Primarily, narcoterrorism is a term coined by former President Belaunde Terry of Peru in 1983, when describing terrorist-type attacks against his nation's antinarcotics police. In the original context, narcoterrorism is understood to mean the attempts of narcotics—actually, recreational drugs—traffickers to influence the policies of government, the enforcement of the law, and the administration of justice by the systematic threat or use of violence. Pablo Escobar's ruthless dealings with the Colombian government is probably the best known and best documented example of narcoterrorism [296].

The term has become a subject of controversy, and it is being increasingly used for known terrorist organizations that engage in drug trafficking activity to fund their operations and gain recruits and expertise. Such organizations include, mainly, FARC, ELN, and AUC in Colombia, Hezbollah in Lebanon, and al-Qaeda throughout the Middle East, Europe, and Central Asia. Although al-Qaeda is often said to finance its activities through drug trafficking, the 9/11 Commission Report notes that "While the drug trade was a source of income for the Taliban, it did not serve the same purpose for al Qaeda, and there is no reliable evidence that Bin Laden was involved in or made his money through drug trafficking."

Although financial considerations seem to be the leading ones, narcoterrorism is often marked, substantially, by a constant attempt to sustain and enlarge the proportion of drug consumers in a given target population, hence weakening the latter physically, mentally, and economically. In that sense, it is indeed a sort of terrorism. But beyond the direct effects of narcoterrorism, it is very meaningful, although secondarily, in that it greatly facilitates the ongoing spread of blood-transmitted pathogens, such as AIDS and hepatitis, having their own significant and demographic attritional impact.

Moreover, usually the drugs consumed by narcomans are in fact psychotropic plant toxins: heroin, cocaine, opium, hashish, marijuana, and so on. Narcoterrorism is often based on massive cultivars of the related plants that are currently being overseen by the concerned terror organization, namely self-production of the involved hallucinogenic phytotoxins thereafter consumed by narcomans. In addition, the terrorists engaged in producing those phytotoxins accumulate the know-how and experience needed, basically, for the manufacturing of typical plant toxins, such as ricin, aconitine, and other potent ones. Chemical refinement is often essential. Also, the financial, technical, and logistical infrastructures involved in drug trading may be appreciably supportive of narcoterrorism, bioterrorism, and agroterrorism altogether. Like agroterrorism, narcoterrorism may be regarded, thus, as an additional variant of bioterrorism, although rather of a different sphere.

Most (more than half, certainly) of drug consumption worldwide is fueled by directed narcoterrorism. Some terrorist groups, like Colombia's FARC, collect taxes from people who cultivate or process illicit drugs on lands that it controls; others, including Hezbollah and Colombia's AUC, traffic in drugs themselves.

Moreover, some terrorist groups are supported by states funded by the drug trade; Afghanistan's former Taliban rulers, for instance, earned an estimated $40 million to $50 million per year from taxes related to opium. The drug trade is also a significant part of the economies of Syria—which has funded terrorist organizations such as Hezbollah, the Popular Front for the Liberation of Palestine-General Command, and Palestinian Islamic Jihad—and Lebanon, a haven for numerous terrorist groups including Hezbollah and Hamas [297].

The drug trade is extremely lucrative. Heroin, cocaine, and marijuana are uncomplicated and cheap to produce, but because they are illegal and therefore risky to supply, they can earn more than their weight in gold on the vast international black market. The United Nations estimated that the illicit drug business generates about $400 billion per year. Also, because the drug trade is secretive, terrorists can amass large sums of cash without being detected by authorities.

The terror organizations involved in narcoterrorism at large are mostly the following ones [298]:

- The Revolutionary Armed Forces of Colombia (FARC), a Colombian leftist group, which raises funds by taxing coca farmers in the Switzerland-sized zone of the country it controls. Experts say FARC may force peasant farmers to grow the coca used to make cocaine. It also makes money by protecting cocaine laboratories and clandestine airstrips and by trafficking in drugs locally.
- The National Liberation Army (ELN), another Colombian leftist group, taxes growers of marijuana and opium poppies and protects drug-lab operations. But it generates far less of its funding from drugs than does FARC.
- The United Self-Defense Forces of Colombia (AUC), which includes several right-wing paramilitary groups, says it gets 70% of its income from processing and exporting cocaine. It claims to be leaving the drug business, but experts doubt that all of its members will comply.
- Remnants of Shining Path, a Peruvian leftist group, finance some operations by "protecting" cocaine smugglers in jungle areas under its control and by taxing the coca trade.
- Some members of the Liberation Tigers of Tamil Eelam, a Sri Lankan separatist group, traffic in heroin, and the group reportedly has close ties to drug-trafficking networks in nearby Burma.
- Hezbollah smuggles Latin American cocaine to Europe and the Middle East and has smuggled opiates out of Lebanon's Bekaa Valley, although poppy cultivation there is declining.
- The Kurdistan Workers' Party (PKK), a Marxist separatist group based in Turkey, taxes ethnic Kurdish drug traffickers, and individual PKK cells traffic in heroin.
- The Real IRA, an Irish Republican Army (IRA) splinter group that opposes the peace process in Northern Ireland, is suspected of trafficking drugs, although the extent of its involvement is unclear.
- Basque Fatherland and Liberty (ETA), a separatist group in Spain, is reportedly involved in drug trafficking.

- al-Qaeda does not appear to have direct links to the drug trade. But its former protector in Afghanistan, the Taliban, supported itself in part through opium poppy production and trafficking.

Chaotic countries constitute warm nests for narcoterrorism. Drug traffickers and terrorists tend to thrive in failed states with ineffective governments that have been destabilized by war and internal conflict, experts say. For example, Colombia—a large, fragmented country in the throes of a decades-long conflict over power and resources—produces 80% of the world's cocaine and 70% of the U.S. heroin supply. Lebanon has been plagued by drug traffickers and terrorist groups since its own harrowing 15-year civil war began in 1975. In Afghanistan, the 1990 retreat by occupying Soviet troops left the economically devastated country vulnerable to control by warlords and Islamist extremists. Furthermore, by promoting violence, tax evasion, and lawlessness, terrorists and drug traffickers make it harder for a weakened state to form a stable central government. All in all, the magnitude of narcoterrorism is a remarkable one, and coping with it is difficult and complicated. Narcoterrorism is, in a sense, a long-term attritional mode of terrorism. It is unlikely to diminish, and the main way to effectively struggle against it is expediently to remove the drug producing cultivars themselves. Significant achievements were thus reached by mass employment of fungi that specifically attack those cultivars: cocaine plantations in Columbia and opium plantations in Uzbekistan—a sensible mode of biological warfare by itself.

Paradoxically—yet sensibly, by all means—vast narcoterrorism cultivars were eliminated by agroterrorism-like warfare launched in the last decade, including the effective use of specific fungi capable of destroying poppy fields in Uzbekistan and coca fields in Columbia.

13.4.22 NOVEL AGENTS

Novel biological agents constitute a category of enormous interest, in many senses. It is apt to chiefly be pronounced in terms of paradigmatic combat power multipliers on the one hand, and plain bioterrorism parameters, on the other hand. Reference is made, however, to the inability of terrorist organizations to develop or acquire novel bioterrorism agents, unless extraneously assisted.

A combat power multiplier is defined, primarily, as a warfare element sufficient enough to balance a quantitative inferiority of troops. This concept bears, however, a broader meaning in the context of strategy and military affaires. In these areas, the power multipliers have greater and more complex implications, starting with terror attacks and ending in an overall geopolitical power balance at its highest level, such as international pacts as we saw in the rivalry between NATO and the Warsaw pact.

The future battle field is absorbing, tentatively, a variety of multifunctional technologies. So, the sheer importance of these power multipliers is less in balancing the quantity disadvantage and more as a pragmatic method to decrease the number of the fighting corps (order of battle). Connectedly, a unique range of action is dedicated to biological, chemical, and radiological guerilla warfare tech-

nologies, both terrorism-oriented and military-oriented. This section will discuss these technologies and their ramifications at the macrolevel, within the biological sphere, synthetic biology being, thereby, the chief platform.

13.4.22.1 Anti-Organism Power Multipliers

Anti-organism power multipliers are based on technologies designed to harm humans, farm animals, or cultivars, whether during offensive, defensive, or calm situations. Although the new generation of these power multipliers is characterized by nonlethal (or sublethal) weaponry, some of them are distinctively lethal.

This new generation include:

- Novel toxins
- Bacteria and viruses in a supremely engineered condition

Toxins are being upgraded as power multipliers. This being the case, through the following biotechnological featuring:

- Molecular design, avoiding or decreasing the body ability to activate an immunological response
- Molecular design that reinforces their toxicity
- Embedding coded genes (regarding protein toxins) in noncontagious bacteria and turning these into "production lines"
- Embedding coded genes in contagious bacteria and viruses and making these even more harmful

The range of toxins designed to perform as power multipliers is vast. Here are two examples, representing both ends of the spectrum: The Pepper spray and the group of agents called "Prions."

The Oleoresin Capsicum (OC) called "the Pepper spray" can be naturally found in hot chilies. The OC has been recently found as more efficient than the common police incapacitating agents, because it causes a faster and longer lasting reaction. The spray can be used for on-spot or wider purposes. Simultaneously, the "Pepper gel" was also developed. This gel is launched from its container by air-pressure; when contact occurs, the gel clings to any surface (if it touches the face, it may cause temporary blindness). The gel formula contains 10% of OC mixed with the gel. The gel is not flammable [299].

Prions, on the other hand, are extremely destructive protein molecules. They are the cause of "Mad Cow Disease" (Creutzfeldt–Jacob Disease). The prions are infectious molecules, which means their penetration to the body brings about normally functioning proteins that turn into abnormal proteins like themselves. The infection-like condition they cause is developing slowly but deadly. They are host-specific. The research of prions, chemically and biologically, is in progressive process and some see them as one of the future measures designed to target a specific civil population for long-term influence. Some prions harm a variety of farm animals [300].

13.4.22.2 Supremely Engineered Bacteria and Viruses

Genetic engineering is intruding this field, in two main ways:

- The probability of finding gene fragments of highly virulent extinct pathogens is more likely than finding the complete genome and succeeding to revive it. At any rate, an intervention of genetic engineering is necessary to reconstruct and assemble the genome so it can imitate the natural pathogen as a living-reproducing system. In that manner, the polio virus has been recently produced, out of the blue, in laboratories. Similarly, the devastating 1918 "Swine Flu" virus has lately been reconstructed and resurrected.
- The ability of the defender to immunize its population even against the most virulent variants forces the offender to engineer them so immunity will turn out as ineffective.

Genetic engineering is covering far more than those two just mentioned, by creating different and sophisticated power multipliers. The current front in genetic research is promising great achievements for the medical treatments of humans, animals, and plants disease by what is referred to as gene therapy. But, a military aspect of this research also exists. This aspect permits a new form of bioterrorism warfare to take place—genetic warfare. An unavoidable outcome is the discussion on how to use these methods of genetic treatment as a weapon: how to deploy these weapons of genetic warfare and how it is possible to expose the deployment of these weapons [301].

In his futuristic–realistic article, Mark Willis predicts the appearance of the biological genetic-engineered warfare agents according to the following criteria [302]:

- Synthetic viruses
- Cellular pathogens bearing unusual virulence
- Cell-like synthetic entities that cannot reproduce, as vectors of biochemical warfare agents
- Dormant and secret pathogens
- Pathogens specific to farm animals and agricultural vegetation
- Pathogens specific to ethnic groups
- Long-lasting or delayed-effect biological warfare agents
- Ethnic pathogens that can cause autoimmune diseases such as infertility

In practice, at the last decade, we saw the use of specific fungus able to destroy poppy fields in Uzbekistan and coca fields in Columbia. In future perspective, there is no doubt that this is just the tip of the iceberg.

13.4.22.3 Anti-Inanimate Object Power Multipliers

Anti-inanimate object power multipliers are derived from technologies aimed to harm, disrupt, or jam weapon systems or other valuable assets. They can be implemented during times of offense, defense, and calm. In this context, power multi-

pliers designed to contaminate water or food sources will not be regarded as an anti-inanimate object power multiplier because water and food are used, in that case, to attack humans, serving as vehicles. To our discussion, mention is made, then, of bacteria that can be fed from key materials, naturally or genetically engineered. That includes [303]:

- Plastic, like polyurethane (for example, digesting and removing the special cover enables specific aircrafts to reduce their radar signatures, and by that allowing their detection)
- Rubber, steel, and paint used in strategic and logistic facilities
- Asphalt used in runways
- Crude oil and petrol

13.4.22.4 Bioengineering Availability

This ethical–technological entanglement has begat a discussion, both locally and globally, concerning increasing or reducing bioengineering availability of the power multipliers being discussed. That, while the freedom of information principle, universal communication interfaces, and the natural curiosity of different scientific circles are taking their place and diverting the reality toward a constant increasing technology availability at large. The fact that a lot of these novel agents are defined as nonlethal (ethical, so to speak) and antiriot countermeasures is contributing to this trend. This trend is also encouraged by the involvement of a university's laboratories in the military R&D process. Those universities, especially in Western countries, mostly get the publication they want.

The latest developments in the fields of political and strategic thinking regarding the use of existing or developing weapon systems (including nonlethal biological weapons) and the ramifications over the operational doctrine in the context of the contemporary trends in the international relations are very significant [304]. This last publication maintains that the alleged revolution of the military-technology affairs has to be considered in light of discussions on military use of nonlethal weapons in existing and future conflicts. The issue is presented from a political-strategic point of view, criticizing the revolution in military affairs as a starting point in the discussion on the use of nonlethal weapons during conflicts. These issues are presented to politicians and strategic analysts asked to formulate a technology-based policy that may be used in future political/social conflicts. The danger of neglecting other important dimensions in politics and strategy, emphasizing the "force to force" aspect, are considered.

Most of the scientific and technological developments mentioned here are openly reported and documented in the United States, which is probably the world leader on these subjects. Russia is, probably, not far behind, but seems to lessen the publishing of this domain. The Russian BWs are very advanced [305], and Russia also puts a lot of effort in biological espionage, trying to get its hands on relevant knowledge and technological means [306].

At large, the global research for upgrading biological power multipliers is striving to develop:

- New measures: both new categories and new means included in already known categories.
- Measures that although they are known, the enemy will not be able to detect, identify, and handle. That may happen due to objective-inherent technological limitations (in such case, then, measures that have to be activated from a far, with no offender presence) or by using a known technological weakness the enemy suffers from.
- Measures that will complicate the enemy's ability—military demogrophical, or economical—significantly and even decisive, although known by the enemy.
- Specific measures designed against a given rival, affecting his military forces, population, or assets uniquely.

The range covered by these new agents is amazing by both its extent and its intensity, starting with incapacitating agents like Pepper spray and ending, hypothetically for now, with ethnical weapons, targeting specific races only. Not in vain, these two examples represent, even if superficially, derivatives of two powerful, inexhaustible technologies—molecular biology and genetic engineering. So, the Pepper spray is becoming a more favorable substitute to the regular tear-gases, being a molecular copy of the biological extract in the hot Mexican chile. So, the biological-ethnic weapons—whose mechanism is using specific genetic elements in the target race or nationality—are conceivably prone to be the unavoidable outcome of highly complex genetic mechanisms, being deciphered by man.

Toxins can be produced in three alternative methods:

- Extracting it from a natural source (the classic mode)
- Chemically synthesizing the biological molecule, after its full and accurate identification
- Producing it by a gene able to code for it (when it is a protein molecule)

The range of scenarios, where the novel agents discussed can be used is vast, in any parameter:

- Activation by state or terror organization, if only by an individual (that can also be sent by state)
- Activation in a concealed or open manner
- Activation in order to achieve an affect in the short, medium, or long range
- Activation during a military conflict or during an international nonmilitary conflict
- Activation against humans, animals, plants, or still objects
- Activation at times of offense, defense, or at calm

Any combination of the parameters or the subparameters is possible.

Today and in the near future it is not expected that the availability of sophisticated biologically engineered power multipliers will proliferate. It will probably be an asset of few supremely qualified laboratories. However, with time they will

become more and more accessible, presumably. With no connection to the BW agents that the Iraqi government has produced in its time (undoubtedly, industrial amounts), it is appropriate to mention two agents reflecting an unusual way of thinking suiting aspects aforementioned, although on an embryonic level [30]:

- Camel poxvirus—a pathogen that can attack humans, but not those who live next to camels and so are naturally immune. The Iraqis have also used this virus as a model to the small pox virus.
- The fungal toxin aflatoxin, which generates terrible diseases, but only on the long term (was apparently destined to be used against the Kurds in Iraq).

In Russia, or elsewhere, chimeras of VEE-smallpox virus, Ebola-smallpox virus, and snake-toxin-gene-bearing influenza virus have possibly been developed successfully, but this has not been verified or refuted.

Furthermore, it was recently argued that advances in nanotechnology could be used in the development of new types of biological (and chemical) weapons, based on the dual-use application of nanotechnology in the fields of biotechnology and medicine, which can be used for offensive purposes. Such a potential military application of nanotechnolgoy could undermine existing international laws that ban biological weapons [307].

To sum, the technological absorbability (of a country) is indeed the cardinal factor, but it is not sufficient for these frontline technologies to be adopted (even more so—for their upgrading) by one. But mention is made of the option that hostile countries or organizations can get their hands on standardized, instantly usable, weapons. The discussed novel agents are very sophisticated, and so transferring, maintaining, and operating them may be very complicated. However, it is possible that hostile elements will get extraneous assistance at these aspects as well. Particularly, a great deal of these weapons includes, so-called, nonlethal and anti-inanimate agents, hence more obtainable.

Referring to the increasing threat of novel bioagents, Steven Block, former president of the Biophysical Society, was quite pessimistic: "The biological weapons threat is multiplying and will do so regardless of the countermeasures we try to take. You can't stop it, any more than you can stop the progress of mankind. You just have to hope that your collective brainpower can muster more resources than your adversaries [308]."

13.4.23 EXPLOITABILITY OF BIOTECHNOLOGY AND BIOMEDICINE

The vast space inevitably formed by biotechnology and biomedicine, in terms of dual usability, is briefly presented. Its affinity to bioterrorism-oriented activities is shown, with regard to both pathogens and toxins. Two prominent toxins—botulinum and ricin—are thereby visited, to accentuate the scarcely observable borderline lying in between legitimacy and illegitimacy.

Apparently, the dual usability marking the fields of biotechnology and biomedicine, namely their capacity to serve for desirable and undesirable purposes at the same time, is the most extreme one, comparing with almost any other scientific

domain. A relatively simple instance of this: the undisputable need to thoroughly understand the mechanisms underlying the above-described alternating profile of drug resistance of *Vibrio cholerae* potentially enables, in parallel, the creation of a multistable pathogen. The shift is fairly slight, if any.

Fundamentally, all categories of biomedicine targeted at infectious diseases—antibacterial and antiviral drugs, vaccines, and antisera—as well as gene therapy are apt to be exploited for improper development, parallel to their impressive, invaluable advancements. Moreover, regretfully, a principle of "amplified reversibility" underlies the undesired, yet inevitable, usability of biomedicine and bioengineering resources for the purpose of bioterrorism. That is to say, although most pathogens and toxins have found a way to become harmless and beneficial, thanks to the scientific comprehension gained from their usefulness in various respects, that very paved course may readily be reciprocal; in particular their road back to pathogenicity and virulence—often appreciably amplified, artificially—may take place in the form of accidental leakage or bioterrorism acts.

In pragmatic terms, two dimensions of exploitability can be observed: One is the general modularity of equipment and materials that can equally be employed for innocent or bioterrorism-oriented activities. The other one is the various untainted activities currently engaging specific pathogens and toxins that are reckoned, at the same time, as potential agents for bioterrorism; hence, they are prone to undergo, in principle, a turnover at the level of intentions and practice of their possessors. Thus, the harvest of a seed virus propagated for subsequent production of a vaccine by attenuation may equally be kept as is, before attenuation takes place, serving as a weapon. In actuality, the two courses are not in contrast with each other; hence, they may expediently be applied in parallel, in whatever proportions the possessor chooses, so as to attain effective camouflage.

The principle is fairly plain, even an old one. In 1939, the active ingredient of curare—an ancient plant toxin weapon still in use by Indians—was isolated for the first time. In 1943, it was introduced successfully into anesthesiology. Curare provided adequate muscle relaxation without the depressant effect of deep anesthesia induced by ether or chloroform. Over the last 20 years, physicians have used curare to ease the stiffened muscles caused by polio and to treat such diverse conditions as lockjaw, epilepsy, and cholea (a nervous disorder characterized by uncontrollable muscle movements). Eventually, more effective treatments were found for these illnesses, but the active ingredient of curare, d-tubocurarine, led to the skeletal muscle relaxant Intocostrin, which has been used in surgery ever since. Synthetic analogs of d-tubocurarine are used tens of thousands of times per day in the operating room [309].

Tubocurarines reflect, yet, but one, relatively marginal example of the dual exploitability of biotechnology and biomedicine. Ricin toxin and botulinum toxin are more actual agents, as shown. Global castor seed production for civilian purposes is around 1 million tons per year. The beans are widely used for the production of castor oil, making their control impossible, practically. The castor oil manufacturer may readily use the remains of the beans for obtaining ricin. Moreover, ricin in itself is typically a dual-use substance.

Because of its cytotoxic potency, modified ricin is being used for the selective killing of unwanted cells and for the toxigenic ablation of cell lineages in transgenic organisms. Ricin is the most commonly used toxin in conjugates for selective cell

killing, so-called targeted toxins. Beneficial uses of ricin include, potentially the treatment of cancer and AIDS. Recently, there is, indeed, increasing interest in the medicinal applications of ricin as immunotoxin, which have been successfully applied in several human diseases. In addition, the mole-cule of ricin in itself is the precursor for the preparation of toxoid and anti-serum.

Ricin can be targeted to specific cells, such as cancer cells, by conjugating the RTA subunit to antibodies or growth factors that preferentially bind the unwanted cells. These immunotoxins have worked very well for *in vitro* applications, e.g., bone marrow transplants. Although they have not worked very well in many *in vivo* situations, progress in this area of research shows promise for the future. In bone marrow transplant procedures, RTA-immunotoxins have been used successfully to destroy T lymphocytes in bone marrow taken from histocompatible donors. This reduces rejection of the donor bone marrow, a problem called "graft-vs-host disease" (GVHD). In steroid-resistant, acute GVDH situations, RTA-immunotoxins helped alleviate the condition. Also, in autologous bone marrow transplantation, a sample of the patients own bone marrow is treated with anti-T-cell immunotoxins to destroy malignant T cells in T-cell leukemias and lymphomas [310]:

For the *in vivo* treatment of solid tumors, considerable problems can arise due to poor access of the immunotoxin to the tumor mass, lack of immunotoxin specificity, and further disadvantages. Still, research efforts to expand and develop immunotoxins and therapies for clinical use in cancer and AIDS are continuing with strategies using recombinant DNA technology [311]. On the whole, the following examples of recent studies may be noted: Oncologic applications: Immunotoxin treatment of brain tumors; cytotoxins directed at Interleukin-4 receptors as therapy for human brain tumors; bispecific monoclonal antibodies for the targeting of type I ribosome-inactivating proteins against hematological malignancies; tyrosine kinase inhibitors against EGF receptor-positive malignancies; targeting tumor vasculature using VEGF-toxin conjugates; and gene therapy with immunotoxins. Alternative applications: effects of selective immunotoxic lesions on learning and memory; targeting toxins to neural antigens and receptors; *in vivo* testing of anti-HIV immunotoxins. All in all promising, apparently, but yet legitimating the access to purified ricin.

Botulinum toxin constitutes another notable case. The most poisonous molecule ever identified, compared with any other natural or synthetic molecule, could not gain, apparently, a title better then "A Bug with Beauty and Weapon [312]."

The germ *Clostridium botulinum*, a gram-positive, anaerobic spore-forming bacterium, is distinguished by its significant clinical applications as well as its potential to be used as a producer of a singular bioterror agent. Growing cells secrete botulinum neurotoxin, a multitype protein bearing exceptional toxicity. Although botulinum toxin is the causative agent of deadly neuroparalytic botulism, it also permits a remarkably effective treatment for involuntary muscle disorders such as torticollus, dystonia blepharospasm, strabismus, hemifacial spasm, certain types of spasticity in children, and other ailments. It is also used for "off label" indications such as migraine headaches. Furthermore, this extraordinarily potent toxin is also used in cosmetology for the treatment of glabellar lines and is well-known as the active component of the anti-aging medications Botox and Dysport. In addition, recent reports show that botulinum neurotoxin can be used as a tool

for pharmaceutical drug delivery. However, botulinum toxin remains the deadliest of all toxins and is a potent agent of bioterrorism. Among seven serotypes, *C. botulinum* type A is responsible for the highest mortality rate in botulism, and thus it has the greatest potential to act as a bioterrorism weapon. Genome sequencing of *C. botulinum* type A Hall strain (ATCC 3502) has been completed. It may readily serve to dually engineer the related molecule in terms of toxicity, antigenicity, and stability.

The availability of medicinal Botox is not likely to contribute to a terrorist attack as the vials contain dilute toxin: approximately 0.3% of the lethal inhalational dose estimate and 0.005% of the lethal oral dose estimate. Yet if available right before being diluted, it would certainly be an attractive object. Obviously, the toxin is needed for producing a toxoid and an antiserum.

Finally, the next two examples may tentatively illustrate an entire scope of the exploitability of biomedicine and biotechnology through its two edges, namely the rudimentary one as against the sophisticated one. The former can be demonstrated, then, by crude fermentation of various fungi for the manufacturing of antibiotics or mycotoxins (a dual-use biotechnology largely adopted by the then USSR), whereas the latter one is the usage—for now experimental—recently made of viruses as drug delivery systems, owing to their unique capacity to inwardly parasitize host cells. This biomedical horizon appears to be fascinating, and a far reaching one, in both a desirable and an undesirable fashion.

13.4.24 PREVENTIVE AND COUNTERMEASURE

Having been recognized as a prime threat with global potentiality, different approaches and schools configured to fight bioterrorism are here discussed, rather exhibiting the absence of adequate preparedness. Moreover, various factors, some inherent, may hinder the effectual establishment of future preparedness and are considered. Much progress has though been achieved and is reviewed, particularly in the United States. An endeavor is taking place in Europe and Russia. All over, the efforts are doctrinal, scientific, and logistical, both preventive and reactive.

Aiming to defy any sort of assistance lent by (or from) states to terrorists within the entire context of biological, chemical, or nuclear weapons, the UN Security Council formulated in 2004 a resolution saying that ". . . All States shall refrain from providing any form of support to non-state actors that attempt to develop, acquire, manufacture, possess, transport, transfer or use nuclear, chemical or biological weapons and their means of delivery. All States, in accordance with their national procedures, shall adopt and enforce appropriate effective laws which prohibit any non-state actor to manufacture, acquire, possess, develop, transport, transfer or use nuclear, chemical or biological weapons and their means of delivery, in particular for terrorist purposes, as well as attempts to engage in any of the foregoing activities, participate in them as an accomplice, assist or finance them . . ." [313].

Globally, apart from many national frameworks, various international initiatives have been founded, aimed at the prevention of, and coping with, possible bioterrorism scenarios. In 2006, the U.N. General Assembly released its new counterterrorism strategy. It recommends development of a "biological incidents" database

by the United Nations and its member countries, in order to fight the threat of bioterrorism [314].

In Europe, much progress was achieved during 2004–2006, owing to the New Dedence Agenda (NDA) (later on renamed as Security and Defence Angenda—SDA)—a regular professional discussion forum involving NATO, the EU, and the World Health Organization plus national ministries, industry figures, and journalists, to debate safety and defense issues. It aims to raise awareness in Europe of the bioterrorism threat and to define a set of recommendations for EU policy makers to prevent and protect against attacks.

The 2004 NDA conference outlined that security awareness at epidemiology research laboratories across the industrialized world is lagging behind the growing threat of bioterrorism. Tighter cooperation is needed among laboratories, international customs, and transport authorities, and NATO could provide important logistical and communications support in the event of a bioterror attack in Europe. Notably, Roger Roffey, research director of the Swedish Defense Ministry's Department of International and Security Affairs, accentuated that "The risk of bioterrorism is on the rise, and one of the deficiencies we all face concerns the control of bioterrorism agents within laboratories and their transfer beyond, especially at labs across the former Soviet Union. We should expect bioterrorists to go beyond an attack by aerosol delivery into product-tampering of crops and animals, into our very food and water supplies. We need new multilateral initiatives to improve biosecurity facilities [315]."

The 2005 NDA conference was an example of excellent EU–U.S. collaboration in the context of bioterrorism. If there was one conclusion that could be drawn from the conference, it was that such teamwork had to be duplicated in the actual fight against bioterrorism. Not that the event lacked ideas, as these were ever present. But there were few signs of real cooperation, and the specter of different "threat perceptions" was forever hovering in the background [316]. This line strengthened in the 2006 SDA conference.

The Interpol and the European Homeland Security Association pay much attention to bioterrorism threats. Interpol President Jackie Selebi recently observed that "Major panic, temporary paralysis of government functions and private businesses and even civil disorder are all likely outcomes of a bioterrorism attack. In fact, bioterrorism appears particularly well suited to the small, well-informed groups. A bioterrorist's lab could well be the size of a household kitchen and the weapon built there could be smaller than a toaster, and the range of options available to terrorists will continue to grow." Furthermore, he warned of bioterror attacks on livestock or the food chain [317].

Interpol Secretary General Ronald Noble added that "There is no criminal threat with greater potential danger to all countries, regions and people in the world than the threat of bioterrorism. There is no crime area where police have as little training than in preventing—or responding to—bioterrorist attacks. Terrorists do want to use biological weapons. The threat is worthy of immediate preparation" [318].

French Interior Minister Dominique de Villepin called for creation of a UN-affiliated organization to track potential biowarfare agents and keep them away from terrorists. He did not propose giving inspection powers to such an agency, but said that biotechnology companies, laboratories, hospitals, and universities need to

better monitor themselves on issues of hiring, pathogen work, and access to sensitive areas [317]. Connectedly, in Britain, MI5 officials recently warned British laboratories that Islamist terrorists—chiefly al-Qaeda, through recruited university students—may try to steal deadly pathogens. Scientists and lab staff handing biological agents such as samples of avian flu, tuberculosis, rabies and polio, have been told their security measures will be vetted by police [319]. In consequence, police is supposed to conduct background checks on scientists and others who work with restricted materials at universities, hospitals and pharmaceutical firms [320]. Government officials are intended to inspect such laboratories, and regular audits are planned of agent inventories. The idea is that it will be up to scientists to prove they have good reason for using the materials in their work, according to a senior of the British National Institute for Biological Standards and Controls.

During 2006, cooperation between prominent European states and Russia considerably strengthened. Thus, in Kyiv, Russia, the highly qualified Interpol Workshop on Preventing Bioterrorism took place. Also, a fairly thorough "Strategic Study on Bioterrorism" produced by 20 high level bio-experts from the Russian Federation and other European countries, was released by the Center for Strategic and International Studies.

In Israel, much concern was raised that regular microbiological laboratories—particularly those located in the Palestinian-occupied territories—may be used as minifactories for producing bioterrorism agents. It has therefore been decided that the National Security Council—in coordination with the General Security Service, Ministry of Health, academic institutions, and industrial bodies—will oversee such laboratories [84]. The Israeli Parliament building and facilities are expected to be reviewed for potential vulnerabilities to biological (and chemical) terrorism. Air conditioning and other ducts are expected to be examined to determine any entry point for airborne agents [321].

In some Muslim states, professional forums intended to fight bioterrorism have been formed. In Iran, parallel to its ongoing, progressing BW program—which includes, among other things, guerilla means for applying bioterrorism warfare—The First Conference on [the] Campaign Against Bioterrorism was held in Tehran. The conference, which was a joint project of the Iranian Red Crescent Society (IRCS) and the infectious diseases department of the Tehran Medical Science University examined the health risks posed by bioterrorism and attempts to develop an action plan for use by relief workers in the event of a bioterror event. Over 300 IRCS relief instructors attended the event along with IRCS managers and students from the University [322].

In Saudi Arabia, where there are still elements in support of al-Qaeda, the Center of Studies and Research at Naif Arab University for Security Sciences in Saudi Arabia held a seminar on bioterrorism. Experts participating in the seminar were from Saudi Arabia, Jordan, Bahrain, Comoros, Sudan, Syria, Palestine, Qatar, Iraq, Kuwait, Lebanon, and Egypt [323].

Beyond comparison, however, is the effort against bioterrorism made by the United States. The preventive and countermeasures taken by the United States against bioterrorism are indeed the most impressive ones, in terms of concept, thoroughness, and scope. They are nourished by fundamentals that preceded the 2001 anthrax attack, which means, dually, that on the one hand the need for preemptive preparedness was soberly recognized in advance, and on the other hand,

that the saboteurs succeeded to carry out their attack plan despite the defensive preparedness already established, then, by the United States.

In principle, a variety of ways in which the U.S. agencies were implementing President George W. Bush's April 2004 Biodefense for the 21st Century initiative, organized around the four "pillars" of awareness, prevention, detection, and response [324]. Project Bioshield Presidential law reflects the genuine national American incentive to get prepared toward the bioterrorism threat. In this fashion, lately (2004), the President of the United States signed a new law to implement a $7.8-billion (estimated) project aimed to develop advanced vaccines. This law permits the government to use, in case of national emergency, medications and treatment not yet approved by the FDA. President Bush said this step will help the country to be better prepared in case of a terror attack. Also, said Bush: "It sends a message about our direction in the war on terror. We refuse to remain idle while modern technology might be turned against us." The President also added: "We will rally the great promise of American science and innovation to confront the greatest danger of our time [325]."

The U.S. Homeland Security Subcommittee on Prevention of Nuclear and Bioterrorism Attack handles the bioterrorism threat. It pointed out that the United States must seek the proper balance between agility of response and countermeasure stockpiling in defending against bioterrorism. Moreover, the United States is pursuing multiple avenues of defense against a possible terrorist attack using bioengineered pathogens [326]. Top leaders such as the Homeland Security Secretary have stepped up calls for greater use of terrorist threat information in setting a hierarchy of planning and spending priorities. Witnesses warned the Government Reform National Security, Emerging Threats and International Relations Subcommittee, though, about limits to what can be known about potential engineered threats. They stressed the need for maintaining a broad, flexible array of countermeasures [327]. Homeland Security and the Health and Human Services Department have developed a strategy to address the potential for a bioengineered attack, a document that highlights monitoring of scientific research around the world, as well as broad countermeasure development to give the United States flexibility when confronting an unknown pathogen. Complementarily, two annexes of the new U.S. National Response Plan are particularly relevant to bioterrorism: Emergency Support Function 8 (Public Health and Medical Services) and the Biological Incident Annex. These annexes describe specialized application of the NRP to the delivery of public health and medical services and biological incidents [328].

Within that colossal program, the Bush administration's fiscal 2006 budget plans for civilian bioterrorism defense measures total at least $5.1 billion, according to a new nongovernmental analysis. The amount brings the total requested since 2001 to at least $27.7 billion. The budget request includes increases for protecting national food and water supplies and a significant decrease for funding state and local public health departments, compared with requested spending last year [329].

Further budgetary and organizational details are worth mentioning, then, as presented in that publication [330]. The fiscal 2006 budgeting, an aggregate of spending across numerous agencies, reflects as much as a $2.5 billion drop from what was sought for fiscal 2005, but the decrease results mostly from the absence of a one-time appropriation last year for drug and vaccine purchases through 2008 as part of the Project Bioshield law. "Civilian biodefense spending, not including

the Bioshield bill, has reached a consistent level of about $5 billion from fiscal 2003 to fiscal 2006," the article says. The fiscal 2006 total in the study does not include Defense Department budgeting for civilian bioterrorism defenses, as do previous years' figures, because the Pentagon "was unable to furnish numbers for the requisite programs," the study says.

Military bioterrorism defense spending for civilians in the previous two fiscal years averaged about $200 million. The analysis says, though, that those figures do not truly account for all Pentagon funding for civilian bioterrorism defense measures. "Some DOD research has direct civilian benefit, but because the majority of these funds are primarily military in application, these lines were excluded from calculation of total DOD expenditures," it says.

As in previous years, the largest amount of money—$4.1 billion according to the article—was budgeted for the Health and Human Services Department, which funds the National Institutes of Health, the Food and Drug Administration, and the Centers for Disease Control and Prevention. The article describes a planned $130 million cut to CDC funding for state and local public health departments, bringing the total CDC budget request down to $797 million. Another substantial cut is a $119 million reduction from the National Institute of Allergy and Infectious Diseases' budget for research facility construction, down to $30 million, and intended to "offset the increase in research funding," the analysis says. The Homeland Security Department's $362 million budget is roughly the same as for fiscal 2005—except for the $2.5 billion drop reflecting the advanced purchase for fiscal 2005 under the Bioshield law.

The Agriculture Department was budgeted $354 million, a 26% increase, for bioterrorism defense activities, the State Department $71.8 million, and the National Science Foundation $31.3 million, particularly, in accordance with Homeland Security Presidential Directive 9 (HSPD-9), Defense of United States agriculture and food, January 30, 2004. Finally, the Environmental Protection Agency received an 87% increase to $185 million, primarily for decontamination capabilities, to protect water and food supplies, and for training, the study says.

Apart from doctrinal and laboratory studies conducted by those agencies, field studies are being carried out as well. Scientists from several agencies released two tracer gases in a 2-km^2 area of midtown Manhattan. In a series of experiments, they are tracking how harmful particles might disperse through street canyons, subway tunnels, and buildings. Dubbed the "Urban Dispersion Project," this Department of Homeland Security-sponsored effort aims to produce a computer model of airflow patterns that could help state and local officials better respond to an emergency or to a bioterrorism act [331]. The studies are intended to conclude in 2007.

Overall, a possible counterproductive outcome has been assessed, naturally, as some scientists are concerned that the increase in the number of researchers working in the United States to counter bioterrorism elevates, potentially, the risk of an attack and the accidental release of biological agents [332]. More than 300 institutions and 12,000 individuals have access to weaponizable biological agents, said Richard Ebright, a Rutgers University molecular biologist and critic of the expansion in biodefense since the anthrax attacks of 2001. Biodefense watchdog, the Sunshine Project, claims that 97% of principal investigators who received grants from the U.S. National Institute for Allergy and Infectious Diseases from

2001 to 2005 to study six biological agents had not previously conducted similar work. The explosion of "NIAID newbies" increases the likelihood of accidents, said Edward Hammond, U.S. director for the Sunshine Project. Jeanne Guillemin, a senior fellow at the Security Studies Program at the Massachusetts Institute of Technology, has the view that increasing access to pathogens heightens the chances that rogue scientists could use them in an attack. "What [NIAID Director Anthony Fauci] and others haven't thought through is the particular kind of expertise, from basic bench work to aerosolization, that comes with defensive biological weapons programs" [332].

Furthermore, the extreme, objective complexity of implementing bioterrorism-defense measures aroused, unavoidably, critics saying that despite substantial funding on bioterrorism defenses since the Sept. 11 terror attacks, the country remains substantially unprepared for a mass-casualty bioterrorism attack [330]. A variety of concrete steps and moves has been conducted, however, as follows.

Nonetheless, a large bioterrorism research network has been established in the United States. The U.S. National Institute of Allergy and Infectious Diseases supports 11 academic institutions throughout the United States, which operate as Regional Centers of Excellence for Biodefense and Emerging Infectious Diseases Research. The new network is working diligently to uncover new knowledge and create preventive, therapeutic, and diagnostic tools that will leave us far less vulnerable to bioterrorism, and is regarded as a key element of a U.S. strategic plan to counter bioterrorism and emerging infectious diseases. Each Center for Excellence leads a group of local universities to conduct research on next-generation treatments for anthrax, smallpox, plague, and other diseases. The consortiums encourage bioterrorism research, train personnel, maintain support resources, push for research on the development of new countermeasures, open facilities to researchers from academia and the business world, and provide support for first responders [333]. Within that framework, an 83,154-square foot Biosafety Level 3 laboratory is to be constructed as part of George Mason University National Center for Biodefense and Infectious Diseases. Personnel at the facility will conduct research on development of techniques and products to combat bioterrorism and treat natural infectious disease outbreaks. Researchers will focus on bioterror threats identified by the U.S. government, such as anthrax, tularemia, and plague, along with diseases such as SARS, West Nile virus, and influenza [334]. In addition, Army Medical Research and Materiel Commander Eric Schoomaker focused on the coming benefits of interagency cooperation at the planned National Interagency Biodefense Campus at Fort Detrick, MD. The Defense, Health and Human Services and Homeland Security departments are participating in the campus project.

At the same time, the multiplicity of pathogen holding research facilities is disadvantageous in that they are vulnerable to technical intelligence assaults, thefts and sabotage acts which may serve bioterrorism. This applies, in principle, to a variety of biotechnological resources at large, and thereby propelled, for example, the Congressional Seminar on Preventing Terrorist Exploitation of the Biotechnology Revolution, (June 5, 2006). Connectedly, perhaps, an FBI secrecy initiative formed with key bio-facilities such as the Public Health Research Institute (PHRI) in Newark, New Jersey, so as to refrain from "publicly disclose which specific select agent pathogens and/or strains are stored at PHRI [335]."

In practical terms, early detection systems of various pathogens gained high priority. BioWatch—a Department of Homeland Security's effort to collect air samples form dozens of cities around the country to detect biological agents—biosensors have been deployed in more than 30 urban areas (at a cost of $79 million for 2006). Air is thus monitored air 24 hours a day and samples are collected daily and taken to labs that are part of the Centers for Disease Control and Prevention Laboratory Response Network. The results are provided within 12 to 36 hours [336].

Connectedly, the U.S. Postal Service has installed more than 1000 biological agents—anthrax plus two undisclosed agents—detectors at 271 mail processing facilities since the 2001 anthrax mailings. Moreover, President Bush has staked out the right of the U.S. government to open citizens' mail without first obtaining a warrant [337].

A further methodology, mass spectrometry based "finger print" data base, has been developed by the Food and Drug Administration (FDA) National Center of Toxicological Research (NCTR), for immediate differentiation between biological contaminants, toxins and other, nontoxic substances. Although the concerned device cannot distinguish between living and dead cells, it is highly advantageous in terms of instant findings [338].

Also, nanotechnology could significantly increase the speed of detection of an act of bioterrorism or a natural outbreak. Using a diagnostic test, researchers can measure the frequency change of a nearinfrared laser while it scatters a virus' DNA or RNA. The change in frequency is distinct [339].

Beyond, the most advanced biodetectors are the Triangulation Identification for Genetic Evaluation of Risks—the first multi-purpose diagnostic system that can work with samples of various materials. It can simultaneously identify all pathogens in a soil, water, air or blood samples within four hours, and roughly five such devices are now being used in the US by the US Army and Agriculture Department [340]. In connection, a comprehensive national surveillance network—Project Tripwire—aimed at detecting diseases in wildlife that may be linked to bioterrorism, is being developed by the Wildlife Center of Virginia [341].

Coping with specific pathogens is complicated, naturally, though the very fact that a certain pathogen is being referred to removes a lot of vagueness. Illustratively, the optional adoption of a pre-attack line of defense, as against a post-attack one, is indeed an intriguing one. Researchers from United States and Canada said post-attack anthrax immunization and antibiotic therapy is more effective than pre-attack vaccination [342]. Still, this is doubtfully the correct strategy concerning smallpox, for instance, particularly considering the irrelevance of antibiotic drugs.

Currently, cities and counties throughout the United States are creating stockpiles of anthrax countermeasures that mirror the drugs available in the Strategic National Stockpile [343]. The distributed stockpiles are necessary because it would take too long to distribute countermeasures from the National Stockpile. The drugs, given to cities to prepare for a terrorist attack, are meant to immediately treat first responders in the event of an anthrax attack without having to wait for drugs from the National Stockpile.

The 2001 anthrax letters sabotage was at any rate a cardinal turning point. Using those attacks as a case study, a group of U.S. researchers have developed a risk-

based decision-making system that they believe will allow governments to make better judgments following a bioterrorism attack [344]. In "Bayes, Bugs and Bioterrorists: Lesson Learned from the Anthrax Attacks," Kimberly Thompson, Robert Armstrong, and Donald Thompson argue that governments must develop "decision trees," or methods for evaluating several courses of action, following a bioterrorism attack. They claim this would improve the evaluation of costs, risks, and benefits and would create more effective policy development [344].

"Using this type of approach, the government can better characterize the costs, risks and benefits of different policy options and ensure the integration of policy development," the report states. "Additionally, confirmed use and refinement of decision trees during exercises will provide analysis of the long-term consequences of decisions made during an event and give policymakers insights to improve initial decisions." The study, dated April 2005 and published by the National Defense University's Center for Technology and National Security Policy, says poor planning prior to the fall 2001 bioterrorism attacks in which anthrax was sent to U.S. Senate office buildings through the mail led to improper allocation of resources after the attack [345]. The report estimates the direct costs to the Postal Service could exceed $3 billion, with additional expenditures of over $1 billion for unnecessary countermeasures.

Despite the attack, coordination between U.S. agencies has made development of a comprehensive response plan difficult. To remedy the problem, the report urges establishing a decision tree so that multiple paths of action can be evaluated at once, making individual agency's responsibility more clear. "With this approach, analysts can quickly communicate with decision makers about the implications of combinations of options," the report says. "We emphasize that this approach of focusing on decisions provides a means to cross interdisciplinary and other boundaries . . . and consequently it provides a useful organization and communication tool to promote effective management." The report adds that decisions should be separated into different categories, including who should be immunized, what response should be, how to allocate Strategic National Stockpile resources, how to contain biological agents, and how much information should be made public. The Health and Human Services Department should head the effort to form the decision tree, drawing on the expertise of other agencies when necessary.

The 2001 anthrax attacks clearly demonstrated the need for a better decision-making process, the report says. Lack of investment in the public health infrastructure, a poor understanding of the disease caused by anthrax, inadequate training of first responders, and poor communication are just a few of the problems that plagued the response to the attack. The report argues that a decision tree would have vastly improved response, allowing for a better understanding of who should be vaccinated, how relevant agencies should have responded, a better plan for containment, and improved information management. The report is careful to say that it is not critical of the 2001 response. However, researchers believe a decision tree would have prevented panic and yielded a more appropriate response. Researchers hope decision trees can guide policy discussions as a comprehensive response plan is formulated. "Given our recent experience with anthrax, the specific decision trees for anthrax are offered, as an analytical tool to aid future policy decisions," the report says. "Indeed, the lessons learned from the 2001 attack should facilitate the use of these trees."

Plague has been visited as well, when a wide-scale drill took place in the United States in November 2003. The drill was an effort to follow up on weaknesses in federal emergency response plans identified in a simulated pneumonic plague bioterrorism attack. That exercise, called Top Off 2, was organized by the Department of Homeland Security and involved 8000 local, state, and federal officials. It simulated a pneumonic plague attack on Chicago (and a radiological attack on Seattle) [219].

As for smallpox, the United States intends to acquire up to 80 million doses of the modified virus Ankara smallpox vaccine, as part of its defense against the threat of smallpox virus being used for bioterrorism purposes. It would be useful for people who could suffer reactions to the existing vaccine. That includes patients with suppressed immune systems or those with the skin condition eczema. The vaccine contract could be worth more than $1 billion [346]. President George W. Bush has ordered all American military personnel to be vaccinated against smallpox and has implemented a voluntary program for vaccinating emergency medical personnel. Stockpiling and vaccination is seriously being reconsidered over many countries. Japan is a recent example; after announcing in 2001 that it would begin stockpiling enough vaccine for 3 million people, a governmental panel of experts recommended—in July 2005—the stockpiling of smallpox vaccine for 56 million people in preparation for a possible bioterrorism attack [347]. Russia, with its efficient oral—plus aerosol—vaccines, does not lag far behind. Lately, an international exercise—the "Atlantic Storm Scenario" in dealing with a series of international terrorist attacks involving smallpox virus has shown that the impact would be catastrophic for almost the entire world, and that the lives of millions of people could be lost. This outcome of the "Atlantic Storm" session seems all the more alarming given all the measures taken to combat bioterrorism since 11 September 2001 [268]. The Atlantic Storm Scenario has been preceded by "Exercise Global Mercury," which was the first worldwide simulation project modeling a smallpox bioterrorism attack [348].

Considering influenza virus to be the most powerful potential bioterrorism weapon, Madjid et al. proposed several steps to address the threat of influenza as a terrorist weapon, including the following [349]:

- The Centers for Disease Control and Prevention should classify influenza virus as a "critical agent" for bioterrorism.
- Immunization should be expanded, possibly by requiring it for all medical personnel.
- Laboratories that work with influenza virus should strengthen their security.
- Antiviral drugs should be stockpiled, and vaccine-making capacity should be increased.
- The government should consider a gene-sequencing and vaccine development program.
- Surveillance efforts should be increased and should include incentives for reporting of clinical cases.
- The fitting of ventilation systems with virus detection and inactivation.

A super-flu virus, particularly a pandemic derivative of the current H5N1 avian flu, would presumably kill 200,000 and up to 1.9 million Americans, plus many millions

sickened, according to recent estimates. A government's plan to fight such contagion designates not just who cares for the diseased, but who will keep the country running amid the chaos. Specific countermeasures include stockpiling of both the anti-flu drug Tamiflu as well as avian flu vaccine [350]. Still, the protean nature of influenza type A virus at large may be defying. Experts in Hong Kong observed that the human H5N1 strain that surfaced in northern Vietnam during 2005 had proved to be resistant to Tamiflu [351]. Also, the present antigenic quality of the H5N1 may undesirably alter. Also, the present intact strain of avian flu, as isolated from its human victims, and although not yet a contagious pathogen, is a putative bioterrorism agent itself, due to its respiratory infectivity, lethality, and panic-causing nature.

In general, then, ideally—although seemingly impractically—a complete genetic inventory of all pathogenic strains found worldwide could provide the proper basis for initial, rather essential, inquiry into bioterrorism acts. It may facilitate, as well, controlling the registration of culture collection so as to hamper theft of dangerous pathogens. Thus oriented, the United States is making an effort to fully catalog and selectively to obtain prioritized pathogenic strains such as those then included in the Soviet BW program. Within that context, Kazakhstan, Azerbaijan, Ukraine, and Georgia are appreciably cooperative.

Consequently, more than 60 pathogens—including anthrax and plague strains—from the former Soviet Union's Azerbaijan-based biological weapons program plus epidemiological system arrived at Dover Air Force Base in Delaware [352]. In Azerbaijan—largely a Muslim country—several facilities—including field-test site—were engaged in the then USSR BW development program plus epidemic control. The samples were transferred as part of the Cooperative Threat Reduction program with Azerbaijan, aimed at getting the U.S. help to improve security for pathogens.

Moving to Russia, a different picture emerges with regard to a country fully acknowledging the essentiality of anti-bioterrorism moves, while still possessing an inventory of BWs and an active BW program [305]. The anti-bioterrorism outline and legislative base that were established in Russia—so as to deny possible access by terrorist states and terrorist groups to dual-use biotechnologies, plus materials—have been described by Vorobiev. He thereupon pointed at potential international cooperative efforts to be implemented, accordingly [353]. Eventually, in 2001, a commitment was achieved between Russian and U.S. Presidents, Vladimir V. Putin and George W. Bush, to pursue cooperation to counter the threat of bioterrorism, including a focus on health-related measures.

American assistance to Russia within the "Reduce the Common (WMD) Threats" program fared much. In the bioterrorism sphere, a chief course of that program for conversion has been the anti-bioterrorism one. The Novosibirsk-based Biopreparat-affiliated Vector microbiological center has been a pioneering facility, within that context. A long time before others, Vector's Director, Academician Sandakhchiev, started to cooperate with international institutions, and already in the early 1990s focused on issues related to monitoring and prevention of bioterrorism [354]. In addition, there are plenty of microbiological laboratories all over Russia eager—for financial, professional, or even ideological reasons—to save forbidden strains, toxins, equipment, and information. On the other hand, with time the Americans became more attentive to Russian arguments about development of anti-terror measures.

Consequently, The Russian-U.S. BioIndustry Initiative (BII) began in 2002, constituting the newest proliferation threat reduction program. It aims to counter bioterrorism through targeted reconfiguration of large-scale, formerly Soviet BW research, development, and production facilities for civilian purposes, by creating Russian-U.S. research partnerships [355]. Collaboration has then been established in 2003 between the International Science and Technology Center (ISTC), Moscow, and the Boston-based Center for Integration of Medicine and Innovative Technology (CIMIT), to implement the BII. Conversion is thus intended to take place through formation of systems in Russia to link scientists, physicians, and engineers to solve medical and scientific problems, and to identify innovative technologies and commercialization opportunities [356]. Also, the U.S. Defense Department has been increasingly engaged in efforts to secure from proliferation dozens of former Soviet pathogen collection and research facilities included within the "anti-plague system," widespread across 11 former Soviet states (excluding Russia). Apparently, many of those facilities lack sufficient safety and security and their scientists on average are poorly paid [357]. The concerned, so called Anti-Plague Institutes, are thus being turned into controllable "central reference laboratories" [358].

13.4.25 PROJECTIONS AND PROGNOSIS

Built-in limitations, which interfere with comprehending and foreseeing the course of bioterrorism, are outlined and discussed, together with objective constrains that restrict the scope of countering it. Nonetheless, the conjunction of methodological intelligence monitoring, systematic biosecurity globalization, and creative scientific research may furnish a crucial tool for effectively fighting bioterrorism.

The very supremacy of mankind, in terms of know-how and technology, may possibly make it prone, paradoxically, to self-destruction, in various manners. Bioterrorism is one main way to materialize that undesirable predisposition. Apparently, an outstanding conjunction marked the recent decade, bringing about the prominence of bioterrorism as a colossal issue, including:

- Internet-contained unclassified and declassified information.
- The outcomes of the birth of the formerly Soviet republics—particularly the Muslim and semi-Muslim ones—with their Soviet BW inheritance, namely highly qualified, equipped facilities, culture collections, and many unemployed experts, plus partial Islamic orientation.
- The accelerated augmentation of international terrorism, at large.
- The rise and persistence of al-Qaeda with its radical philosophy and unlimited financial resources.
- The global strengthening of Islam and its fundamentalistic inclination.
- Extremely meaningful breakthroughs made in life sciences and apparatus engineering.
- The increasing emergence and reemergence of infectious diseases worldwide.

Altogether, the ongoing integration of those various, interacting factors will probably shape, both conceptually and practically, the future of bioterrorism, one way or another. If a new breed of anarchistic multinational terrorists—not necessarily connected with al-Qaeda—is currently sprouting up, as at times claimed, the outcome may be unforeseeably catastrophic.

The outlining—let alone structuring—of a defensive alignment that would fully address the bioterrorism threat is, objectively, an impossible mission. Even while referring, primarily, to natural (nonengineered) pathogens and toxins, and assuming a consensus prioritizing anthrax, smallpox, plague, influenza, ricin, and botulinum, one can hardly face the two main resultant questions:

a. How to be best prepared toward each of those agents?
b. Should other potential bioterrorism agents be totally ignored, and if not—what ought to be the respecting mode of preparedness?

And, beyond, of course—what about potential engineered pathogens and toxins? Is it unfeasible, for instance, to form an anthrax germ resistant to the antibiotic Ciproflaxin? Overall, the immeasurable complexity thus formed seems to be insoluble even if budgetary aspects are ignored. Although frustrating, those issues can and should in part be practically administrated by bioterrorism-strategic planners, provided they are fully aware of and acknowledging the concurrent constraints and limitations.

Increasing success of acts of so-called conventional terrorism is not regarded to decrease the potentiality and potency of bioterrorism (or other WMD-terrorism). Recurrent operations of conventional sabotage—even if fully effective—may intensify a perpetrator's daring quest for escalation and resonance through varitype means and modes of terrorism. Perhaps the most significant feature of bioterrorism, the ratio between the low probability of threat realization on the one hand, as against the high impact generated in case of threat realization on the other hand, is an extremely problematic factor for the defender. Let alone, that bioterrorism act that took place—the enthrax letters—in effect looks, in part, successful. In a sense, the very fact that the anthrax letter attack—apparently the most significant bioterrorism act ever conducted—has not been deciphered since 2001 is no less meaningful and important than this unprecedented act of bioterrorism itself.

Apparently, the prime and ultimate apparatus to cope with the bioterrorism threat is effective monitoring by intelligence sources, at least in that if adequately structured it would expediently shape the real and concrete needs and deeds of defense, in whatever sense. Therefore, intelligence ought to be supremely prioritized. All defensive measures have to actually form as derivatives of the intelligence picture, which may certainly be dynamic, though, in itself. The defense planner would not like that dynamics, in case the latter is not a plainly evolving one, but this is an inherent disadvantage. Conversely, yet, or rather complementarily, the defense planner may rely on his own considerations, as long as they can objectively be figured out. The significance of intelligence has been accentuated by the U.S. House of Representatives Homeland Security Subcommittee on Prevention of Nuclear and Biological Attack Chairman John Linder, who called for better coordination between intelligence and disease-fighting agencies. "Science, tools, reagents and technology may be ubiquitous. Scientists, however, are not," Linder

said. “We have to do a better job of keeping track of those individuals with skill sets that are attractive to potential terrorists [359].”

In conjunction, it has been accentuated that a harmonized international regime that enhances biosecurity is essential for reducing the risk of bioterrorism [360]. Presumably, like other security regimes, this will entail mutually reinforcing strands, which need to include enactment of legally binding control of access to dangerous pathogens, transparency for sanctioned biodefense programs, technology transfer, and assistance to developing countries to jointly advance biosafety and biosecurity, global awareness of the dual-use dilemma and the potential misuse of science by terrorists, and development of a global ethic of compliance. To work, this effort must be undertaken collectively, using the international and regional institutions that already have a role to play in providing safety and security.

To those two essential elements—methodological intelligence monitoring and systematic international endeavor—should be added the dimension of creative scientific research. Apparently, the prospects for attaining a breakthrough in upgrading preparedness lie in the integral formed, then, by those three different spheres (beyond the self-evident readiness achieved by means of doctrine-structuring and medical stockpiling). The scientific sphere seems to bear enormous potential. Specific immunoglobulins may constitute a good example of a not yet adequately developed defensive tool, which potentially can be very efficient against pathogens and protein toxins, both for instant prophylaxis and treatment for as well as detection. This tool may be valid against both recognized and future engineered agents, provided that biotechnological processes will allow for at once production of fully specific immunoglobulins against a given agent.

Seemingly, to the least, this direction is worth elaborating on. Unlike vaccines and antibiotics, which are largely prioritized, antisera are less noticed, apparently unjustifiably. Antisera could constitute an optimal means for treatment, provided that instant and specific ethiological diagnosis is available. Studies and case reports evaluating convalescent plasma as therapy (or prophylaxis) of infectious diseases showed to be fairly promising. In the event of a bioterrorism attack, the usefulness of active immunization may be limited. Vaccine efficacy often requires time, multiple doses, and a competent immune system. Prophylactic immunization might provide an effective defense against bioterrorism agents but has the disadvantage that many individuals would have to be vaccinated to protect against an attack that might never occur. In this situation, even a small number of vaccine-related side effects would be unacceptable. In addition, vaccines do not induce protective immunity in all recipients, especially immunocompromised individuals [361]. Such inadequacies should carefully be considered. Yet in contrast, passive immunization involves the administration of preformed antibody to provide a state of immediate immunity. The two modes of immunization are used together in certain circumstances, such as rabies prophylaxis following possible exposure, where a passive antibody provides immediate protection and a vaccine elicits a protective immune response.

A protective antibody suitable for passive immunization could be used in concert with vaccines and drugs to provide a multilayered defense against attacks with biological agents. It should be possible to create a strategic reserve of immunoglobulins against the major biological warfare agents that can be rapidly administered to exposed individuals in the event of an attack. The availability of a strategic

reserve of specific antibody preparations would have a significant deterrent value, as aggressors would be aware that the lethality of their weapon could potentially be counteracted by prompt administration of antibody to susceptible individuals. As antibody can be administered intramuscularly, immunoglobulin preparations could be packaged in self-injectable, disposable, single-use containers. Self-administration of antidote would avoid taxing the health-care system with the need for intravenous administration. Given the stability of immunoglobulin preparations, it should be possible to store antibody for many years. Developing, producing, and stockpiling antibody reagents for defense against bioterrorism agents is a sensible strategy that needs to be considered as steps are taken to prepare against the threat of bioterrorism [336]. On the whole, so it seems, the practicality of antisera should rather equalize that of vaccines and drugs, if not beyond. Connectedly, it has been highlighted that, in the U.S. National Institute of Allergy and Infectious Diseases work on boosting the human innate immune system, a strategy is formed that could lead to countermeasures that would be useful against a wide variety of different agents [359].

Such strategy may become vital, owing to the considerably diminishing usefulness of antibiotics against bacterial pathogens, as predicted by Prof George Poste, Director of the Biodesign Institute at Arizona State University and an advisor to the U.S. President: “Frankly, most governments are asleep at the switch”; he predicts that from 2010 to 2015 will be a “window of vulnerability” when the toll of the super-bug will reach its peak as a result of naturally augmenting antibiotic resistance [362]. Antibiotics may therefore be appreciably replaced by other protective agents, such as antibodles, receptor decoys, dominant-negative inhibitors of translocation, small-molecule inhibitors, and substrate analogues [363].

A new horizon may be gained through the Neugene antisense technology. Neugene antisense “rapid response therapeutics” are synthetic compounds that mirror a critical portion of a disease-causing organism’s genetic code and bind to specific portions of the target genetic sequence. Like a key in a lock, Neugene antisense compounds are designed to match up perfectly with a specific gene sequence, blocking the function of the target gene [364]. Resultant antisense preparations have been able to block the cellular mechanisms used by the causative agents of anthrax, Ebola and Marburg, during pathogenesis. Another variant has been reported to block ricin toxin as well [365].

Relying on a similar principle, a novel drug has lately been developed that could expectedly be used to treat people exposed to anthrax bacteria specifically engineered to overcome antibiotics, due to an increasing concern that therapeutics developed for bioterrorism agents may be rendered ineffective if the microbial target is altered intentionally. This problem could be overcome, however, by designing inhibitors that block host proteins used by pathogens or their toxins to cause disease [366].

Thus, although the bioterrorism threat stemming from nonengineered pathogens and toxins is more or less characterized, in terms of expected impacts (although not in terms of likelihood, timing, and locality), the vagueness marking the threat posed by engineered pathogens and toxins is intriguing. Synthetic biology may be a key arena. Security experts fear that scientists building synthetic biochemical compounds could create a pathogen with no natural countermeasures, hence the possibility of making an unprecedented deadly bioterrorism weapon [367].

Synthetic biologists are combining existing chemical components of DNA or RNA taken from cells and viruses to form compounds that do not occur naturally. Scientists hope to use this technology to produce computers, medicines, and energy sources. The field is attracting attention from investors and prominent biologists; yet some biologists and security experts warn that these new compounds could be used to develop a biological weapon. "There are certainly a lot of national security implications with synthetic biology."

Concerns were played down that a new agent could exterminate the human race but warned that the threat of new, engineered pathogens remains serious [368]. Scientists are already exploring ways to self-police synthetic biological research, including requiring reports of sales of materials that could be used to create a tailored biological-weapon. "There are now tens of thousands of people, worldwide, who could engineer drug-resistant anthrax," said Professor Kenneth Alibek, who as a consultant to the U.S. government has received numerous briefings on U.S. and Soviet biological weapon programs.

A testimony prepared to the House of Representatives Homeland Security Subcommittee on Prevention of Nuclear and Biological Attack may well illustrate the issue of bioengineered agents. Addressing it, National Institute of Allergy and Infectious Diseases Director Anthony Fauci contented that agents could be made more virulent through "resistance to one or more antibiotic or antiviral drugs, increased infectiousness or pathogenicity or, in the somewhat longer term, a new virulent pathogen made by combining genes from more than one organism. As the power of biological science and technology continues to grow, it will become increasingly possible that we will face an attack with a pathogen that has been deliberately engineered for increased virulence." Fauci added, however, that creating an agent whose transmissibility could be sustained on such a scale, even as authorities worked to counter it, would be a daunting task. "Would you end up with a microbe that functionally will . . . essentially wipe out everyone from the face of the Earth? . . . It would be very, very difficult to do that," he said.

Centers for Disease Control and Prevention Director Julie Gerberding said a deadly agent could be engineered with relative ease that could spread throughout the world if left unchecked, but that the outbreak would be unlikely to defeat countries' detection and response systems. "The technical obstacles are really trivial," Gerberding said. "What's difficult is the distribution of agents in ways that would bypass our capacity to recognize and intervene effectively."

Today, the CDC's list of pathogens that must be reviewed comprises more than 60 agents. Each of them may completely be explored, so as to become fully manageable. But the catch is in that the existent pathogens are recognized—hence controllable—yet currently available for the potential attacker, whereas the unknown future engineered pathogens will scarcely be available, yet hardly controllable. The dichotomic menace thus emerging is an extremely challenging one. Possibly, as mentioned, immunoglobulins, polyvalent inhibitors, and other opproaches, may furnish a solution.

All in all, the threat of bioterrorism is indeed a challenging one and bears, potentially, overwhelming, somewhat enigmatic impacts. Henry Crumpton, the US State Department Coordinator for Counter-Terrorism, described a biological attack on West "simply a matter of time", adding that such an attack could pose an even greater menace to security than a nuclear strike [369].

U.N. Secretary General Kofi Annan, in the General Assembly, laid emphasis on the hazardous conjunction of bioterrorism and biotechnology:

"The international community must give a higher priority to developing new strategies against bioterrorism. Biotechnology has value in the fight against disease, but scientific advances could also "bring incalculable harm if put to destructive use by those who seek to develop designer drugs and pathogens. Soon, tens of thousands of laboratories worldwide will be operating in a multibillion-dollar industry," Annan said, according to the Associated Press. "Even students working in small laboratories will be able to carry out gene manipulation. U.N. nations should consider organizing of forum of governmental officials and science and public health experts to develop a strategy "to ensure that biotechnology's advances are used for the public good and that the benefits are shared equitably around the world [370]."

Finally, perhaps most plainly forwarded by the head of the Interpol, Ronald Noble, the bioterrorism treat has been featured as a global, severe, unprecedented menace: "The world is ill prepared for the looming threat of a bioterrorism attack. The danger of an al-Qaeda attack has not diminished since the 9/11 strikes on the US. The potential cost of a bioterrorism attack left no room for complacency. When you talk about bioterrorism, that's one crime we can't try to solve after it happens because the harm will be too great. How could we ever forgive ourselves if millions or hundreds . . . or tens of thousands of people were killed simply because our priorities did not include bioterrorism?" Noble acknowledged that governments and security agencies were better organized against the threat than ever before, but "none of us can let our guards down and assume that the problem has been addressed". Were al-Qaeda to launch a "spectacular bioterrorism attack which could cause contagious disease to be spread, no entity in the world is prepared for it," he said. "Not the US, not Europe, not Asia, not Africa [371]." He may possibly be right.

Syngenta Bt corn, 1433, 1440

T-2 toxin, 1551–1552, 1554–1555
Target product profile, 94
Target selection, 89–90, 92
TCDD, 511, 517, 520–521
Technetium radionuclides, 883, 902
  See also radionuclides
Telomerase, 1318
Telomeres, 1362–1364
Therapeutic proteins
  characteristics, 1222
Thread-induced thrombosis assay, 545
Thrombisis assay, 512, 545
Thrombolytic assay, 512, 546
Total error, 573, 578, 582, 584
Toxicology, 103
Toxicology and biodistribution of Ad5FGF-4, 956–969
Trichothecene mycotoxins, 513–514
Trade mark, 1396
Trade related aspects of intellectual property rights (TRIPs), 1401, 1428
Trade secret, 1394
Transfer RNA (tRNA)
  "wobbling" of, 26
Transmission electron microscopy (TEM), 1300
Tuberculosis, 1525, 1548
Tumor necrosis factor α (TNFα), 1117–1174, 1193
Tumor targeting, 1052
Twin arginine translocation (TAT), 6

Urotoxicity, 511, 522

Vaccination, 997
Vaccine classification, 1549*t*
Vaccine formulations, 1149–1157
Vaccines
  active immunotherapy, 851, 870
  anti-infectious diseases vaccines, 993
  antitumor vaccines, 995–997
  classification, 1379*t*
  DNA vaccine, 871
  formulations, 1162–1163
  plasmid DNA-based anti-tumor vaccines, 995–997
  smallpox vaccine, 692
  subunit vaccines, 738–739
Vasopressin, 709
Vector construction, 958–959
Vector decomplexation, 1044
Vectors, 1263
Viral clearance studies, 333–336
Viral diseases, 1132–1133
Viral infections, 1123–1124
Virosomes, 1157–1158, 1158*f*
Virus Removal, 36

West-Nile encephalitis, 1536–1537
Working cell bank, 959

Yeasts, 6–10, 8*t*, 9*t*
  yeast cells as artificial chromosomes (YACs), 59–60, 61*f*, 63
  yeast display, 859–860
  yeast protein extraction, 1493
Yeast oestrogen assay, 551–552
Yellow fever, 1549–1550
Yield, 697
Yttrium radionuclides, 913
